Running head: Recombination and disease-associated mutations

Abstract

Although mutations that are detrimental to the fitness of organisms are expected to be rapidly purged from populations by natural selection, some disease-causing mutations are present at high frequencies in human populations. Several non-exclusive hypotheses have been proposed to account for this apparent paradox (high new mutation rate, genetic drift, overdominance or recent changes in selective pressure). However, the factors ultimately responsible for the presence at high frequency of disease-causing mutations are still contentious. Here we establish the existence of an additional process that contributes to the spreading of deleterious mutations: GC-biased gene conversion (gBGC), a process associated with recombination which tends to favor the transmission of GC-alleles over AT-alleles. We show that the spectrum of amino-acid altering polymorphisms in human populations exhibits the footprints of gBGC. This pattern cannot be explained in terms of selection and is evident with all nonsynonymous mutations, including those predicted to be detrimental to protein structure and function, and those implicated in human genetic disease. We present simulations to illustrate the conditions under which gBGC can extend the persistence time of deleterious mutations in a finite population. These results indicate that gBGC meiotic drive contributes to the spreading of deleterious mutations in human populations.

Introduction

The majority of disease-causing mutations (DMs) detected in human populations are very recent, having only been transmitted over a few generations at most [Slatkin and Rannala, 2000]. A substantial fraction of DMs nevertheless correspond to more ancient mutations that have persisted for a large number of generations. Several non-exclusive hypotheses have been proposed to explain why such detrimental mutations could have escaped negative selection. First, detrimental mutations that have a limited impact on reproductive success (e.g. mutations causing late-onset diseases) can spread simply by genetic drift [Kryukov, et al., 2007] Second, some DMs confer a selective advantage upon heterozygotes (overdominance) [Dean et al., 2002], Third, some DMs may have attained a high population frequency in the past because they were once_advantageous under environmental conditions that no longer pertain [Di_Rienzo and Hudson, 2005], Finally, some DMs may occur at high frequency because of a high <u>de novo</u> mutation rate or a germ-line selective advantage [Choi et al., 2008].

Population genetic models indicate that <u>in addition to genetic drift and natural selection</u>, there is a third process that can contribute to the spreading of mutations within a population: biased gene conversion (BGC). Gene conversion occurs during homologous recombination and involves the non-reciprocal transfer of sequence information between the two recombining DNA molecules. This process is said to be biased if one of the two DNA molecules <u>involved</u> is more likely than the other to be the donor. Gene conversion can affect paralogous sequences duplicated in the genome <u>or different alleles at a given locus [Chen et al., 2007]</u>. In the case of allelic gene conversion, BGC leads to an excess of the 'favored' allele in the pool of gametes and hence tends to increase the frequency of this allele in the population. Theoretical analyses have shown that, as with selection, BGC can increase the probability of fixation of the favored allele [Nagylaki, 1983].

Although the theoretical consequences of the BGC process have been known for some time, the potential practical importance of this phenomenon has remained largely unstudied. Recently, the analysis of polymorphism and nucleotide substitution patterns in primates has provided firm evidence for BGC acting genome-wide, favoring GC alleles over AT alleles (for a review, see <u>Duret and Galtier</u>, 2009a). Indeed, this process of GC-biased gene conversion (gBGC) appears to be the major determinant of the evolution of base composition at silent sites (non-coding regions, synonymous codon positions) in primate genomes [Duret and Arndt, 2008], Further, there is now good evidence that gBGC has impacted upon the evolution of functional sequences, both in regulatory non-coding sequences [Duret and Galtier, 2009b; Galtier and Duret, 2007] and in protein-coding exons [Berglund, et al., 2009; Galtier, et al., 2009], Importantly, these results indicate that, in our species' evolutionary past, gBGC is likely to have hampered the action of purifying selection and led to the fixation of deleterious mutations.

Here we <u>have sought to determine whether gBGC influences the frequency of deleterious</u> non-synonymous polymorphisms in extant human populations. <u>To this end</u>, we investigated the segregation patterns of AT \rightarrow GC and GC \rightarrow AT single nucleotide polymorphisms (SNPs) according to the local recombination rate. We <u>also</u> analyzed different classes of nonsynonymous SNPs, predicted to be deleterious or known to be involved in genetic disease, <u>using synonymous and non-coding SNPs as a neutral control.</u> All classes of SNPs were found to <u>display</u> the hallmarks of the <u>gBGC</u> process. <u>Further</u>, we provide evidence that these segregation patterns cannot be explained by ascertainment bias in SNP detection, artifacts in SNP orientation, or <u>other biological processes such as natural selection</u>. In support of these observations, we present simulations to illustrate the conditions <u>under</u> which <u>gBGC</u> can extend the persistence of deleterious mutations in finite populations. We conclude that <u>gBGC</u>

Material and methods

As a complement, we used an independent polymorphism dataset comprising 39,440 autosomal SNPs, found exclusively in coding sequences, at both synonymous and non-synonymous positions [Lohmueller, et al., 2008], These SNPs were determined by direct exon sequencing in 10,150 transcripts, for two population samples (hereafter termed AFR and CAU): 15 African-American individuals (30,718 SNPs) and 20 European-American individuals (22,514 SNPs, Supp. Table $\underline{S}2$).

Inference of ancestral and derived alleles. We determined the ancestral and derived states of human polymorphisms using human-chimpanzee whole-genome alignments, obtained from the UCSC Genome Browser [Rhead et al., 2010] through Galaxy [Giardine et al., 2005].

To confirm that this first approach had not been misled by ancestral 'misinference' issues, we also used a second approach, developed by Hernandez, et al. [2007a], which corrects the spectrum of derived allele frequencies, obtained by parsimonious reasoning, using a context-dependent model of sequence evolution (software kindly provided by Ryan D. Hernandez). We only considered SNPs found within a constant 5'-3' context, as defined above. As indicated by the authors, we further restricted our dataset to positions where the chimpanzee nucleotide corresponded to one of the two alleles observed in the human population. The context-dependent site frequency spectrum obtained by maximum parsimony was then corrected using the model proposed by Hernandez, et al. [2007a].

As noted previously [Gibbs, et al., 2007], for disease-associated mutations, the diseaseassociated allele sometimes represents the ancestral state; here, we focused exclusively on SNPs for which the derived allele was associated with the disease.

The number of genotyped chromosomes varies widely between individual SNPs. The

correction method developed by Hernandez, et al, [2007a] requires the derived allele

frequency spectrum to be constructed employing the same number of chromosomes for all

SNPs. To fulfill this requirement, we applied the following procedure (as proposed by

Hernandez et al. [2007b]): we computed the minimum number of sampled chromosomes

 (n_{min}) for a given SNP dataset and then estimated the derived allele frequencies for a dataset

reduced to n_{min} chromosomes. For a SNP that was originally present in n out of m sampled

chromosomes, the probability that it will be present at a frequency *i* in the reduced sample is

given by the hypergeometric distribution: $\frac{C_n^i \times C_{m-n}^{n_{\min}-i}}{C_m^{n_{\min}}}$, where C_u^v is the number of choices of

v elements among u. Using this formula, we can generate the expected derived allele

frequency spectrum in a subsample of n_{min} chromosomes. Note that this procedure was

applied independently for each class of SNPs analyzed here (intergenic, intronic, synonymous

SNPs, etc.). The n_{min} values for each SNPs sample and for each region are given in Supp.

Recombination rates and hotspots. The positions of 34,136 recombination hotspots were taken from HapMap release 21 [Myers et al., 2005], and converted from hg17 to hg18 assembly coordinates using the *liftover* utility from the UCSC Genome Browser [Rhead et al., 2010]. We also computed the regional recombination rates in 10kb sliding windows for autosomal mutations using the genetic maps provided by [Frazer et al., 2007], release 36.

Disease-associated mutations. We extracted 45,751 disease-associated mutations occurring in protein-coding sequences from HGMD release 2008.3 [Stenson et al., 2009]. Using annotations from the Ensembl database [Hubbard et al., 2009] release 49, we were able to

Table <u>S</u>5.

map unambiguously onto the human genome the positions of 43,953 <u>disease-associated</u> mutations. 193 mutations were synonymous <u>and hence were excluded</u> <u>-</u><u>here we only analyzed</u> non-synonymous mutations (34,814 missense and 8,946 nonsense).

HGMD mutations are allocated to four distinct classes with respect to their association with disease: DM, mutations regarded as being a direct cause of disease; DP, polymorphisms exhibiting a significant statistical association with disease but without additional functional evidence supporting their involvement; DFP, disease-associated polymorphisms with additional functional evidence supporting their direct involvement; FP, polymorphisms reported to affect the structure, function or expression of the gene (or gene product), but with no known disease association (Supp. Table $\underline{S}3$).

PolyPhen predictions. To predict which non-synonymous SNPs present in HapMap are potentially damaging for protein structure and function, we used PolyPhen predictions for dbSNP build 126 [Sunyaev, et al., 2001]. For the exon sequencing dataset, we used the PolyPhen predictions provided by the authors [Lohmueller, et al., 2008] (Supp. Table <u>S4</u>). We focused on the SNPs predicted to be "probably damaging", for which the derived allele has been shown to be the deleterious allele in 99% of cases [Lohmueller, et al., 2008].

Definition of recombination classes. To define regions of high and low recombination, we sorted each SNP dataset according to the minimum distance to a recombination hotspot, and then divided the dataset into three equal-sized classes. Only the first and the third classes were compared in order to maximize the crossover rate difference between the high and low recombination regions. This procedure was applied independently for each genomic region

(intergenic, intronic, coding synonymous etc.) and for each HGMD and PolyPhen subset of SNPs.

Statistical analyses. All statistical analyses were performed with the R environment [R] Development Core Team, 2008]. To test the effect of gBGC, we compared the mean derived allele frequencies (DAF) for AT \rightarrow GC and GC \rightarrow AT mutations. Given that the distribution of DAF is non-Gaussian, we used a randomization procedure to test the statistical significance of the mean difference ($d = \text{mean}(\text{AT}\rightarrow\text{GC})\text{-mean}(\text{GC}\rightarrow\text{AT})$). To do this, we randomized the direction of AT \rightarrow GC and GC \rightarrow AT SNPs and compared the observed d value with those obtained from 1000 randomized datasets. We computed a p-value corresponding to the proportion of simulated datasets for which the d value was higher than that observed in the real dataset; our test was thus one-tailed.

We also analyzed the difference in mean DAF between the two mutation classes (*d*) for regions of high and low recombination. To test if the difference in d (Δd) between the two recombination classes was statistically significant, we developed a randomization procedure: we drew randomly two sets of sites (from all possible SNPs in a given genomic region), equal in size to the original low recombination and high recombination classes, and computed Δd for the simulated dataset. A one-tailed p-value was computed by comparing the observed Δd value with 1000 simulated datasets.

Simulation of the impact of gBGC on the derived allele frequency spectrum

We use<u>d</u> simulations to determine the expected distribution of derived allele frequencies (DAF) at loci that are subject to mutation, negative selection and biased gene conversion. The initial population was homozygous and finite following a Fisher_Wright probabilistic model_

The alleles that can segregate at each locus belong to one of two classes: S(trong) (G or C) or W(eak) (A or T). The fitness of genotypes SS, SW and WW are denoted respectively ω_{ss} , ω_{sw} and ω_{ww} . The mean fitness value in the population is ω :

 $\overline{\omega} = z_{SS}\omega_{SS} + z_{SW}\omega_{SW} + z_{WW}\omega_{WW}$ where z denotes the zygotic frequencies.

For individuals that are heterozygous at a given locus (SW), we termed u the probability of conversion $S \to W$ and v the probability of conversion $W \to S$. The gene conversion bias at this site is measured through $\delta = v - u$ and has positive values when gBGC occurs. The frequency of the S allele is denoted p and hence the frequency of allele W is 1-p. The model describes the transition from one generation, n, to the next, n+1, admitting panmixia, with the following equations:

Results

gBGC hallmarks are observed for deleterious SNPs

To investigate whether gBGC affects the segregation of deleterious mutations in human populations, we studied the spectrum of derived allele frequencies (DAFs) of nonsynonymous SNPs as a function of the local recombination rate across human chromosomes. We first analyzed the HapMap dataset of human SNPs, which provides frequencies of each allele in different human populations [Frazer et al., 2007], We inferred the ancestral and derived alleles for SNPs by means of a maximum likelihood approach that incorporates CpG hypermutability [Duret and Arndt, 2008], using the chimpanzee genome as an outgroup. Three distinct subsets of non-synonymous polymorphisms were investigated: 1) all HapMap non-synonymous SNPs; 2) HapMap non-synonymous mutations for which the impact on the function of the protein was predicted by PolyPhen [Sunyaev, et al., 2001] to be 'probably 2 damaging'; and 3) HapMap SNPs corresponding to disease-associated non-synonymous mutations reported in the HGMD database [Stenson et al., 2009]. We further split the HGMD dataset in order to analyze specifically those inherited mutations which are considered to be a direct cause of disease (DM), thereby excluding those mutations that have only been associated statistically with disease (Supp. Table S3). As a control, we also analyzed SNPs at silent sites, for which evidence of gBGC has already been reported [Galtier et al., 2001; Spencer, et al., 2006; Webster and Smith, 2004] As expected, DAFs were found to be negatively correlated with the strength of purifying selection: SNPs in non-coding regions or at synonymous codon positions exhibited the highest mean DAFs, whereas the lowest mean DAFs were observed for mutations that are known to be involved in genetic disease or that were predicted by PolyPhen to be deleterious (Fig. 1, Supp. Tables S8-S10).

The gBGC model makes two firm predictions: first, in regions of high recombination, the spectrum of derived allele frequencies (DAFs) for SNPs is expected to be skewed, with higher

Human Mutation

frequencies for $AT \rightarrow GC$ than for $GC \rightarrow AT$ mutations; second, this skewing is expected to be weaker in genomic regions characterized by a lower recombination rate. To test these predictions, we classified SNPs into groups of high and low recombination on the basis of their physical distance to the nearest recombination hotspot [Myers et al., 2005]; similar results were obtained when the recombination classes were computed on the basis of the average crossover rate in fixed-size sliding windows (not shown). We found that in regions of high recombination, $AT \rightarrow GC$ mutations segregated at higher frequencies than $GC \rightarrow AT$ mutations (Fig. 2, Supp. Tables S8-S10, Supp. Fig. S2-S4). This difference was statistically significant in all HapMap samples, both for silent SNPs and for the three sets of nonsynonymous SNPs (Table 1). This pattern was evident even within the DM subset. For this class, the tests remained significant in only one of the HapMap samples. Nevertheless, given that our observations for the more abundant classes of mutations (silent sites, nonsynonymous SNPs) were always in agreement with the gBGC hypothesis, and significantly so, the uncertainty related to the DM class is most likely only a consequence of the reduced sample size. As predicted by the gBGC model, the difference between the mean $AT \rightarrow GC$ and $GC \rightarrow AT$ frequencies is much stronger for SNPs located in regions of high recombination rate as compared to SNPs located in regions of low recombination rate (Fig. 1, Table 1, Supp. Tables S13-S15). Thus, all classes of SNPs exhibit the hallmarks of the gBGC process, not only the silent sites but also the three subsets of non-synonymous sites.

Control for variations in selective pressure on non-synonymous mutations

We observed that at non-synonymous sites, $GC \rightarrow AT$ mutations segregate at lower frequency than $AT \rightarrow GC$ mutations. One potential explanation for this observation is that $AT \rightarrow GC$ nonsynonymous mutations might be, on average, less deleterious than $GC \rightarrow AT$ non-synonymous mutations. To test this hypothesis, we compared $AT \rightarrow GC$ and $GC \rightarrow AT$ SNPs that lead to the

Deleted: :

same amino-acid replacement and hence are expected to have the exact same fitness impact. In total, there are 10 amino-acid changes that can be caused both by AT \rightarrow GC and GC \rightarrow AT mutations. For each of the three populations, we performed pairwise comparisons of the mean DAF of AT \rightarrow GC and GC \rightarrow AT SNPs causing the same amino-acid changes: in 23 out of 30 comparisons, the AT \rightarrow GC SNP had the highest mean DAF (Supp, Table S19). For example, the mean DAF of Q \rightarrow H non-synonymous SNPs in the CEU population is 0.19 when it results from an AT \rightarrow GC mutation, compared to 0.16 when it results from a GC \rightarrow AT mutation. Conversely, the mean DAF of the reverse amino-acid change (H \rightarrow Q) is 0.35 when it results from an AT \rightarrow GC mutation, compared to 0.23 when it results from a GC \rightarrow AT mutation. Thus, the mean DAF varies according to the direction of the GC-content change (AT \rightarrow GC vs. GC \rightarrow AT), independently of the nature of the amino-acid change. Hence, the observed differences in mean DAF between AT \rightarrow GC and GC \rightarrow AT non-synonymous SNPs cannot be attributed to differences in selective pressure on the corresponding amino-acid changes.

Control for SNP ascertainment bias and ancestral misidentification

The HapMap dataset is known to be biased towards high frequency polymorphisms, and this representation bias can confound some population genetic analyses [Clark et al., 2005]. There is however no *a priori* reason why this ascertainment bias should differentially affect $AT \rightarrow GC$ - and $GC \rightarrow AT$ -derived allele frequencies. This notwithstanding, to ensure that our observations were not affected by this intrinsic bias in HapMap data, we repeated our analysis on an independent polymorphism dataset that was acquired through direct exon re-sequencing in two human populations [Lohmueller, et al., 2008], and which should therefore be free of ascertainment bias. Our conclusions remained unchanged with the re-sequencing dataset: in regions of high recombination, $AT \rightarrow GC$ mutations segregated at higher frequencies than $GC \rightarrow AT$ mutations and this excess was higher than in regions of low recombination. This pattern was observed in both populations, not only for the synonymous sites but also for the

three datasets of non-synonymous sites (Table 1, Supp. Tables $\underline{S}11-\underline{S}12$, $\underline{S}16-\underline{S}17$, Supp. Fig. $\underline{S}5-\underline{S}6$). We may therefore conclude that the observed skewing of derived allele frequencies was not simply a consequence of ascertainment bias. It <u>may be noted that the pattern appears</u> to be stronger with the HapMap dataset <u>as compared to the re-sequencing dataset (Table 1)</u>. By <u>means of simulations</u>, we showed that this difference is due to the fact that the HapMap

One other potential artifact that had to be <u>considered and</u> assessed was the possibility that the observed gBGC-like pattern stemmed from ancestral 'misinference' [Hernandez, et al., 2007a]; when the mutational pattern is biased towards AT, and most notably in the case of strong context dependence (such as CpG dinucleotide, mutational hotspots in mammalian

SNP sampling strategy provides greater power to detect gBGC (see Supporting Information).

genomes), maximum parsimony tends to incorrectly ascribe directionality for $GC \rightarrow AT$ mutations, yielding an apparent excess of high-frequency $AT \rightarrow GC$ SNPs [Hernandez et al., 2007a]. Nevertheless, we are confident that this artifact has not influenced our results for the following reasons. First, instead of using parsimony-based reasoning, we determined SNP directionality using a maximum-likelihood approach that takes CpG hypermutability into

account [Duret and Arndt, 2008], Second, our conclusions were unchanged when CpG sites were excluded (Supp. Table ≤ 7). Third, we repeated our analyses using the context-dependent model proposed by Hernandez and colleagues [Hernandez, et al., 2007a] to correct for potential ancestral allele misidentification. With this method, the results remained in agreement with our previous observations (Supp. Table ≤ 6). Finally, it should be highlighted that the difference between the mean DAFs of AT \rightarrow GC and GC \rightarrow AT mutation was found to be much stronger in regions of high recombination (Fig. 1). This observation, which is consistent with the gBGC model, cannot be explained by an ancestral misinference artifact. Indeed, the pattern of substitution is more biased toward AT in regions of low recombination as compared to regions of high recombination [Duret and Arndt, 2008], Thus, an artifactual Deleted: can Deleted: ic

Simulation of the impact of gBGC in a finite population

To investigate the impact of gBGC on the fate of deleterious mutations (AT \rightarrow GC or GC \rightarrow AT), we performed simulations in a finite population (effective population size N_e =10,000), considering recessive mutations subject to different selection coefficients (*s*) and gBGC coefficients (δ ; see methods). The population-scale gBGC coefficient ($N_e \delta$) in the human genome was estimated by Spencer et al. [2006] by analyzing the DAF spectra of noncoding SNPs. In genomic regions of high recombination (defined as the top 20% of the genome with the highest recombination rate; average crossover rate= 2.5 cM/Mb) their estimate was $N_e \delta$ =0.325. Given that, in the human genome, recombination <u>is</u> essentially <u>confined to hotspots</u> (typically less than 2 kb long), with an average crossover rate of about 40 cM/Mb [Myers et al., 2006], it is expected that the gBGC coefficient should be about 16 times higher in these hotspots. Recombination hotspots vary in intensity [Myers et al., 2006]. We therefore considered two values for the population-scale gBGC coefficient: $N_e \delta$ =1.3 (for a moderate recombination hotspot) and $N_e \delta$ =13 (for a more intense recombination hotspot).

With gBGC parameters corresponding to those of a moderate human recombination hotspot, the impact of gBGC on the DAF spectrum was clearly detectable for both nearly-neutral ($|N_es|$ = 1) and mildly deleterious mutations ($|N_es|$ = 10): compared to a situation without gBGC ($N_e\delta$ =0), AT→GC segregate at higher frequency, whereas GC→AT segregate at lower frequency (Fig. 3), For the more intense recombination hotspots, the impact of gBGC on the DAF spectrum was detectable even for highly deleterious mutations ($|N_es|$ = 100).

Human Mutation

Recombination hotspots occupy only a small fraction of the genome: among the nonsynonymous SNPs that we analyzed, 6% were located within 2kb of the center of a recombination hotspot. Thus, only a limited fraction of SNPs is expected to be affected by gBGC. This explains why the skewing observed in real data (Fig. 2) is intermediate between the patterns obtained in simulations corresponding to moderate hotspots ($N_e \delta = 1.3$) or to the absence of gBGC ($N_e \delta = 0$) (Fig. 3). Thus, the pattern observed with real data appears to be compatible with the hypothesis that the skew in the DAF spectrum is due to gBGC affecting deleterious mutations in recombination hotspots. It should be noted that the location of recombination hotspots is extremely dynamic [Baudat et al., 2010; Myers et al. 2010], which suggests that the fraction of SNPs that are at some time affected by gBGC, might be larger than that estimated above. To obtain a more realistic estimation of the expected DAF spectra, it would be necessary to take into account not only the intensity recombination hotspots but also their dynamics.

Discussion

We <u>have shown</u> that all functional classes of SNPs, including non-synoynmous SNPs known to be implicated in human disease, and non-synonymous SNPs predicted to be damaging for protein structure and function, exhibit the hallmarks of gBGC: the derived allele frequency of $AT \rightarrow GC$ mutations is higher than that of $GC \rightarrow AT$ mutations, and <u>this is more promounced in</u> regions <u>characterized by high recombination rates</u>. Importantly, we <u>demonstrated that the</u> observed excess of high-frequency SNPs in regions of high recombination does not result from sampling biases nor from artifacts of SNP directionality determination.

Js gBGC the only possible explanation for these observations? One alternative hypothesis to explain the fact that non-synonymous GC→AT mutations segregate at lower frequency than $AT \rightarrow GC$ mutations is that $GC \rightarrow AT$ mutations could be more deleterious that the $AT \rightarrow GC$ mutations. For instance, it has been recently shown that $GC \rightarrow AT$ mutations at hypermutable CpG sites within coding regions are under stronger purifying selection than other nonsynonymous mutations [Schmidt et al., 2008], Several observations however argue against this hypothesis. First, we note that our conclusions remained unchanged when SNPs occurring within a CpG context were excluded (Supp. Table <u>S7</u>). Second, comparison of $GC \rightarrow AT$ and $AT \rightarrow GC$ mutations causing the same amino-acid changes confirmed that the higher mean DAF of the latter cannot be attributed to a weaker impact on the encoded protein. Moreover, this hypothesis that $AT \rightarrow GC$ mutations are relatively less deleterious cannot explain why their mean DAF increases with the recombination rate. Finally, we have shown that the DAF pattern is consistent over all classes of SNP, including those located in intergenic and intronic regions, which may be presumed to be largely free of selective pressure. It has been previously demonstrated that the relationship between recombination and the evolution of GC-content in non-coding regions is the consequence of gBGC and not selection [Duret and

Deleted: implications

Arndt, 2008], Hence, the most parsimonious explanation for our findings is that both silent

sites and non-synonymous sites are subject to gBGC.

Taken together, the data <u>presented</u> are consistent with the hypothesis that biased gene conversion is responsible for the excess of AT \rightarrow GC SNPs segregating at high frequency in regions of high recombination. This result has important <u>implications for human</u> health because it indicates that recombination, via gBGC, leads to an increase in the frequency of disease-causing AT \rightarrow GC mutations in human populations. It should be stressed that the impact of gBGC on deleterious mutations is not always negative. Indeed, a majority (58.7%) of known DMs correspond to GC \rightarrow AT mutations. Thus, for a majority of DMs, gBGC acts in such a way as to limit their probability of spreading. However, the price to pay for this positive influence of gBGC is that it can lead to an increase in the frequency of diseasecausing AT \rightarrow GC mutations in human populations. We speculate that the genes most likely to be influenced by this effect will be those that are AT-rich (*i.e.* for which there are more opportunities for AT \rightarrow GC mutations) and which coincide with recombination hotspots: an additional argument for these hotspots being an Achilles' heel of the human genome [Duret_ and Galtier, 2009b; Galtier and Duret, 2007].

Figure legends

Figure 1. Mean derived allele frequencies for AT \rightarrow GC and GC \rightarrow AT alleles in regions of high and low recombination, for the HapMap YRI sample, for different genomic regions and classes of non-synonymous SNPs. Dark gray: AT \rightarrow GC, light gray: GC \rightarrow AT mutations. Solid bars: low recombination, hatched bars: high recombination. Probably damaging: HapMap non-synonymous SNPs predicted by Polyphen to be probably damaging. HGMD: entire HGMD dataset. DM: inherited mutations known to be a direct cause of disease (HGMD mutations minus those that have only been associated statistically with disease).

Figure 2. Derived allele frequency spectra for the HapMap YRI sample, for different genomic regions and classes of non-synonymous SNPs. The data presented here relate only to the high recombination class. Dark gray: $AT \rightarrow GC$ mutations, light gray: $GC \rightarrow AT$ mutations.

Figure 3. Derived allele frequency spectrum obtained through simulations with different parameter sets. Represented in light gray are the distributions of derived allele frequencies for $GC \rightarrow AT$ alleles, and in dark gray, those of $AT \rightarrow GC$ alleles. The population-scaled selection coefficient (Nes) and the population-scaled biased gene conversion parameter (Ne δ) is indicated for each graph.

Deleted: Table legends¶ Table 1: Summary table for the BGC hallmarks for the HapMap and resequencing SNP datasets. The difference in mean derived allele frequencies between AT \rightarrow GC and GC \rightarrow AT SNPs is denoted by d. d_H is the value of d in regions of high recombination. Δd represents the difference in d between the high and low recombination regions. Dark green: values are positive and significantly different from zero, with a p-value < 0.05. Light green: values are positive but not significantly different from zero. Light red: values are negative but not significantly different from zero. No cases were found where d_H or Δd were significantly lower than zero.

Human Mutation

Table 1: Summary table for the BGC hallmarks for the HapMap and resequencing SNP datasets. The difference in mean derived allele frequencies between $AT \rightarrow GC$ and $GC \rightarrow AT$ SNPs is denoted by *d*. d_H is the value of *d* in regions of high recombination. Δd represents the difference in *d* between the high and low recombination regions. Bold font: values are positive and significantly different from zero, with a p-value < 0.05. Italic font: values are positive but not significantly different from zero. Normal font: values are negative but not significantly different from zero. Normal font: values are negative but not significantly different from zero. Normal font: values are negative but not significantly different from zero. No cases were found where d_H or Δd were significantly lower than zero.

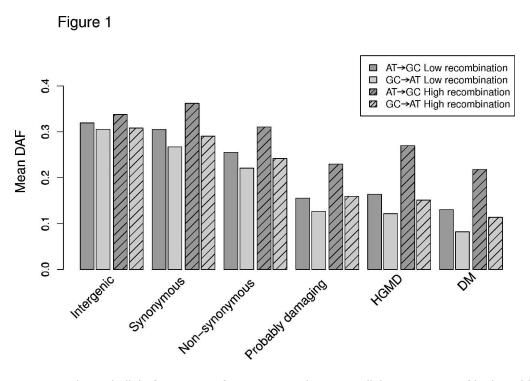

Figure 1. Mean derived allele frequencies for AT→GC and GC→AT alleles in regions of high and low recombination, for the HapMap YRI sample, for different genomic regions and classes of non-synonymous SNPs. Dark gray: AT→GC, light gray: GC→AT mutations. Solid bars: low recombination, hatched bars: high recombination. Probably damaging: HapMap non-synonymous SNPs predicted by Polyphen to be probably damaging. HGMD: entire HGMD dataset. DM: inherited mutations known to be a direct cause of disease (HGMD mutations minus those that have only been associated statistically with disease).

210x144mm (600 x 600 DPI)

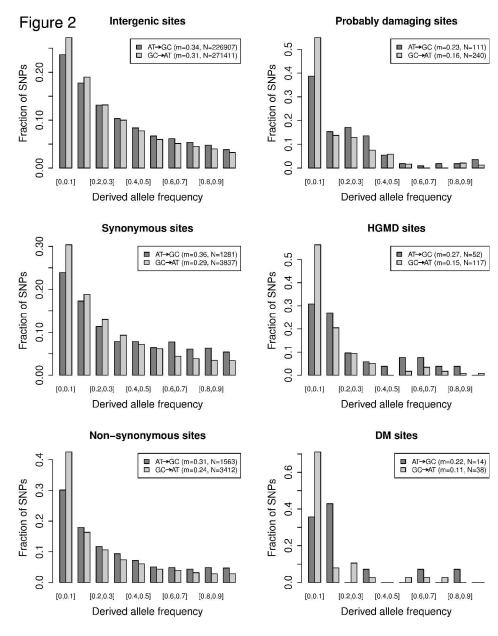

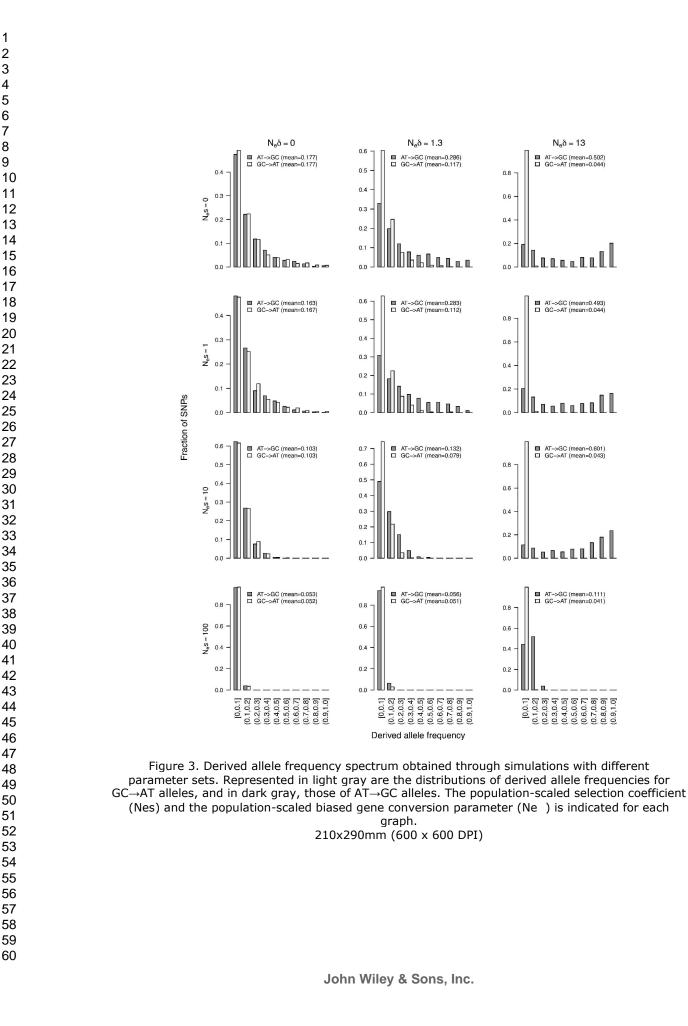

Figure 2. Derived allele frequency spectra for the HapMap YRI sample, for different genomic regions and classes of non-synonymous SNPs. The data presented here relate only to the high recombination class. Dark gray: AT→GC mutations, light gray: GC→AT mutations. 192x245mm (600 x 600 DPI)

The effect of sampling bias on the power of gBGC detection

To search for a potential effect of gBGC, we measured the difference between the mean $AT \longrightarrow GC$ and $GC \longrightarrow AT$ frequencies (denoted d) in regions of low or high recombination. We performed this analysis on two independent SNP datasets: the HapMap SNP dataset (Frazer *et al.*, 2007), and the SNP dataset from Lohmueller *et al.* (2008), which was obtained by direct exon resequencing. Both datasets revealed the hallmarks of gBGC (Table 1): i) in regions of high recombination, d is positive; ii) d increases with the recombination rate. This pattern is observed not only for the silent sites but also for the three classes of non-synonymous sites (Table 1).

We noted however that for the two subsets of non-synonymous sites under the strongest purifying selection (DM and probably damaging mutations), the parameter d was lower in the re-sequencing dataset than in the HapMap dataset, and was no longer significantly different from zero (Table 1). We suspected that this difference might be a consequence of the differences between the SNP sampling strategies that were used to prepare the two datasets. On the one hand, the HapMap dataset prioritized using validated SNPs in order to focus resources on common (rather than rare or false positive) candidate SNPs from the public databases (Frazer *et al.*, 2007). This strategy would omit very rare alleles. On the other hand, the SNP dataset from Lohmueller *et al.* (2008) was obtained by direct exon resequencing, and therefore contains no *a priori* bias in allele frequencies. To assess the impact of these two sampling strategies on the detection of biased gene conversion, we performed theoretical simulations.

First we simulated populations $(N=10^4)$ whose genome is subject to mutation, mild negative selection (ω =0.9999) and medium gBGC (δ =0.00013), as described in the main text (Methods). We recorded the allele frequencies at each polymorphic locus (SNP) in these initial populations. Simulations were performed on a large number of loci, so as to obtain a total of more than 10,000 SNPs within each initial population. We sampled N_c chromosomes from these initial populations. Two values were tested for N_c : 120 (60 pairs of chromosomes in a sample, similar to the number of chromosomes in the HapMap samples), 40 (20 pairs of chromosomes in a

sample, similar to the Lohmueller et al. (2008) sample). In order to test the influence of sampling alone, both strategies were compared for the same value of N_c .

To simulate the re-sequencing strategy used by Lohmueller et al. (2008), we randomly drew SNPs in the initial population, and then determined their DAF in the sample of N_c chromosomes. SNPs for which only one allele was present in the sample (*i.e.* that were not detected as polymorphic) were discarded. This random sampling of SNPs was repeated until a dataset of 100 W \rightarrow S and 100 S \rightarrow W SNPs was obtained. Then we calculated the statistic d, which is defined as the difference between the mean DAFs of W \rightarrow S SNPs and of S \rightarrow W SNPs. To obtain the distribution of the d statistic, this procedure was repeated until at least 60 independent SNP datasets were obtained (Supplementary Table S18).

We used the same procedure to simulate the HapMap strategy, except that rare SNPs (*i.e* SNPs whose DAF in the initial population was lower or higher than given thresholds) were excluded. The threshold values for rare SNPs were chosen in order to have 95% of DAFs in the final sample within the interval [0.03, 0.97].

In the initial simulated population, the derived allele frequency spectrum shows the hallmark of gBGC: DAFs are significantly higher for W \rightarrow S SNPs than for S \rightarrow W SNPs (Figure 3). This excess of high-frequency W \rightarrow S SNPs (*i.e.* a positive *d* statistic) was detected with both sampling strategies. However, independently of the number of sampled chromosomes ($N_c=120$ or $N_c=40$), the *d* statistic obtained by the re-sequencing strategy was on average lower than that obtained with the HapMap strategy (Supplementary Figure S1. For $N_c = 40$ - Resequencing: d=0.1129; HapMap: d=0.146, Wilcoxon rank sum test: $p=1e^{-4}$. For $N_c = 120$ - Resequencing: d=0.0893; HapMap: d=0.1318, Wilcoxon rank sum test: p=0.). This indicates that all else being equal, the HapMap SNP sampling strategy has a greater power to detect the effect of gBGC than the re-sequencing strategy. This can be explained by the fact that the impact of gBGC is more readily detectable on the upper part of the DAF spectrum.

2 Supplementary Figures

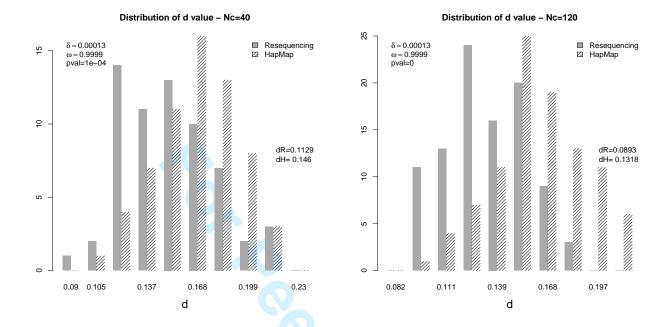

Figure S1: The distribution of the statistics d in the case of an initial spectrum frequencies obtained with values of $\delta = 0.00013$ and $\omega = 0.9999$. Left panel: simulations for $N_c = 40$; right panel: for $N_c = 120$. Gray bars: the histogram of d in the case of HapMap sampling strategy. Hatched bars: the histogram of resequencing sampling strategy. The p-value corresponds to the Wilcoxon rank sum test, for a comparison of medians of the two distributions. The mean value of d is also given in the case of HapMap (dH) and resequencing (dR) sampling strategies.

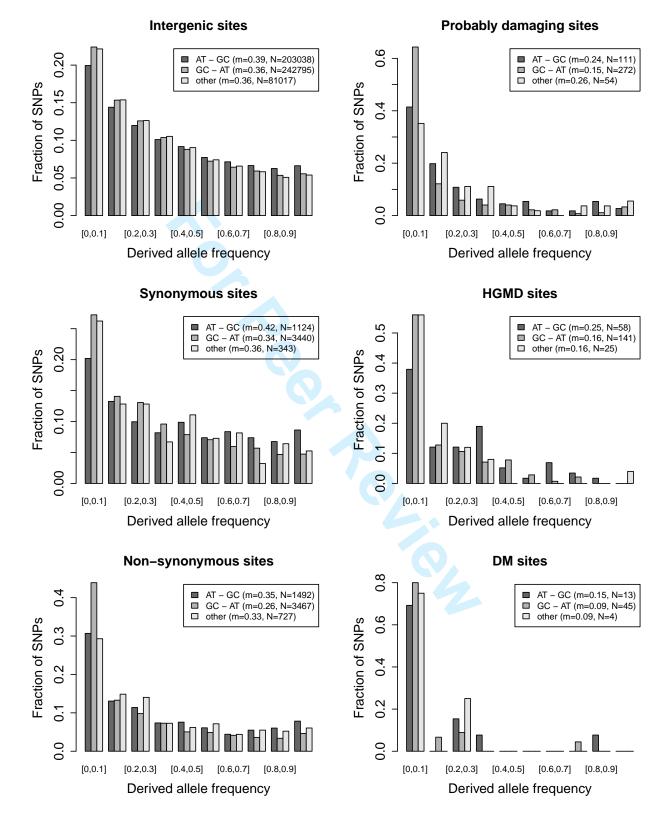

Figure S2: Derived allele frequencies spectra obtained for the HapMap CEU sample, for high recombination regions (as defined by the distance to recombination hotspots). The ancestral and derived alleles were determined using a maximum likelihood method that takes into account CpG hypermutability (Duret and Arndt, 2008). m represents the mean derived allele frequency, and N is the number of SNPs in each category.

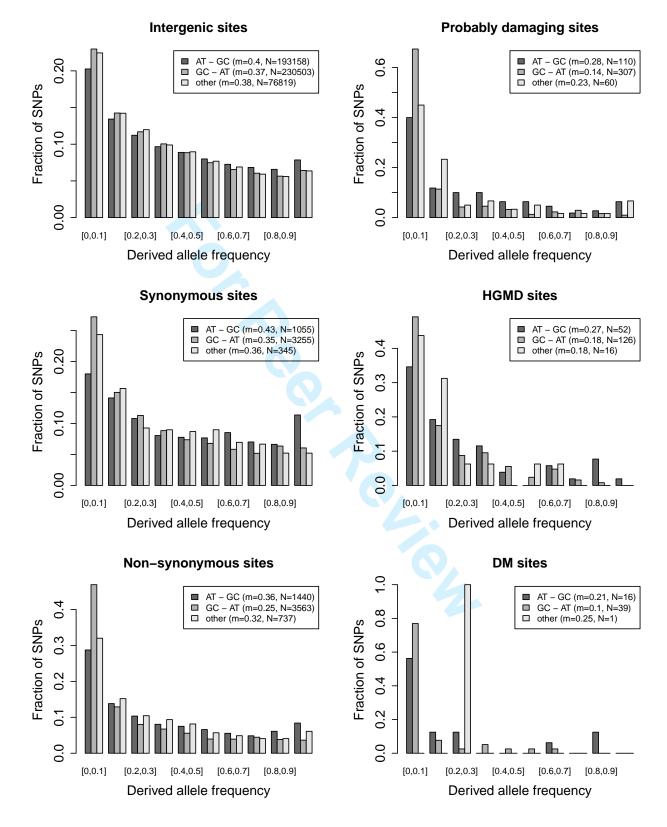

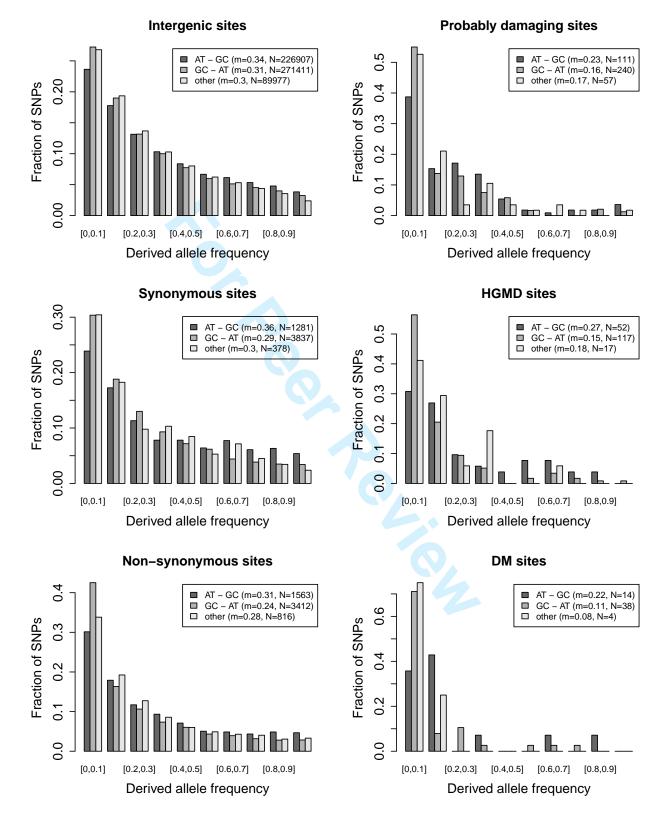

Figure S3: Derived allele frequencies spectra obtained for the HapMap CHB+JPT sample, for high recombination regions (as defined by the distance to recombination hotspots). The ancestral and derived alleles were determined using a maximum likelihood method that takes into account CpG hypermutability (Duret and Arndt, 2008). m represents the mean derived allele frequency, and N is the number of SNPs in each category.

Human Mutation

Figure S4: Derived allele frequencies spectra obtained for the HapMap YRI sample, for high recombination regions (as defined by the distance to recombination hotspots). The ancestral and derived alleles were determined using a maximum likelihood method that takes into account CpG hypermutability (Duret and Arndt, 2008). m represents the mean derived allele frequency, and N is the number of SNPs in each category.

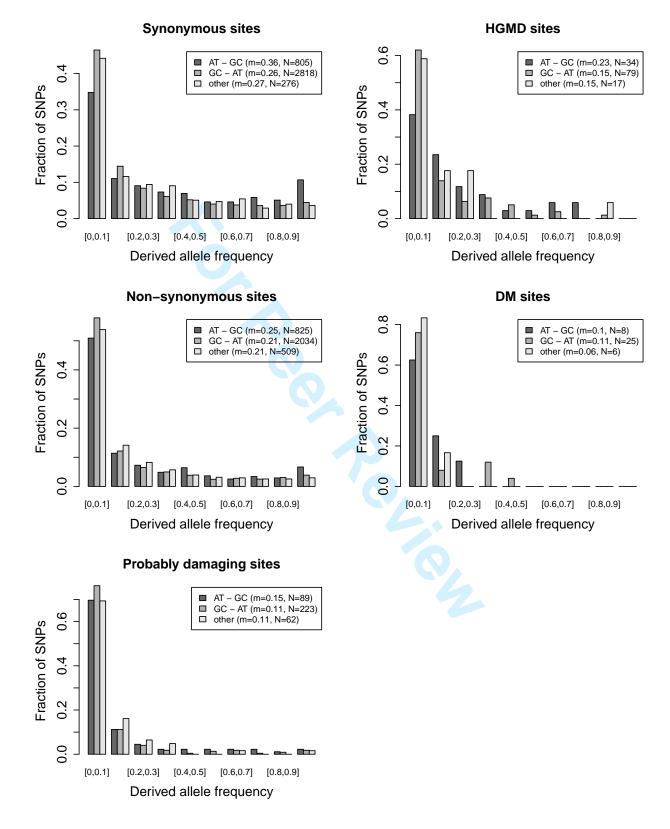

Figure S5: Derived allele frequencies spectra obtained for the Lohmueller *et al.* (2008) CAU sample, for high recombination regions (as defined by the distance to recombination hotspots). The ancestral and derived alleles were determined using a maximum likelihood method that takes into account CpG hypermutability (Duret and Arndt, 2008). m represents the mean derived allele frequency, and N is the number of SNPs in each category.

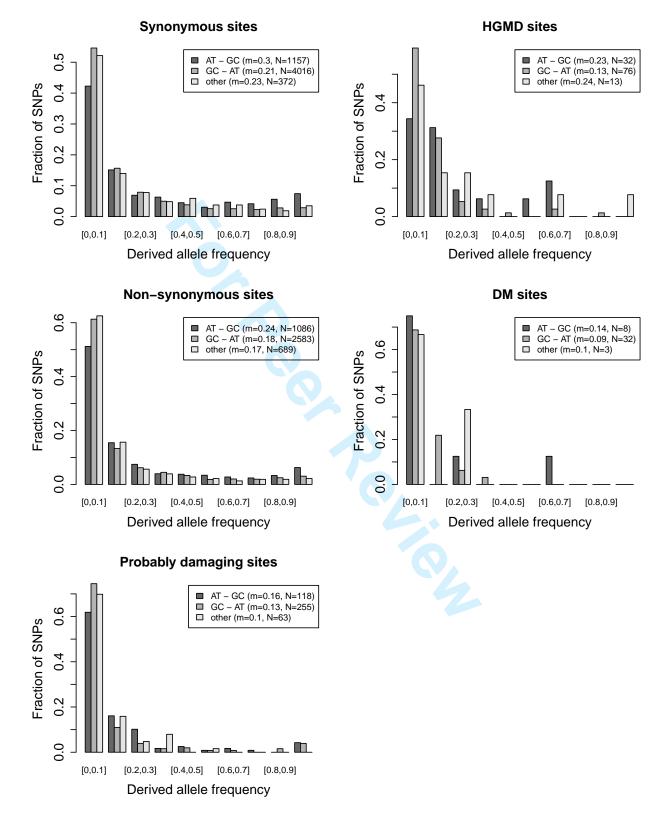

Figure S6: Derived allele frequencies spectra obtained for the Lohmueller *et al.* (2008) AFR sample, for high recombination regions (as defined by the distance to recombination hotspots). The ancestral and derived alleles were determined using a maximum likelihood method that takes into account CpG hypermutability (Duret and Arndt, 2008). m represents the mean derived allele frequency, and N is the number of SNPs in each category.

Range initial freq.	0.061-0.939	0.036-0.964	0.055-0.945	0.031-0.969

Table S18: Table of the number of classes each of size 100 polymorphic loci and the range of initial frequencies for the HapMap biased sampling strategy. These variables depend on the values of gBGC (δ) and the fitness of the derived allele (ω) which were used to obtain the initial distribution of derived alleles, as well as the number of chromosomes analyzed.

Table S19: Mean values for $AT \rightarrow GC$ and $GC \rightarrow AT$ non-synonymous mutations, for those amino-acid changes that can result from both classes of mutations. The values in parantheses represent the sample sizes. Dark green: the difference between mean values was statistically significant (randomization, p-value < 0.05), and the mean was higher for AT \rightarrow GC mutations. Light green: the difference between mean values was not statistically significant (randomization test, p-value $\geq =0.05$), and the mean was higher for AT \rightarrow GC mutations. Light red: the difference between mean values was not statistically significant (randomization test, p-value $\geq =0.05$), and the mean was lower for $AT \rightarrow GC$ mutations. No cases were found where the mean is significantly lower for $AT \rightarrow GC$ mutations. John Wiley & Sons, Inc.
