**Abstract.** A set of genes that are proximately located on multiple chromosomes often implies their origin from the same ancestral genomic segment or their involvement in the same biological process. Among the numerous studies devoted to model and infer these gene sets, the recently introduced APPROXIMATE COMMON INTERVAL (ACI) models capture gene loss events in addition to the gene insertion, duplication and inversion events already incorporated by earlier models. However, the computational tractability of the corresponding problems remains open in most of the cases. In this contribution, we propose a unifying model for ACI, namely MULTI-RELATED-SEGMENTS (MRS), and demonstrate that capturing gene losses induces intractability in many cases (answering an open question raised in [19,20]).

## 1 Introduction

The genetic blueprint of an organism is encoded in a set of DNA sequences, known as chromosomes. During evolution, some subsequences of a chromosome diverged while others were conserved among different organisms. Many of these conserved subsequences correspond to functional elements – referred to as *genes*, which are of paramount importance in understanding evolution. Therefore, in many studies, a chromosome is represented as a sequence of genes and evolution is described as a series of discrete events, such as gene insertion, loss, duplication and inversion. Two genes with highly similar sequences, typically arising via speciation or duplication, are considered as belonging to the same gene family. In this paper, a gene family and its constituent genes are assigned the same label. One of the most important goals in comparative genomics is to identify a set of genes that are in proximate locations on multiple chromosomes and their actual chromosomal occurrences. Indeed, preservation of gene co-locality tends to indicate that the corresponding genes either form a functional unit (*e.g.*, operons) or result from speciation or duplication events [12]. In the literature, the former is termed “*gene cluster*”,

whereas the latter is known as “*synteny*” [21]. Both were extensively studied during the past decade, and numerous models and algorithms were proposed to define and identify them. Most gene cluster models are formally defined [3] while many synteny detection methods are *ad hoc* and lack formal definitions. In this contribution, we will focus only on formally defined models and present the corresponding results from an algorithmic point of view.

## 2 Gene Proximity: Properties and Models

Modeling gene proximity based on biological intuition is known to be difficult. Nevertheless, some key properties have been raised by Hoberman *et al.* [12]. We will present briefly these properties and show that they are inadequately captured by existing models. We then present a formalization of the biological intuition of *gene proximity modeling* by developing the notion of MULTI-RELATED-SEGMENTS (MRS).

### 2.1 Key Properties of Gene Proximity

The first crucial property consists in *evidence of any gene of interest as being ancestral*. This property is usually related to observing a minimum number of  $\beta$  occurrences of such a gene, thereby reducing the possibility of misinterpreting what is in fact a chance occurrence.

Based on the fact that genes of interest appear, with relative proximity, in different chromosomes, most of the models consider chromosomal regions, usually referred as *segments* or *intervals*, as being of interest. Naturally, such segments are subjected to constraints in order to confirm their common origin. First of all, each *contributes sufficiently* to the ancestral gene set. More formally, it means that such a segment has to contain a minimum number of  $\epsilon_m$  different ancestral genes. Then, considering evolutionary events that may have occurred, those segments may not necessarily contain all the ancestral genes (*i.e.*, gene losses). Meanwhile, they may contain genes not belonging to the ancestral gene set (*i.e.*, gene insertions).

For the segment to be relevant, some constraints on gene insertions and losses have to be imposed, which are referred to as *local* and *global ancestral gene densities*. The local density is captured by a maximum number of interleaving genes between two consecutive ancestral genes in a segment (usually referred as  $\alpha$ ). On the other hand, global density is captured by the maximum number of  $\epsilon_l$  gene losses in the segment and the maximum overall number of  $\epsilon_t$  gene losses of all segments of interest. One can easily conceive that  $\epsilon_l$  and  $\epsilon_t$  play different roles: while  $\epsilon_l$  controls

locally in a segment the preservation of a maximum number of ancestral genes, constraining only  $\epsilon_t$  may allow for a long unconserved region to occur within some segment of interest.

## 2.2 Existing Models

Consider  $k$  chromosomes, each represented as a permutation over a given gene set  $\mathcal{G}$ . A CONSERVED SEGMENT [13] consists of a set of genes that occur consecutively in the same order on every input chromosome. Once the constraint of the preserved ordering is removed, it leads to the COMMON INTERVAL (CI) model definition [18]. If the unordered pair of the first and the last genes of a CI is the same on each chromosome, this CI is moreover called *conserved*. Furthermore, if we relax the constraint that genes in a CI have to be consecutive in each chromosomal occurrence – namely, two genes belonging to a CI can be interleaved by a bounded number of genes not belonging to it – the definition of GENE-TEAMS (GT) (also referred as MAX-GAP) model [4] follows. The GT model is of higher biological relevance compared to the CI model since it further captures gene insertions, *i.e.*, genes not belonging to the CI.

So far, we assumed chromosomes as gene permutations, which is rarely the case in reality. To elevate the biological accuracy, chromosomes are represented as strings over gene set  $\mathcal{G}$  such that multiple occurrences of genes, arising via duplication events, can occur on the same chromosome. The aforementioned model definitions naturally apply to strings, but the number of gene sets complying with the model may increase significantly.

More recently, APPROXIMATE COMMON INTERVAL (ACI) models were introduced [1,16,7]. Unlike previous models, in ACI, not all genes of interest have to be present in every chromosomal occurrence. MEDIAN GENE CLUSTER (MGC) model [7] is the most recent formulation of ACI in which the problem is to identify in chromosomes (represented as strings)  $S_1, S_2, \dots, S_k$ , the gene set  $\mathcal{A}$  (of interest) and its chromosomal occurrences  $S'_1, S'_2, \dots, S'_k$  satisfying  $\sum_{i=1}^k (|\mathcal{A} \setminus \mathcal{CS}(S'_i)| + |\mathcal{CS}(S'_i) \setminus \mathcal{A}|) \leq \delta$  and  $\sum_{i=1}^k (|\mathcal{A} \setminus \mathcal{CS}(S'_i)| + |\mathcal{CS}(S'_i) \setminus \mathcal{A}|) \leq \sum_{i=1}^k (|\mathcal{A}' \setminus \mathcal{CS}(S'_i)| + |\mathcal{CS}(S'_i) \setminus \mathcal{A}'|)$ , for all  $\mathcal{A}' \subseteq \mathcal{G}$ . In this formulation,  $S'_i$  is a substring of  $S_i$ ;  $\mathcal{CS}(S')$  denotes the character set (or gene set) of  $S'$ ; and  $\delta$  is the maximum overall content difference allowed between  $\mathcal{A}$  and the  $S'_i$ s. In addition,  $|\mathcal{A}|$  has to be large enough to be biologically meaningful. Note that according to this definition, any character of  $\mathcal{A}$  has to belong to at least  $\frac{k}{2}$  substrings.

## 2.3 Multi-related segments model

We now present our attempt to formalize the biological intuition of gene proximity modeling in the notion of MULTI-RELATED-SEGMENTS (MRS).

Similar to other models, a MRS can be defined as consisting of a set of segments of interest, each evolved from an ancestral segment with gene set  $\mathcal{A}$  by gene insertion, loss, duplication, and inversion events. Formally, a MRS is defined as follows. To ensure *evidence of being ancestral genes*, any gene belonging to  $\mathcal{A}$  has to occur in at least  $\beta$  ( $\geq 2$ ) segments. Each segment of interest has to contain at least  $\epsilon_m$  different ancestral genes and be maximal (*i.e.*, not extendable by including surrounding genes) – thus, imposing a constraint on the *minimum contribution to  $\mathcal{A}$* . As previously done in the GT model, the *local ancestral gene density* is obtained by an upper bound  $\alpha$  controlling the number of non-ancestral genes between any two consecutive ancestral ones in each segment. To capture *global ancestral gene density*, we require each segment to induce no more than  $\epsilon_l$  gene losses and the total number of gene losses of all segments to be lower than  $\epsilon_t$ . Then, given a set of chromosomes and parameters  $\alpha, \beta, \epsilon_m, \epsilon_l$  and  $\epsilon_t$ , the general problem is to identify all MRS.

Compared to existing models, the MRS definition has the following biological advantages. First of all, it captures previous models. MRS corresponds to a CI when  $\beta = k$ ,  $\epsilon_m = |\mathcal{A}|$  and  $\alpha = 0$ , and to a GT when  $\alpha \geq 0$ . Compared to these two models, MRS further captures gene loss events. Note that this aspect was already considered in the MGC model [7]. Nevertheless, there are several major differences. Firstly, MRS captures the same origin of more than two segments in the absence of strong pairwise similarity information, such as differential gene loss [17] and uber-operon [8] – which is not the case for MGC due to the requirement that segments pairwise share some common genes. Moreover, the minimum evidence of a gene being ancestral is more flexible in MRS by requiring  $\beta$  occurrences of any ancestral gene – which has to be at least  $\frac{k}{2}$  in MGC. Finally, the local ancestral gene density is not required in MGC – which is, as explained in [12], crucial.

From an algorithmic point of view, regarding all above mentioned models, complexity increases when chromosomes are delineated as strings rather than permutations: the problem is still tractable when considering CI [2,9] but folds into the hardness as soon as conserved CI is considered [5,6]. The GT model, which captures gene insertions, duplications and inversions, is polynomial on permutations [4] but exponential over strings [15]. The complexity of ACI models, which further captures gene losses, remain totally open [16,7] until this contribution. Although an algorithm with  $O(kn^3 + occ)$  run time over strings was proposed [1], the bound of output size  $occ$  is unknown. In this paper, we consider from an algorithmic point of view the problem of MRS inference by applying

various restrictions on the model definition. Since known algorithmic results are available in previous modeling of gene duplications, insertions and inversions, our focus is on deriving if the problem is tractable when trying to model gene losses.

### 3 Complexity of capturing gene losses using MRS

We first consider the case when the ancestral gene set  $\mathcal{A}$  is *a priori* known. The problem, termed LOCATEMRS, then corresponds to locate, given  $k$  chromosomes  $\mathcal{S} = \{S_1, S_2, \dots, S_k\}$  represented as strings, every feasible MRS originating from  $\mathcal{A}$ . We prove that this problem is **NP**-hard even in the restricted case where  $|\mathcal{CS}(S_i)| = |S_i|$  and meanwhile, at most one substring per  $S_i$  can belong to the resulting MRS, for every  $S_i \in \mathcal{S}$ . It follows that LOCATEMRS problem is **NP**-hard. Next, we prove LOCATEMRS to be fixed-parameter tractable (FPT) [10], and provide an efficient dynamic programming solution. Then, we prove that the optimization problem to identify all MRS is hard to approximate. Finally, we show that with the removal of the maximum number of gene loss constraint and the maximum number of substrings per input sequence constraint, a polynomial algorithm can be derived. Due to space constraint, some proofs are deferred to the full version of the paper (but are included in the Appendix).

#### 3.1 Identify All MRS Given $\mathcal{A}$

Let us consider that no gene insertion is allowed ( $\alpha = 0$ ),  $\beta \geq 2$  and  $\epsilon_t = \epsilon_l = \infty$ . Then, by definition, each MRS consists of substrings involving only genes in  $\mathcal{A}$ . Thus, each input chromosome can be pre-processed in order to remove any gene not belonging to  $\mathcal{A}$ , resulting in a sequence of substrings. One may then filter out any substring that does not respect the *minimum contribution to  $\mathcal{A}$*  criterion (*i.e.*, using  $\epsilon_m$ ). Any remaining substring will be referred as *of interest*. Finally, since in the MRS definition, we are looking for maximal substrings (*i.e.*, not extendable by including surrounding genes), any substring of interest will be either kept or fully removed in the solution.

**Definition 1.** LOCATEMRS: *Given a character set  $\mathcal{A}$ , a string set  $\mathcal{S} = \{S_1^1, S_1^2, \dots, S_2^1, S_2^2, \dots, S_k^1, S_k^2 \dots\}$  where  $S_j^i$  corresponds to the  $i^{\text{th}}$  substring of interest of  $S_j$  (*i.e.*, the  $j^{\text{th}}$  chromosome), find all subsets  $\mathcal{S}' \subseteq \mathcal{S}$  corresponding to a MRS, such that  $\mathcal{A} = \bigcup_{S \in \mathcal{S}'} \mathcal{CS}(S)$  and each character of  $\mathcal{A}$  appears in at least two elements of  $\mathcal{S}'$ , and for any two  $S_i^a, S_j^b \in \mathcal{S}'$ ,  $i \neq j$ .*

$$\begin{array}{l}
\mathcal{S}_{\mathcal{T}} \left\{ \begin{array}{l}
T_1 = \mathbf{u_1 X_1 u_2 X_2 u_3 X_3} - v_1 w_1 v_2 w_2 v_3 w_3 z_3 \\
T_2 = v_2 x_2 v_3 x_3 u_4 x_4 - \mathbf{u_2 W_2 u_3 W_3 Z_3 V_4 W_4 Z_4} \\
T_3 = w_3 x_3 v_4 x_4 u_5 x_5 - \mathbf{u_3 V_3 Z_3 u_4 W_4 Z_4 V_5 W_5 Z_5} \\
T_4 = \mathbf{W_4 X_4 V_5 X_5 u_6 X_6} - u_4 v_4 z_4 u_5 w_5 z_5 v_6 w_6 \\
T_5 = v_1 x_1 w_5 x_5 v_6 x_6 - \mathbf{u_1 W_1 u_5 V_5 Z_5 u_6 W_6}
\end{array} \right. \\
\\
\mathcal{S}_{\mathcal{X}} \left\{ \begin{array}{l}
S_{1,1} = \mathbf{x_1} \quad S_{2,1} = \mathbf{x_2} \quad S_{6,1} = \mathbf{x_6} \\
S_{1,2} = u_1 - \mathbf{w_1} \quad S_{2,2} = u_2 - \mathbf{w_2} \quad S_{6,2} = u_6 - \mathbf{w_6} \\
S_{1,3} = u_1 - \mathbf{v_1} \quad S_{2,3} = u_2 - \mathbf{v_2} \quad S_{6,3} = u_6 - \mathbf{v_6} \\
S_{1,4} = w_1 - \mathbf{v_1} \quad S_{2,4} = w_2 - \mathbf{v_2} \quad S_{6,4} = w_6 - \mathbf{v_6} \\
\\
S_{3,1} = \mathbf{x_3} \quad S_{4,1} = \mathbf{x_4} \quad S_{5,1} = \mathbf{x_5} \\
S_{3,2} = u_3 - \mathbf{v_3} \quad S_{4,2} = \mathbf{u_4} - v_4 \quad S_{5,2} = \mathbf{u_5} - v_5 \\
S_{3,3} = \mathbf{w_3} - v_3 \quad S_{4,3} = w_4 - \mathbf{v_4} \quad S_{5,3} = \mathbf{w_5} - v_5
\end{array} \right.
\end{array}$$

**Fig. 1.** Illustration of the construction on the following instance of X3C:  $\mathcal{X} = \{1, 2, 3, 4, 5, 6\}$  and  $\mathcal{T} = \{(1, 2, 3), (2, 3, 4), (3, 4, 5), (4, 5, 6), (1, 5, 6)\}$ . A correspondance between the solutions of the problems is highlighted in bold.

We will prove that LOCATEMRS is hard but fixed-parameter tractable. We first consider that  $|S| = |\mathcal{CS}(S)|$  for any  $S \in \mathcal{S}$  (*i.e.*,  $S$  is a permutation). Note that this problem is in **NP**. Indeed, given a subset  $\mathcal{S}'$  of  $\mathcal{S}$ , one can check in polynomial time that each character of  $\mathcal{A}$  appears in at least two elements of  $\mathcal{S}'$  and that no more than one substring  $S_j^i$  of any  $S_j$  belongs to  $\mathcal{S}'$ . To prove that this problem is moreover **NP**-hard, we provide a polynomial reduction from the **NP**-complete problem EXACT COVER BY 3-SETS (X3C) [11]: Given a finite set  $\mathcal{X} = \{x_1, \dots, x_{|\mathcal{X}|}\}$  and a family  $\mathcal{T} = \{t_1, \dots, t_{|\mathcal{T}|}\}$  of triples over  $\mathcal{X}$ , is there a subfamily  $\mathcal{T}' \subseteq \mathcal{T}$  such that every  $x_i \in \mathcal{X}$  is contained in exactly one element of  $\mathcal{T}'$ ?

X3C problem is hard even in the special case where each element of  $\mathcal{X}$  appears at most three times in  $\mathcal{T}$  [11]. Then, it is sufficient to consider the case where each element appears either two or three times. Indeed, any triple containing some element that occurs only once has to be part of any solution and can be removed from further consideration. According to the problem definition, a solution corresponds to a selection of one among the at most three occurrences of any element of  $\mathcal{X}$ . Without loss of generality, we fix the triple order in  $\mathcal{T}$ .

Let us now provide the construction from any instance  $(\mathcal{X}, \mathcal{T})$  of X3C problem (an example is given in Figure 1). The set  $\mathcal{S}$  will be built on  $|\mathcal{T}|$  sequences, which represent the triples of  $\mathcal{T}$ , and four (resp. three) additional sequences, which represent any element of  $\mathcal{X}$  occurring twice (resp. three times) in  $\mathcal{T}$ . Let  $\mathcal{S}_{\mathcal{T}} = \{T_1, \dots, T_{|\mathcal{T}|}\}$  (resp.  $\mathcal{S}_{\mathcal{X}}$ ) be the set of sequences representing the triples (resp. the elements of  $\mathcal{X}$ ). Moreover,

we use the symbol “-” to separate the non-adjacent substrings in a given string, *e.g.*,  $S = S^1 - S^2 - S^3$ . Note that, the order of the characters in these substrings is not important according to the definition of MRS. Let us first construct  $\mathcal{S}_{\mathcal{T}}$  as follows. First, for each element  $x_i \in \mathcal{X}$  occurring twice in  $\mathcal{T}$ , concatenate  $u_i x_i$  (resp.  $v_i x_i$ ) to  $T_j^1$  (initially empty) and  $v_i w_i$  (resp.  $u_i w_i$ ) to  $T_j^2$  (initially empty) if the first (resp. second) occurrence of  $x_i$  appears in the  $j^{\text{th}}$  triple of  $\mathcal{T}$ . Second, for each element  $x_i \in \mathcal{X}$  occurring three times in  $\mathcal{T}$ , concatenate  $u_i x_i$  (resp.  $v_i x_i$  and  $w_i x_i$ ) to  $T_j^1$  and  $v_i w_i z_i$  (resp.  $u_i w_i z_i$  and  $u_i v_i z_i$ ) to  $T_j^2$  if the first (resp. second and third) occurrence of  $x_i$  appears in the  $j^{\text{th}}$  triple of  $\mathcal{T}$ . Let us now construct the set  $\mathcal{S}_{\mathcal{X}}$ . For each element  $x_i \in \mathcal{X}$  occurring two times in  $\mathcal{T}$ , add the following four sequences to  $\mathcal{S}_{\mathcal{X}}$ :  $S_{i,1} = x_i$ ,  $S_{i,2} = u_i - w_i$ ,  $S_{i,3} = u_i - v_i$ ,  $S_{i,4} = w_i - v_i$ . And, for each element  $x_i \in \mathcal{X}$  occurring three times in  $\mathcal{T}$ , add the following three sequences to  $\mathcal{S}_{\mathcal{X}}$ :  $S_{i,1} = x_i$ ,  $S_{i,2} = u_i - v_i$ ,  $S_{i,3} = w_i - v_i$ . We finally define  $\mathcal{A}$  to be the set of all characters used in the construction.

**Lemma 1.** *There exists a solution  $\mathcal{T}' \subseteq \mathcal{T}$  to X3C problem over  $(\mathcal{X}, \mathcal{T})$  if and only if in the corresponding built instance  $(\mathcal{A}, \mathcal{S})$  of LOCATEMRS there exists a subset  $\mathcal{S}' \subseteq \mathcal{S}$  corresponding to a MRS.*

Correctness of Lemma 1 (see appendix) implies the following result.

**Theorem 1.** *LOCATEMRS problem is NP-complete even in the special case where none of the input strings contains duplicated characters and at most one substring  $S_j^i$  of every  $S_j$  can belong to any solution  $\mathcal{S}'$ .*

We now prove that LOCATEMRS belongs to the class of the fixed-parameter tractable (FPT) problems [10]. In other words, it can be solved efficiently by an algorithm exponential only with respect to a fixed parameter –  $|\mathcal{A}|$  in our case – while polynomial in the size of the input.

**Theorem 2.** *LOCATEMRS problem is Fixed-Parameter Tractable in  $|\mathcal{A}|$*

To show this, we provide a dynamic programming solution. According to LOCATEMRS definition, one has to select exactly one substring of interest among all of them in each sequence  $S_j$ . A naive algorithm may try all such combinations and check for each if any character appears in at least two substrings. Such an algorithm has an exponential running time. We will prove that by using an efficient dynamic programming strategy, one may hold the exponential factor in the size of the ancestral gene set. Note that one does not need to compute the exact number of times each character occurs but only to ensure that it occurs in at least two substrings in

the solution. According to this remark, consider a fixed ordering of characters  $(a_1, a_2, \dots, a_{|\mathcal{A}|})$  of  $\mathcal{A}$ , we compute after adding substring  $S$  to the current solution a vector  $\mathcal{C} = (c_1, c_2, \dots, c_{|\mathcal{A}|})$ , where  $c_i \in \{0, 1, 2\}$  denotes respectively that  $a_i$  is not contained, contained in one, or contained in at least two substrings. For example, consider  $\mathcal{A} = \{1, 2, 3, 4, 5\}$  and current solution  $\mathcal{S}' = \{124\}$ , one may derive a vector  $\mathcal{C} = (2, 1, 0, 2, 1)$  after adding substring “1445” to  $\mathcal{S}'$ . The main property of this representation is that, given  $\mathcal{A}$ , there are only  $3^{|\mathcal{A}|}$  possible vectors. Further, let  $\mu(x)$  and  $\chi_S(x)$  denote, respectively, the position of  $x$  in the fixed ordering of  $\mathcal{A}$  and the boolean function indicating whether  $x$  occurs in  $S$ . We define a boolean dynamic table  $D$  indexed by the last substring added and the vector  $\mathcal{C}$  for the current solution. The main recursive function is defined as follows

$$D(S_j^i, (c_1, \dots, c_{|\mathcal{A}|})) = \begin{cases} 1 - \text{if } \exists i' < i, j' < j \text{ s.t. } D(S_{j'}^{i'}, (c'_1, \dots, c'_{|\mathcal{A}|})) = 1 \\ \quad \text{and } \forall 1 \leq l \leq |\mathcal{A}|, c_l - c'_l = \chi_{S_j^i}(x) \\ \quad \text{where } \mu(x) = l \\ 0 - \text{otherwise} \end{cases}$$

---

**Algorithm 1** LOCATEMRS( $\mathcal{A}, \mathcal{S} = \{S_1^1, S_1^2, \dots, S_2^1, S_2^2, \dots, S_k^1, S_k^2\}$ )

---

1: Initialize all entries of  $D$  to 0  
2: **for** each  $S_1^i \in \mathcal{S}$  **do**  $D(S_1^i, (c_1, \dots, c_{|\mathcal{A}|})) = 1$  where  $\forall x \in S_1^i, c_{\mu(x)} = \chi_{S_1^i}(x)$  **done**  
3: **for**  $j = 2$  to  $k$  **do**  
4:   **for** each  $S_j^i \in \mathcal{S}$  **do** Fill out  $D(S_j^i, (c_1, \dots, c_{|\mathcal{A}|}))$  **done**  
5: **end for**  
6: **for** each  $S_k^i \in \mathcal{S}$  **do**  
7:   **if**  $D(S_k^i, (2, \dots, 2)) = 1$  **then return** True **end if**  
8: **end for**  
9: **return** False

---

Given this function, one can apply Algorithm 1. The algorithm computes, for each sequence  $S_j$  the possible character set solution induced by any combination of substrings of interest from sequences  $S_{j'}$  with  $j' < j$ . Therefore, any entry  $D(S_j^i, (2, \dots, 2)) = 1$  corresponds to a MRS being found. One may, using a simple back-tracking technic, rebuild one optimal solution. Let us now prove the time complexity of this algorithm. In order to fill out  $D$ , one has to compute  $|\mathcal{S}| \times 3^{|\mathcal{A}|}$  entries. Indeed, there are at most  $|\mathcal{S}|$  different substrings and  $3^{|\mathcal{A}|}$  possible character sets. The main recursion needs, for each entry, to browse at most  $|\mathcal{S}| \times 3^{|\mathcal{A}|}$  other entries of  $D$ . This leads to an overall  $O((|\mathcal{S}| \times 3^{|\mathcal{A}|})^2)$  running time algorithm. Hence, the problem is FPT with respect to  $|\mathcal{A}|$ .

### 3.2 Identify All MRS When $\mathcal{A}$ Is Unknown

We will prove that finding all MRS problem is hard even in the special case where none of the sequences contains duplicated characters and in any solution  $\mathcal{S}'$ , for any sequence  $S_j$  at most one substring  $S_j^i \in \mathcal{S}'$  (i.e.,  $\alpha = 0, \beta \geq 2, \epsilon_t = \epsilon_l = \infty$ ).

First, note that the problem is in **NP** since given a subset  $\mathcal{S}'$  of  $\mathcal{S}$ , one can polynomially check that each element of  $\mathcal{A}$  appears in at least two substrings and no more than one substring of any sequence belongs to  $\mathcal{S}'$ . To prove that this problem is moreover **NP**-hard, we provide a polynomial reduction from the **NP**-complete problem X3C [21] based on a slight modification of the reduction of the previous section. Indeed, if one replaces each of the separations “ $\_$ ” between substrings of interest by a unique character appearing only once in  $\mathcal{S}$ , then by definition, those added characters will never be part of a MRS since any character should appear at least twice in a MRS. Due to the unextendability property of MRS, one should be able to find neither a smaller nor a bigger substring of interest in each sequence than in the LOCATEMRS formulation. The rest of the proof still holds, leading to the following theorem.

**Theorem 3.** *Finding a MRS problem is **NP**-complete even in the special case where none of the sequences contains duplicated characters and in any solution  $\mathcal{S}'$ , at most one substring from each  $S_j$  belongs to  $\mathcal{S}'$ .*

Let us then consider the optimization version of the problem (Definition 2) where one wants to find a MRS induced by the maximum unknown ancestral gene set (in other words, one constrains the minimum size of  $\mathcal{A}$ ), and at the same time, at most one substring of each  $S_j$  can belong to the MRS.

**Definition 2.** MAXMRS: *Given a set of  $k$  strings  $\mathcal{S} = \{S_1, \dots, S_k\}$ , find any possible  $(\mathcal{A}, \mathcal{S}')$  where  $\mathcal{S}' = \{S'_1, S'_2, \dots, S'_k : S'_i \text{ is a substring of } S_i\}$ ,  $\mathcal{A} = \bigcup_{i=1}^k \mathcal{CS}(S'_i)$ , and  $|\mathcal{A}|$  is maximum.*

We will demonstrate that this optimization problem is hard to approximate – answering an open question raised in [19,20]. Meanwhile, we show that the inapproximability of this problem may stem from forbidding more than one substring per input chromosome, the relaxation of which leads to polynomiality.

In the following, we consider that  $\beta \geq 2, \alpha = 0, \epsilon_m = 1$ , and  $\epsilon_t = \epsilon_l = \infty$ . We prove the inapproximability of MAXMRS below by proposing a reduction from the MINIMUM SET COVER (MINSC) problem: Given a family  $\mathcal{F}$  of subsets of a finite universe  $\mathcal{U}$ , find a set cover  $\mathcal{F}'$  for  $\mathcal{U}$  – that is a subfamily  $\mathcal{F}' \subseteq \mathcal{F}$  whose union is  $\mathcal{U}$  – of the minimum cardinality.

Since any character appearing once in an input string will not be part of a MRS, we use the symbol “-” to denote any such character. The presence of symbol “-” will induce, in MAXMRS problem, that characters appearing before and after it in any input string cannot be part of the same solution. Given any instance  $(\mathcal{F}, \mathcal{U})$  of MINSC, where  $\mathcal{U} = \{u_1, \dots, u_n\}$  and  $\mathcal{F} = \{F_i : F_i = \{u_i^1, u_i^2, \dots, u_i^{n_i}\}, 1 \leq i \leq m\}$ , we define a set of strings  $\mathcal{S} = \{S_0, \dots, S_{k=2m}\}$  with  $S_0 = u_1 \dots u_n$ ,  $S_i = S_i^1 - S_i^2 = u_i^1 u_i^2 \dots u_i^{n_i} - v_i$  and  $S_{m+i} = v_i$ , for  $1 \leq i \leq m$ .

**Lemma 2.** *If there exists a cover  $\mathcal{F}' \subseteq \mathcal{F}$  for  $\mathcal{U}$  (i.e.  $\mathcal{U} = \bigcup_{F \in \mathcal{F}'} F$ ) then there exists a solution  $(\mathcal{A}, \mathcal{S}')$  (i.e. a MRS) for the built up instance  $\mathcal{S}$  of MAXMRS such that  $|\mathcal{A}| = n + m - |\mathcal{F}'|$ . (See proof in the appendix)*

**Lemma 3.** *Given a solution  $(\mathcal{A}, \mathcal{S}')$  for a built up instance  $\mathcal{S}$  of MAXMRS, we can construct in polynomial-time a cover  $\mathcal{F}' \subseteq \mathcal{F}$  for  $\mathcal{U}$ , such that  $|\mathcal{F}'| \leq m - (|\mathcal{A}| - n)$ .*

*Proof.* We first define a polynomial-time subroutine that transforms any solution  $(\mathcal{A}, \mathcal{S}')$  to an equally good solution where  $\mathcal{CS}(S_0) \subseteq \mathcal{A}$ . For any character of  $S_0$  not belonging to  $\mathcal{A}$  – say  $u_j$ , add to  $\mathcal{S}'$  one substring  $S_i^1$  that was not in  $\mathcal{S}'$  but contains  $u_j$ , meanwhile, remove from  $\mathcal{S}'$  correspondingly two substrings  $S_i^2$  and  $S_{m+i}$ . Every such replacement operation will change a given  $v_i$  by  $u_j$  in  $\mathcal{A}$  without decreasing the cardinality of  $\mathcal{A}$  (i.e. an equally good solution). Once this subroutine has been applied to  $(\mathcal{A}, \mathcal{S}')$ , one can build a cover  $\mathcal{F}' = \{F_i : S_i^2 \notin \mathcal{S}'\}$ . The subroutine guarantees that all elements of  $S_0$  belong to  $\mathcal{F}'$  – a cover for  $\mathcal{U}$ . Clearly,  $|\mathcal{A}| - n$  corresponds to the number of  $v_j$ s belonging to  $\mathcal{A}$ . Considering  $S_1, S_2, \dots, S_m$  (where  $S_j^2$ s appear), there exist at most  $m - (|\mathcal{A}| - n)$  strings such that  $S_j^2 \notin \mathcal{S}'$ ; inducing that  $|\mathcal{F}'| \leq m - (|\mathcal{A}| - n)$ .  $\square$

**Theorem 4.** *MAXMRS is APX-hard even in the special case where, for every input string  $S_i$ ,  $|\mathcal{CS}(S_i)| = |S_i|$ .*

*Proof.* Consider MINIMUM 3-SETCOVER-3 (MIN3SC-3), a subproblem of MINSC, where the size of any set in  $\mathcal{F}$  is bounded by 3 as well as the number of times each character of  $\mathcal{U}$  occurs in  $\mathcal{F}$ . We will prove the theorem by contradiction, assuming that MAXMRS admits a Polynomial-Time Approximation Scheme (PTAS), i.e. one would be able to find an approximation algorithm leading to an approximate solution  $(\mathcal{A}_{APX}, \mathcal{S}_{APX})$ , which compared to the optimal solution  $(\mathcal{A}_{OPT}, \mathcal{S}_{OPT})$ , induces  $|\mathcal{A}_{APX}| \geq (1-\epsilon) \cdot |\mathcal{A}_{OPT}|$  for a parameter  $\epsilon > 0$ . Accordingly, under the same assumption, we will prove that MIN3SC-3 also admits a PTAS, i.e. one would be able to find an approximation algorithm leading to an approximate

solution  $\mathcal{F}_{APX}$ , which compared to the optimal solution  $\mathcal{F}_{OPT}$ , induces  $|\mathcal{F}_{APX}| \leq (1 + \gamma) \cdot |\mathcal{F}_{OPT}|$  for a parameter  $\gamma > 0$  – a contradiction to the fact that MIN3SC-3 is **APX**-hard [14].

Since each character of  $\mathcal{U}$  occurs at most three times in  $\mathcal{F}$ , the size of the ground set used to build  $\mathcal{F}$  is at most  $3n$ , leading to  $m \leq 3n$ . Moreover, any cover  $\mathcal{F}' \subseteq \mathcal{F}$  of  $\mathcal{U}$  is at least of size  $\frac{n}{3}$  since  $\mathcal{F}$  is composed of sets of size at most three. Hence,  $\frac{n}{3} \leq |\mathcal{F}_{OPT}|$  and consequently,  $m \leq 9 \cdot |\mathcal{F}_{OPT}|$ .

If we have an approximate solution  $(\mathcal{A}_{APX}, \mathcal{S}_{APX})$ , then

By Lemma 3,  $|\mathcal{F}_{APX}| \leq m - (|\mathcal{A}_{APX}| - n)$

By assumption,  $m - (|\mathcal{A}_{APX}| - n) \leq m - ((1 - \epsilon) \cdot |\mathcal{A}_{OPT}| - n)$

By Lemma 2,  $|\mathcal{A}_{OPT}| = n + m - |\mathcal{F}_{OPT}|$

Which leads to,  $|\mathcal{F}_{APX}| \leq \epsilon \cdot n + \epsilon \cdot m + (1 - \epsilon) \cdot |\mathcal{F}_{OPT}|$

$(m \leq 3n \leq 9|\mathcal{F}_{OPT}|)$   $\leq 12\epsilon \cdot |\mathcal{F}_{OPT}| + (1 - \epsilon) \cdot |\mathcal{F}_{OPT}|$

Finally,  $\leq (1 + 11\epsilon) \cdot |\mathcal{F}_{OPT}| \quad \square$

We now prove the following surprising result when every input sequence contains no duplicated characters.

**Theorem 5.** *If one restricts neither the maximum number of gene losses per substring of interest, nor the maximum number of substrings of interest per chromosome, finding all the MRS becomes a polynomial task.*

*Proof.* Consider a graph  $G = (V, E)$  obtained from  $\mathcal{S}$  in such a way that a vertex is assigned to every character in each string  $S_i \in \mathcal{S}$  and a red (resp. blue) colored edge is created between any two adjacent characters (resp. any two vertices representing identical characters). Given this representation, the notion of character set naturally extends to any subgraph  $G[V']$  of  $G$  as the set of represented characters by  $V'$ . Our method consists in an iterative procedure which stops when none of the following operations can be applied anymore. The results will consist of a set of connected components, each corresponding to a MRS. The first operation consists in removing from  $V$  any vertex which is only incident to red colored edges. This polynomial operation results in the removal of genes not appearing twice in a candidate connected component. The second operation gets rid of candidates not fulfilling the minimum contribution to the ancestral gene set by pruning any red edge-induced subgraph  $G'$  such that  $|\mathcal{CS}(G')| < \epsilon_m$ . This operation can be done in linear time by browsing any connected component. Once none of these operations can be done anymore, it is easy to see that each remaining connected component corresponds to a MRS.  $\square$

## Appendix

### Missing proofs for main results

**Lemma 1.** *There exists a solution  $\mathcal{T}' \subseteq \mathcal{T}$  to X3C problem over  $(\mathcal{X}, \mathcal{T})$  if and only if in the corresponding built instance  $(\mathcal{A}, \mathcal{S})$  of LOCATEMRS there exists a subset  $\mathcal{S}' \subseteq \mathcal{S}$  corresponding to a MRS.*

*Proof.* ( $\Rightarrow$ ) Suppose such  $\mathcal{T}' \subseteq \mathcal{T}$  exists for the instance  $(\mathcal{X}, \mathcal{T})$ . Let us prove that we can compute in polynomial time an  $\mathcal{S}' \subseteq \mathcal{S}$  corresponding to a MRS in the corresponding built instance of LOCATEMRS. For any triple  $t_q \in \mathcal{T}$ , if  $t_q \in \mathcal{T}'$  then add  $T_q^1$  to  $\mathcal{S}'$ ; add  $T_q^2$  otherwise. Moreover, for  $1 \leq i \leq |\mathcal{X}|$ , add  $S_{i,1}$  to  $\mathcal{S}'$ . For any element  $x_i \in \mathcal{X}$  occurring two times in  $\mathcal{T}$ , if the first triple containing  $x_i$  is in  $\mathcal{T}'$  then add  $S_{i,2}^2, S_{i,3}^2, S_{i,4}^2$  to  $\mathcal{S}'$ ; add  $S_{i,2}^1, S_{i,3}^1, S_{i,4}^1$  to  $\mathcal{S}'$  otherwise. For any element  $x_i \in \mathcal{X}$  occurring three times in  $\mathcal{T}$ , if the first triple containing  $x_i$  is in  $\mathcal{T}'$  then add  $S_{i,2}^2, S_{i,3}^1$  to  $\mathcal{S}'$ ; if the second triple containing  $x_i$  is in  $\mathcal{T}'$  then add  $S_{i,2}^1, S_{i,3}^1$  to  $\mathcal{S}'$ ; add  $S_{i,2}^1, S_{i,3}^2$  to  $\mathcal{S}'$  otherwise (see Figure 1). Let us now prove that  $\mathcal{S}'$  is indeed a MRS, *i.e.*,  $\mathcal{A} = \bigcup_{S \in \mathcal{S}'} \mathcal{CS}(S)$  and any element of  $\mathcal{A}$  appears at least twice in  $\mathcal{S}'$ . First note that, by definition, in  $\mathcal{T}'$ , there is exactly one triple containing any element of  $\mathcal{X}$ . Thus, by construction, there is exactly one substring per sequence in  $\mathcal{S}'$ . Let us consider any element  $x_i \in \mathcal{X}$  which occurs twice in  $\mathcal{T}$  – say in triples  $t_q$  and  $t_{q'}$  for the first and respectively second occurrences of  $x_i$ . Then, since  $\mathcal{T}'$  is an exact cover, there exists exactly one among  $t_q$  and  $t_{q'}$  in  $\mathcal{T}'$  – say  $t_q$ . Therefore, by construction,  $\{T_q^1, T_{q'}^2, S_{i,1}, S_{i,2}^2, S_{i,3}^2, S_{i,4}^2\} \subseteq \mathcal{S}'$  (the reader may, for example, consider  $x_1$  in Figure 1). Consequently, a) two occurrences of  $x_i$  appear in  $\mathcal{S}'$  (one from  $S_{i,1}$  and one from  $T_q^1$ ), b) two occurrences of  $u_i$  appear in  $\mathcal{S}'$  (one from  $T_q^1$  and one from  $T_{q'}^2$ ), c) two occurrences of  $v_i$  appear in  $\mathcal{S}'$  (one from  $S_{i,3}$  and one from  $S_{i,4}$ ), and d) two occurrences of  $w_i$  appear in  $\mathcal{S}'$  (one from  $S_{i,2}$  and one from  $T_{q'}^2$ ). With a similar reasoning, one can check that any of  $x_i, u_i, v_i, w_i$  appears twice when  $t_{q'} \in \mathcal{T}'$ . Let us now consider each element  $x_i \in \mathcal{X}$  that occurs three times in  $\mathcal{T}$  – say in triples  $t_q, t_{q'}$  and  $t_{q''}$  for the first (resp. second and third) occurrence of  $x_i$ . Then, since  $\mathcal{T}'$  is an exact cover, there exists exactly one among  $t_q, t_{q'}$  and  $t_{q''}$  in  $\mathcal{T}'$  – say  $t_q$ . Therefore, by construction,  $\{T_q^1, T_{q'}^2, T_{q''}^2, S_{i,1}, S_{i,2}^2, S_{i,3}^1\} \subseteq \mathcal{S}'$  (the reader may, for example, consider  $x_3$  in Figure 1). Consequently, a) two occurrences of  $x_i$  appear in  $\mathcal{S}'$  (one from  $S_{i,1}$  and one from  $T_q^1$ ), b) three occurrences of  $u_i$  appear in  $\mathcal{S}'$  (one from  $T_q^1$ , one from  $T_{q'}^2$  and one from  $T_{q''}^2$ ), c) two occurrences of  $v_i$  appear in  $\mathcal{S}'$  (one from  $T_{q''}^2$  and one from  $S_{i,2}$ ), d) two occurrences of  $w_i$  appear in  $\mathcal{S}'$  (one from  $S_{i,3}$  and one from

$T_{q'}^2$ ), and e) two occurrences of  $z_i$  appear in  $\mathcal{S}'$  (one from  $T_{q'}^2$  and one from  $T_{q''}^2$ ). With a similar reasoning, one can check that any of  $x_i, u_i, v_i, w_i, z_i$  appears at least twice when  $t_{q'} \in \mathcal{T}'$  or  $t_{q''} \in \mathcal{T}'$ . We have completed the proof that each element of  $\mathcal{A}$  appears at least twice in  $\mathcal{S}'$ ; inducing that  $\mathcal{S}'$  is indeed a MRS.

( $\Leftarrow$ ) Suppose now that such a set  $\mathcal{S}' \subseteq \mathcal{S}$  exists for the corresponding built instance of LOCATEMRS  $(\mathcal{A}, \mathcal{S})$ . We will prove that we can compute in polynomial time a  $\mathcal{T}' \subseteq \mathcal{T}$  corresponding to a solution for the instance  $(\mathcal{X}, \mathcal{T})$ . For any  $1 \leq i \leq |\mathcal{T}|$ ,  $t_i \in \mathcal{T}'$  if  $T_i^1 \subseteq \mathcal{S}'$ . Let us now prove that  $\mathcal{T}'$  is indeed an exact cover of  $\mathcal{T}$ . Note that, any solution  $\mathcal{S}'$  is a subset of  $\mathcal{S}$  since we are looking for unextendable substrings (inducing that any substring of interest is either fully kept or removed). Moreover, recall that we consider here the special case of the problem where in any solution  $\mathcal{S}'$ , for any string  $S_j$ , at most one substring  $S_j^i \in \mathcal{S}'$ . Let us first prove that given two triples  $t_q$  and  $t_{q'}$  both containing one of the two occurrences of  $x_i \in \mathcal{X}$  (*i.e.* the case where  $x_i$  appears twice in  $\mathcal{X}$ ), then, exactly one of the substrings  $T_q^1$  and  $T_{q'}^1$  belongs to  $\mathcal{S}'$  (the reader may, for example, consider  $x_1$  in Figure 1). By contradiction, suppose this is not the case, *i.e.*  $\{T_q^1, T_{q'}^1\} \subseteq \mathcal{S}'$ . Then, in  $\mathcal{S}'$ , there are already one occurrence of  $u_i$ , one occurrence of  $v_i$  and two occurrences of  $x_i$ . Note that the set of elements related to variable  $x_i$ , *i.e.*,  $\{x_i, u_i, v_i, w_i\}$ , appears in the following sequences  $\{T_q, T_{q'}, S_{i,1}, S_{i,2}, S_{i,3}, S_{i,4}\}$ . Since, by definition, in  $\mathcal{S}'$ , every element should appear at least twice, using exactly one of the substrings of each of these sequences, one should be able to obtain another  $u_i$ , another  $v_i$  and two  $w_i$ . Unfortunately, this is not possible in any combination of the corresponding substrings excluding, by hypothesis,  $T_q^2$  and  $T_{q'}^2$ ; a contradiction. Now consider the three triples  $t_q, t_{q'}$  and  $t_{q''}$ , each containing one of the three occurrences of  $x_i \in \mathcal{X}$  (*i.e.* the case where  $x_i$  appears three times in  $\mathcal{X}$ ), then, exactly one among the substrings  $T_q^1, T_{q'}^1$  and  $T_{q''}^1$  belongs to  $\mathcal{S}'$  (the reader may, for example, consider  $x_3$  in Figure 1). By construction, the occurrences of  $z_i$  belong to  $T_q^2, T_{q'}^2$  and  $T_{q''}^2$ . In order to obtain at least two occurrences of  $z_i$  in  $\mathcal{S}'$ , at least two of the substrings among  $\{T_q^2, T_{q'}^2, T_{q''}^2\}$  should be in  $\mathcal{S}'$ . Moreover, since the occurrences of  $x_i$  belong to  $\{T_q^1, T_{q'}^1, T_{q''}^1, S_{i,1}\}$ , exactly one of  $\{T_q^1, T_{q'}^1, T_{q''}^1\}$  should be in  $\mathcal{S}'$ . We have proved that for each element  $x_i$  occurring twice (*resp.* three times) in  $\mathcal{T}$ , exactly one of the triples containing  $x_i$  is kept in  $\mathcal{T}'$ . Thus,  $\mathcal{T}'$  is indeed an exact cover of  $\mathcal{T}$ .  $\square$

**Lemma 2.** *If there exists a cover  $\mathcal{F}' \subseteq \mathcal{F}$  for  $\mathcal{U}$  (*i.e.*,  $\mathcal{U} = \bigcup_{F \in \mathcal{F}'} F$ ) then there exists a solution  $(\mathcal{A}, \mathcal{S}')$  (*i.e.*, a MRS) for the built up instance  $\mathcal{S}$  of MAXMRS such that  $|\mathcal{A}| = n + m - |\mathcal{F}'|$ .*

*Proof.* Consider the following solution  $\mathcal{S}' = \{S_0\} \cup \{S_i^1 \in \mathcal{S} : F_i \in \mathcal{F}'\} \cup \{S_i^2, S_{m+i} \in \mathcal{S} : F_i \notin \mathcal{F}'\}$ . By definition,  $\mathcal{S}'$  is indeed a MRS since it cannot be extended (it is made of one unextendable substring of each sequence) and any element appears twice. Moreover, its character set  $\mathcal{A} = \mathcal{U} \cup \{v_i : F_i \notin \mathcal{F}'\}$  which is of size  $n + m - |\mathcal{F}'|$ .  $\square$
