Abstract

Congenital chloride diarrhea (CLD) is an autosomal recessive disorder with around 250 cases reported so far. Life-long secretory diarrhea is caused by mutations in the solute carrier family 26 member 3 (*SLC26A3*) gene disrupting the epithelial $\text{Cl}^-/\text{HCO}_3^-$ transport in the ileum and colon. Although salt substitution allows favorable outcome, possible manifestations include renal impairment, intestinal inflammation, and male infertility. At least 55 mutations, of which 21 (38%) novel are reported here, cause CLD. Majority of the mutations are single-nucleotide substitutions (n=30; 55%) with 18 missense, 7 nonsense, and 5 splice-site mutations. Additional mutations are minor deletions/insertions or their combinations (n=21; 38%), major deletions (n=3; 5%), and a major insertion (n=1; 2%). Distinct founder mutations appear in Finland, Poland, and Arab Countries, whereas patients from other countries carry rare homozygous or compound heterozygous mutations. None of the studied *SLC26A3* mutants shows significant $\text{Cl}^-/\text{HCO}_3^-$ exchange activity *in vitro*, and accordingly, evidence of genotype-phenotype differences remain nonexistent. The domain interaction between *SLC26A3* and the cystic fibrosis transmembrane conductance regulator (CFTR) raises a possibility of CFTR modulation in the pathogenesis of CLD. This review summarizes the current knowledge of *SLC26A3* mutations and polymorphisms, and their biological and clinical relevance.

Deleted: any

Background

Congenital chloride diarrhea (CLD; OMIM #214700) is a rare disease with an autosomal recessive inheritance (Norio et al., 1971). It is characterized by chronic secretory diarrhea containing an excess of chloride. Due to the intrauterine onset of diarrhea, CLD pregnancies are complicated by polyhydramnios and infant meconium is lacking (Holmberg, 1986). Children with CLD are often premature and soon after birth, profuse diarrhea leads to dehydration, hypochloremic and hypokalemic metabolic alkalosis, and failure to thrive. CLD diagnosis is based on the clinical picture and measurement of high fecal chloride (>90 mmol/L) after correction of the fluid and salt depletion. While untreated disease is mostly lethal during the first weeks or months of life, oral salt substitution with NaCl and KCl allows normal growth and development, and favorable outcome (Holmberg, 1986; Hihnala et al., 2006a; Wedenoja et al., 2010). Untreated or poorly treated disease is associated with impaired renal function and nephrocalcinosis, and even with end-stage renal disease (Wedenoja et al., 2008b). Associated morbidity involves intestinal inflammation, hyperuricemia, inguinal hernias, spermatoceles, and male subfertility (Hihnala et al., 2006a; Hoglund et al., 2006).

After the first CLD descriptions in two Americans partly of Italian descent, more than 250 cases have been reported worldwide with around one-fifth of the patients originating from Finland (Darrow, 1945; Gamble et al., 1945; Hoglund et al., 1998). For the rarity of CLD, most of its clinical and genetic studies have been performed in the genetically homogeneous series of Finland, where the incidence is in the range of 1 in 30,000 to 40,000 live births.

Other countries with a higher than global incidence are Poland (1 in 200,000), Kuwait, and Saudi Arabia. In the countries around the Persian Gulf, and especially in Kuwait, local estimates of incidence total as high as around 1 in 3,200 due to consanguineous marriages

Deleted: -

Deleted: -average

1
2 (Hoglund et al., 1998). Single cases with CLD appear worldwide, both in developing and
3 more affluent countries, making diagnostics challenging. If a suspicion of CLD arises,
4 especially in low-incidence countries, mutation analysis may be required to establish the
5 diagnosis (Hoglund et al., 1996; Makela et al., 2002).
6
7
8
9

10 CLD is caused by mutations in the solute carrier family 26 member 3 (*SLC26A3*) gene
11 (OMIM #126650) (Kere et al., 1993; Hoglund et al., 1996). Initially, *SLC26A3* was cloned
12 with the name down-regulated in adenoma (*DRA*) as a potential tumor suppressor gene based
13 on its abundant expression in the colon but its absence from colonic adenomas and
14 adenocarcinomas (Schweinfest et al., 1993; Taguchi et al., 1994). The genomic sequence of
15 *SLC26A3* spans around 37.8 kb on the minus strand of chromosome 7q31.1
16 (www.ncbi.nlm.nih.gov: NG_008046.1). The full-length cDNA, around 3.2 kb on Northern
17 blot (Schweinfest et al., 1993) (www.ncbi.nlm.nih.gov: NM_000111.2), has an open reading
18 frame of 2,295 bp, the 5' untranslated region (UTR) of 211 bp, and the 3' UTR of 388 bp. The
19 promoter region fragment flanking the area between -398 and -102 bp is responsible for the
20 basal level of *SLC26A3* transcription, and the region between -398 and -688 bp is necessary
21 for high-level transcriptional activation induced by sodium butyrate (Alrefai et al., 2007).
22 Total of 21 exons, of which 20 are coding, range from 55 to 234 bp in size. The translation
23 start codon ATG (Met 1) in exon 2 is followed by the termination codon TAA in exon 21
24 (Haila et al., 1998).

41 *SLC26A3* encodes for an 85-kDa transmembrane glycoprotein with 764 amino acids forming
42 the predicted 12 to 14 hydrophobic membrane-spanning domains in addition to the
43 cytoplasmic N- and C-terminal domains (Byeon et al., 1996; Bairoch et al., 2005). The
44 *SLC26A3* protein is an apical exchanger which transports Cl⁻ across the apical cell membrane
45 in exchange of HCO₃⁻ (Hoglund et al., 1996; Moseley et al., 1999) and in conjunction with
46 other epithelial ion transporters (Melvin et al., 1999; Koo et al., 2002; Lamprecht and Seidler,

1
2 2006). C-terminal amino acids 525 to 720 form the cytoplasmic sulphate transporter and anti-
3 sigma antagonist (STAS) domain—a binding site for the R domain of cystic fibrosis
4 transmembrane conductance regulator (CFTR) (Aravind and Koonin, 2000; Ko et al., 2002).
5
6

7
8 Four C-terminal amino acids of SLC26A3, glutamic acid-threonine-lysine-phenylalanine
9 (ETKF), form PDZ [postsynaptic density protein (PSD95), the Drosophila homologue Disc-
10 large, and the tight junction protein ZO-1] interaction motif which interacts with several PDZ
11 adapter proteins and couples the activity of SLC26A3 and Na⁺/H⁺ exchanger 3 (NHE3)
12 (Melvin et al., 1999; Lamprecht and Seidler, 2006). Loss of the SLC26A3-mediated Cl⁻
13 /HCO₃⁻ exchange activity in the ileum and colon, with secondary disruption of the Na⁺/H⁺
14 transport, results in intestinal loss of both NaCl and fluid, and to the profuse diarrhea of CLD
15 (Moseley et al., 1999; Melvin et al., 1999; Holmberg, 1978).

24 In both humans and rodents, expression of *SLC26A3* mRNA and protein emerges in the
25 absorptive surface epithelium of the small intestine, especially in the ileum but also in the
26 duodenum, and in the surface epithelium of the colon. In the intestinal crypts, the signal is
27 lacking (Hoglund et al., 1996; Jacob et al., 2002). In the human male reproductive tract,
28 SLC26A3 expression appears in the testis, efferent ducts of the testis and proximal
29 epididymis, and in the epithelium of the seminal vesicle (Hihnala et al., 2006b). Moreover,
30 SLC26A3 is expressed in the epithelium of the human sweat gland (Haila et al., 2000). In cell
31 cultures, expression of SLC26A3 appears in epithelial cells derived from the pancreatic duct
32 (Greeley et al., 2001) and trachea (Wheat et al., 2000). In intestinal adenomas and
33 adenocarcinomas, expression of SLC26A3 is significantly down-regulated or even
34 undetectable (Schweinfest et al., 1993; Antalis et al., 1998). In addition to colon cancer,
35 reduced *SLC26A3* expression may play a role in the pathogenesis of ulcerative colitis (Yang
36 et al., 1998; Asano et al., 2009), and reduction of *SLC26A3* promoter activity by the

2
3 inflammatory mediator interferon-gamma (IFN- γ) may contribute to the pathogenesis of
4
5 intestinal inflammation (Alrefai et al., 2007).
6

7
8 SLC26A3 belongs to the human solute carrier family 26 (SLC26) with 11 structurally
9
10 homologous anion exchangers (Mount and Romero, 2004). Three of these anion exchangers
11
12 are associated with rare autosomal recessive diseases: SLC26A3 with CLD (OMIM
13
14 #214700), SLC26A4 with Pendred syndrome (OMIM #274600) (Everett et al., 1997), and
15
16 SLC26A2 (alias DTDST) with a continuum of skeletal dysplasia phenotypes including
17
18 diastrophic dysplasia (OMIM #222600), achondrogenesis type IB (OMIM #600972),
19
20 atelosteogenesis type II (OMIM #256050), and multiple epiphyseal dysplasia (OMIM
21
22 #226900) (Hastbacka et al., 1994; Superti-Furga et al., 1996; Hastbacka et al., 1996; Superti-
23
24 Furga et al., 1999).
25

26 27 **Variants of the *SLC26A3* gene**

28
29
30 After finding that *SLC26A3* causes CLD (Hoglund et al., 1996), altogether 30 different
31
32 mutations and 4 polymorphisms have been reported by the Finnish researchers (Makela et al.,
33
34 2002), and 4 mutations by others (Heinz-Erian et al., 2008; Choi et al., 2009). When the 21
35
36 novel mutations of this paper are added to the spectrum of *SLC26A3* mutations, these novel
37
38 changes represent 38% of the total 55 mutations (Table 1).
39

40
41 The reported *SLC26A3* mutations have been identified by automated sequencing after PCR
42
43 amplification of genomic DNA with intronic primers to cover all the exons and the complete
44
45 coding sequence (Haila et al., 1998; Heinz-Erian et al., 2008), except for the recent paper
46
47 with 3 novel mutations identified by whole-exome sequencing (Choi et al., 2009). The
48
49 mutation nomenclature is partly different from the previous mutation update (Makela et al.,
50
51 2002) and based on the current recommendations of the Human Genome Variation Society
52

1
2 (HGVS) checked using the Mutalyzer program (<http://www.LOVD.nl/mutalyzer/>) (den
3
4 Dunnen and Antonarakis, 2000; den Dunnen and Paalman, 2003; Wildeman et al., 2008). As
5
6 for reference, RefSeq sequences NG_008046.1 (genomic) and NM_000111.2 (cDNA) were
7
8 used with the nucleotide numbering +1 denoting the first nucleotide (A) of the translation
9
10 start codon (ATG; codon 1) in exon 2 of the *SLC26A3* gene.

13 ***Mutation types***

14 Majority of the *SLC26A3* mutations are single-nucleotide substitutions (n=30; 55%). Of
15
16 these, 13 are transversions with a substitution of a purine for a pyrimidine or vice versa, and
17 Deleted: .
18
19 17 are transitions changing a purine to another purine or a pyrimidine to another pyrimidine.
20
21 This excess of transitional over transversional substitutions, resulting from the relatively high
22
23 rate of mutation of methylated cytosines to thymine, is consistent with the findings
24
25 throughout the genome (Arnheim and Calabrese, 2009). At protein level, 18 (60%) of point
26
27 mutations result in a change of one amino acid (missense), 7 (23%) introduce a stop codon
28
29 resulting in truncation of the protein product (nonsense), and 5 (17%) are splice site
30
31 mutations most probably affecting RNA splicing.

32
33
34 Additional mutations are minor deletions (n=15; 27%) and insertions (n=3; 5%) or their
35
36 combinations (n=3; 5%). Only three major deletions (n=3; 5%) and one major insertion (n=1;
37
38 2%) have been found in association with CLD. All major deletions result in loss of one or
39
40 several exons and, most likely, absence of the *SLC26A3* protein. The largest deletion found
41
42 in association with CLD is the 8.6 kb deletion reported in this study. This mutation was found
43
44 in a Swedish patient with Lebanese origin. As for other mutations, direct sequencing was
45
46 used in mutation analysis. After the failed PCR amplification of exon 1, we selected several
47
48 SNPs (single nucleotide polymorphisms) in the promoter and intron 1 and identified the
49
50 borders of the deletion by finding the closest markers to exon 1 present in the patient DNA.

Thereafter, we designed primers around the approximate deletion, spanning from 4.3 kb upstream and 4.2 kb downstream from the exon 1, and PCR amplified and sequenced the exact nucleotides around the breakpoint of the deletion. Similarly, we proved the carriership of this deletion in the parents who were first cousins. As this large deletion removes not only the non-coding exon 1 but also the promoter region essential for the basal level of *SLC26A3* transcription (Alrefai et al., 2007), it is the only mutation that, most likely, disrupts transcription of the gene. The clinical phenotype of this patient is, however, similar to that observed in other patients with different mutations for CLD.

When larger deletions and insertions or their combinations are excluded, all minor deletions and insertions except for 3 introduce a frame-shift with a change of some amino acids, and finally, stop codon terminating the protein synthesis. Those 3 CLD-associated mutations with in-frame deletion/insertion are the Finnish founder mutation c.951_953del (p.V318del) in exon 8, the Polish founder mutation c.2024_2026dup (p.I675dup) in exon 18, and c.1579_1581del (p.Y527del) in exon 14 found in one Polish patient (Table 1).

Deleted: one

Deleted: TAT

Intragenic mutations

Among the all mutations, 82 % (n=45) are located in exons, 13 % (n=7) in or next to intronic splice sites, and 5% (n=3) involve deletion of both exonic and intronic sequences. Although the mutations are scattered across the whole gene, their distribution is uneven (Figure 1A). While 6 mutations (11%) appear both in exon 5 and 12, none of the mutations is located in exons 2, 16, 20, and 21. Most of the mutations are scattered between the exons 3 and 6, and between the exons 12 and 15. At least codon 120, harboring the mutation c.358G>A (p.G120S) in four independent families from different populations, codon 124 with the c.371A>T (p.H124L) mutation reported in 5 patients from 3 different populations, and codons 131 and 454, involving three and two different mutations at the same locus, are

1
2 evident mutation hotspots (Table 1). In the case of transitions, such as p.G120S, the likely
3
4 mechanism for mutations is methylation of cytosine-guanine (CpG) dinucleotides while
5
6 microdeletions and insertions scattered between the exons 12 and 15 may be associated with
7
8 short nucleotide repeats (Makela et al., 2002; Arnheim and Calabrese, 2009).
9

10
11 Of those 7 intronic splice site changes, 5 are located at the 3' splice site which terminates the
12
13 intron with an almost invariant AG sequence. Mutations in this splice acceptor sites are likely
14
15 to cause splicing error and loss of function of the protein. Although one of the novel splice
16
17 site mutations is located next to the consensus sequence GU of the 5' splice site
18
19 (c.2205+3A>G), its heterozygous presence in a patient with another heterozygous mutation
20
21 (c.951_953del; p.V318del) and typical clinical picture of CLD predict disease-associated
22
23 disruption of splicing at the splice donor site. In addition, homozygous insertion of an *Alu* Y
24
25 subfamily sequence (GenBank U14569.1) next to the intron donor site
26
27 (c.131+2_131+3insU14569.1) is likely to disrupt protein synthesis in a patient with both
28
29 parents, being first cousins, carrying this insertion in a heterozygous form (Table 1).
30
31

Deleted: ,

32 ***Founder Mutations***

33
34 In Finland, genetic studies of CLD have revealed the single ancestral founder mutation
35
36 c.951_953del (p.V318del) in a homozygous form in all but one patient. Similarly, the
37
38 founder mutation c.559G>T (p.G187X) accounts for >90% of CLD-causing mutations in
39
40 Arab Countries, whereas the Polish major mutation c.2024_2026dup (p.I675dup) is involved
41
42 in almost 50% of the CLD-associated chromosomes (Hoglund et al., 1998). Outside these
43
44 founder populations, mutation analysis is very likely to show rare, and often previously
45
46 unreported, *SLC26A3* mutations responsible for CLD (Table 1).
47
48
49
50
51
52
53
54
55
56
57
58
59
60

De Novo Mutations

So far, we have been able to verify the carriership of heterozygous *SLC26A3* mutations in all the parental DNA samples studied for the mutation(s) found in their child with CLD. Although *de novo* mutations remain nondetermined so far, the vast spectrum of *SLC26A3* mutations suggests that novel mutations in this gene may be more common than expected based on the CLD incidence (Hoglund et al., 1998).

Polymorphisms

All the SNPs reported in the coding region of *SLC26A3* are presented in Table 1. Of these 17 SNPs, 4 has been identified in association with genetic studies of CLD (Makela et al., 2002) and 16 exist in the dbSNP public database among the total of 311 *SLC26A3* SNPs (Sherry et al., 2001). Only 5 of the coding-area SNPs are silent, while the other SNPs alter the amino acid sequence (Table 1). Functional data confirming the neutral role of an sequence altering variant exist only for the missense change c.921T>G (p.C307W) (Hoglund et al., 1996; Moseley et al., 1999).

Biological Relevance

Animal Model of CLD

The *SLC26A3* protein is the colon's most essential apical anion transporter. Evidence for this is not only the life-threatening diarrheal phenotype of CLD but also existence of *SLC26A3*-deficient mice with a diarrheal phenotype closely similar to that of CLD. *SLC26A3*-deficient mice exhibit, however, unique features uncharacteristic of human CLD. These include significant growth retardation, occasionally development of prolapsed rectums, and an

1
2 aberrant growth pattern of the colonic mucosa with an expanded proliferative zone of colonic
3
4 crypts and hyperplasia of the surface epithelium (Schweinfest et al., 2006).
5
6

7 ***Protein structure***

8
9
10 Although the exact structure of the SLC26A3 protein remains undetermined, the UniProt
11 prediction suggests the presence of 12 to 14 transmembranic protein domains (Bairoch et al.,
12 2005). Using the prediction of 12 domains and those 45 mutations (82% of total 55
13 mutations) associated with the coding sequence only, 2 mutations are located in the
14 cytoplasmic N terminal domain, 28 between the first and last transmembranic domain, and 15
15
16 in the cytoplasmic C terminus (Figure 1B).
17
18
19
20
21

Deleted: s

22
23 STAS domain, the amino acids 525 to 720 (Aravind and Koonin, 2000; Bairoch et al., 2005),
24 involves 10 different mutations representing 18% of all mutations. The regulatory action
25 through the R domain of CFTR and STAS domain of SLC26A3 seems to be essential for
26 epithelial HCO₃⁻ secretion in the tissues where both these transporters are expressed, meaning
27 at least the small intestine (Jacob et al., 2002; Greger, 2000; Rossmann et al., 2005),
28 pancreatic duct (Greeley et al., 2001; Ko et al., 2004), and tracheal epithelium (Wheat et al.,
29 2000). As this essential physical association between CFTR and SLC26A3 requires intact R
30 and STAS domains, and at least one CLD-causing mutation on the STAS domain of
31 SLC26A3 prevent the activation of CFTR as well, CFTR may also play a role in the
32 pathogenesis of CLD (Ko et al., 2004).

43 None of the *SLC26A3* mutations is located in the PDZ motif, comprising the four C-terminal
44 amino acids. This motif enables the binding with PDZ adapter proteins and couples the action
45 of SLC26A3 with other transporters such as NHE3 to promote electroneutral NaCl
46 absorption (Melvin et al., 1999; Lamprecht and Seidler, 2006). To underline the importance
47 of this coupled transport, *NHE3* knock-out mice have increased levels of intestinal *SLC26A3*
48
49
50
51
52

11

mRNA, and *SLC26A3*-deficient mice show massive upregulation of intestinal *NHE3* mRNA and protein (Melvin et al., 1999; Schweinfest et al., 2006).

Functional Studies on *SLC26A3* mutations

Functional data on mutant forms of *SLC26A3* are limited. Regarding the Finnish founder mutation c.951_953del (p.V318del), the anion exchange activity is lacking despite the normal levels of *SLC26A3* mRNA and protein in the CLD colon (Hoglund et al., 1996; Moseley et al., 1999;). An associated feature of this mutation is a substitution of tryptophan for cysteine ten codons upstream c.921T>G (p.C307W), the frequency of which alone is around 14% in the healthy Finnish population. This variant is compatible with normal anion exchange activity, neutral in conjunction with the mutation c.951_953del (p.V318del), and is therefore considered a meaningless *SLC26A3* polymorphism (Hoglund et al., 1996; Moseley et al., 1999).

Deleted: , as expected,

The mouse p.V318del-homologue mutant (p.V310del) is retained in the endoplasmic reticulum, failing to show any expression on the apical plasma membrane. Similar to the human p.V318del, some other CLD-associated mouse mutants, e.g., p.L489R (human p.L496R) and p.I668-669ins (human p.I675dup), are expressed on the plasma membrane (Ko et al. 2002). The mutations located in the STAS domain are likely to result in loss of the functional protein at the plasma membrane either by disrupting the STAS domain directly (p.I675dup and p.G702Tins9) or by affecting protein folding and/or trafficking pathway (p.Y527del and p.I544N) (Dorwart et al., 2008). Among the functionally studied mutants (those mentioned above plus p.S706AfsX6), only p.Y527del shows some $\text{Cl}^-/\text{HCO}_3^-$ exchange activity in cell cultures (Ko et al., 2002; Chernova et al., 2003; Dorwart et al., 2008).

Clinical and Diagnostic Relevance

Differential Diagnosis

The simple measurement of fecal Cl⁻ is still sufficient to confirm the diagnosis in most of the cases. Differential diagnosis of CLD includes other inherited diarrheas such as congenital sodium diarrhea (Holmberg and Perheentupa, 1985; Booth et al., 1985), glucose-galactose malabsorption (Martin et al., 1996), congenital sucrase-isomaltase deficiency (Ouwendijk et al., 1996), lysinuric protein intolerance, acrodermatitis enteropathica, and microvillus inclusion disease (Field, 2003). In these diseases and in other secretory diarrheas, alkaline stool pH and metabolic acidosis exclude the possibility of CLD, the hallmarks of which are acidic stools and metabolic alkalosis (Holmberg, 1986; Field, 2003). Importantly, CLD may be confused with other salt-wasting diseases, such as Bartter syndrome (Choi et al., 2009).

Genotype-Phenotype Correlation

Despite the various types of mutations and their wide distribution in different regions of the *SLC26A3* gene, evidence of genotype–phenotype differences in CLD is nonexistent (Makela et al., 2002). Even the identical genetic background of CLD may, however, result in variable clinical course if the diagnosis is delayed or salt substitution insufficient, resulting in severe dehydration, and thereby, reduction in the amount of diarrhea (Holmberg et al., 1977; Hoglund et al., 2001). In addition, the patients with even the same genotype may show different responses to diarrhea-modulating agents such as butyrate, shown to reduce the amount of diarrhea in an Italian patient but not in the Finnish series of CLD (Canani et al., 2004; Wedenoja et al., 2008a). Whether different mutations modulate disease characteristics such as male subfertility, described only in the highly homogenous series of Finland so far (Hoglund et al., 2006), remains to be determined.

Deleted: -

Molecular Diagnostic Strategies

So far, genetic testing for CLD is available by a clinical laboratory (HUSLAB, Helsinki University Central Hospital) only for the Finnish founder mutation c.951_953del (p.V318del). After finding the gene for CLD (Hoglund et al., 1996), more than 160 patients with a clinical suspicion have been tested for *SLC26A3* mutations in our laboratory at research basis. Because CLD is rare and the outcome of treated disease is favorable, prenatal diagnostics or carrier testing are rarely requested or performed. In addition to our laboratory, some other research laboratories have recently reported CLD-associated *SLC26A3* mutations (Heinz-Erian et al., 2008; Choi et al., 2009).

In patients originating from founder populations, a feasible strategy for mutation analysis is to search for the known founder mutations present in 99% of the Finnish, >90% of the Arabic, and around 50% of the Polish CLD-associated chromosomes (Hoglund et al., 1998). In contrast, most patients outside these geographical regions are likely to have rare, and often previously unreported, homozygous or compound heterozygous mutations identified only through sequencing of the whole coding region of *SLC26A3* (Table 1; Figure 1). At least rare homozygous mutations for CLD, such as the large homozygous deletion of 8.6 kb reported here, are likely to arise from areas where consanguineous marriages are relatively common, for instance from the countries around the Persian Gulf (Hoglund et al., 1998). On the other hand, those rare mutations found in single patients from different countries may actually arise from the same population, and therefore, the country of residence may not reveal the roots of the families (Table 1). Because single cases with CLD arise worldwide and the spectrum of mutations is wide, such CLD infrequency makes misdiagnoses highly probable. Especially in low-incidence countries, negative family history in association with difficulties in refining the early clinical diagnosis are likely to delay the diagnosis and result in lethal complications

1
2 in early childhood, or in those with the delayed diagnosis, induce retarded growth, and later,
3
4 development of chronic kidney disease (Wedenoja et al., 2008b).

5
6 Our mutation analysis has failed to find CLD-causing mutations in 6 patients so far (Makela
7
8 et al., 2002). Certainly, any difficulties in assessing phenotypic characteristics may make
9
10 genetic diagnostics unreliable, or alternatively, mutations may be localized in the areas
11
12 uncovered by sequencing, such as promoter and non-coding regions outside the exon-intron
13
14 boundaries. In addition, any major deletions or insertions may be simply missed through
15
16 direct sequencing. Most probably, these events are relatively rare in association with CLD,
17
18 supported by the high success rate of our mutation analysis and by the fact that larger
19
20 deletions or insertions have been found in only 4 [of these 165](#) patients [studied](#) so far (Table
21
22 1).

23
24
25 When many of the *SLC26A3* mutations found are novel, prediction of their pathogenicity
26
27 may remain uncertain without functional testing. *SLC26A3* is, however, likely to be sensitive
28
29 for any coding region mutations because (i) polymorphisms in the coding region are
30
31 relatively rare (Table 1), (ii) all the studied mutants result in loss of the $\text{Cl}^-/\text{HCO}_3^-$ activity
32
33 (Moseley et al., 1999; Ko et al., 2002; Chernova et al., 2003; Dorwart et al., 2008), and (iii)
34
35 the clinical picture of CLD is invariable independently of genotype. Even up to the 8.6 kb
36
37 deletion, reported in this study, results in the typical clinical course of CLD despite the fact
38
39 that it eliminates the promoter region responsible for the basal level *SLC26A3* transcription
40
41 (Alrefai et al., 2007). These data make assessment of mutations with unknown functional
42
43 significance relatively conclusive if only the clinical picture is typical for CLD, a highly
44
45 conserved amino acid is involved, mutations are confirmed on a second PCR product, and
46
47 parental DNA samples prove the localization of compound heterozygous mutations on
48
49 separate alleles. Although evidence of *de novo* mutations remain non-existent and we have
50

1
2 found heterozygous changes in all parental samples studied, the spectrum of mutations
3
4 suggests that novel *SLC26A3* mutations are relatively common.
5
6

7 **Future Prospects**

8
9
10 Despite the advantages of genetic testing, large-scale mutation analysis is performed only as
11 a part of research programs so far. Measuring high fecal chloride (>90 mmol/L) in a patient
12 with a typical clinical picture and corrected electrolyte and acid-base balance is a reliable
13 sign of CLD, independently of mutation analysis. As measurement of fecal chloride is fast
14 and unexpensive, it remains to be the first line test to confirm/exclude the diagnosis of CLD.
15
16 It is worth remembering, however, that excessive volume and salt depletion reduces the
17 amount of diarrhea and may result in a low fecal Cl⁻ of even 40 mmol/L (Holmberg, 1978).
18
19 Therefore, many patients are likely to die before the diagnosis and treatment, and in those
20 suspected cases of CLD, mutation data may be essential to confirm the unsure diagnosis.
21
22
23
24
25
26
27

28 Establishment of local sequencing possibilities for the countries with a higher-than-average
29 incidence of CLD and with known founder mutations would be easy and reliable in the first
30 line diagnostics of CLD. In the future, genetic testing will most probably become easier and
31 faster, allowing genetic diagnostics for CLD and other rare diseases locally. Outside the
32 known founder populations for CLD, a future prospect is that the spectrum of found
33 *SLC26A3* mutations will expand, and hopefully, many of the patients with CLD will get their
34 diagnosis based on both early clinical characterization and mutation analysis. Only better
35 diagnostics could reveal the figures of incidence of CLD which, most probably, are notably
36 higher than expected based on those around 250 cases reported so far. Finally, only the
37 analysis of different genotypes in relation to phenotypes could provide data on genotypic-
38 phenotypic differences—if any—in CLD.

Figure legends

Figure 1. A) Different types of mutations within the *SLC26A3* gene. The exons are shown in scale but introns out of scale. The shaded areas in the first and last exons represent non-coding sequences.

B) Structure of the SLC26A3 protein modified according to the Uniprot prediction by using the model with 12 transmembranic domains (Bairoch et al., 2005). SLC26A3 involves 764 amino acids with 12 (to 14) transmembranic domains, and cytoplasmic N and C terminal ends. The arrows point to the approximate positions of different coding-area mutations from which large deletions and non-coding mutations are excluded. Numbers in the figure denote the amino acid positions. Two codons involve 2 (codon 454) or 3 (codon 131) different mutations at the same locus. The cytoplamic STAS domain involves amino acids 525 to 720 which are shown with the dashed line (Aravind and Koonin, 2000; Bairoch et al., 2005).

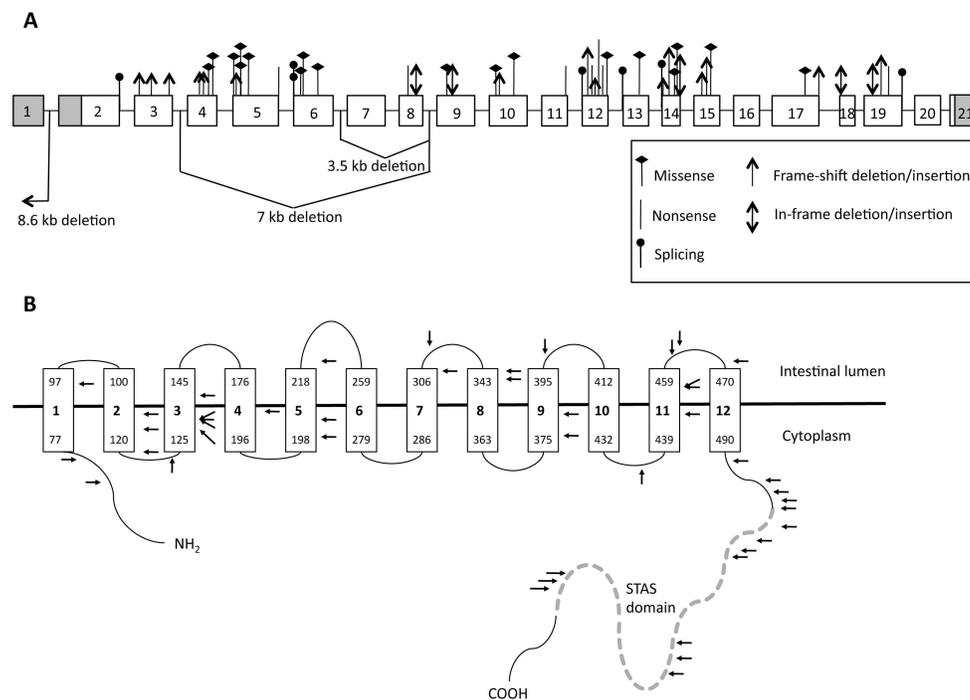

Figure 1. A) Different types of mutations within the SLC26A3 gene. The exons are shown in scale but introns out of scale. The shaded areas in the first and last exons represent non-coding sequences.

B) Structure of the SLC26A3 protein modified according to the Uniprot prediction by using the model with 12 transmembranic domains (Bairoch et al., 2005). SLC26A3 involves 764 amino acids with 12 (to 14) transmembranic domains, and cytoplasmic N and C terminal ends. The arrows point to the approximate positions of different coding-area mutations from which large deletions and non-coding mutations are excluded. Numbers in the figure denote the amino acid positions. Two codons involve 2 (codon 454) or 3 (codon 131) different mutations at the same locus. The cytoplasmic STAS domain involves amino acids 525 to 720 which are shown with the dashed line (Aravind and Koonin, 2000; Bairoch et al., 2005).

260x190mm (300 x 300 DPI)

Table 1. *SLC26A3* mutations and coding-region single-nucleotide polymorphisms (SNPs).
