#### 11 Abstract

10

3

With technical advances in wildlife telemetry, the study of cryptic predators' responses to prey

distribution has been revolutionised. Considering marine predators, high resolution tagging

devices were developed lately to collect long and precise diving datasets. In this study, we

investigated, at fine temporal and spatial scales, changes in the horizontal movements and

diving patterns of a marine predator, the southern elephant seal. Satellite tracking data collected

on nine seals were processed with switching state-space models. Seals' body condition, as a

proxy for foraging success, was estimated through changes in drift rate from Time Depth

Recorder (TDR) data. We identified (1) statistically distinct behavioural modes along the

- tracking data (intensive vs. extensive foraging modes) and (2) dive classes from the TDR diving
- data (drift, exploratory, shallow active and deep active dives). Mass gain over the animals'
- foraging trip was also linked with the proportions of intensive foraging zones and dive classes.
- <sup>23</sup> Active dives, associated with vertical foraging and chasing, were more numerous when the seals
- <sup>24</sup> were in intensive foraging mode. Improved body condition and mass gain of seals were also
- 25 associated with the occurrence of intensive foraging mode and, within the vertical dimension,
- with sets of highly active dives. In conclusion, proportions of dive classes displayed by the seals
- 27 proved to vary according to their horizontal behaviour. The results allow us to conclude that
- 28 intensive foraging detected from surface tracking data is a good predictor of the diving activity
- <sup>29</sup> and foraging success occurring in the vertical dimension.
- 30 Keywords: area-restricted search, dive classification, drift dive, fine scale behaviour, movement
- analysis

## <sub>2</sub> 1 Introduction

Understanding the responses of predators to spatial and temporal variability of their prey distribution is fundamental for determining how animals may respond to global changes in their environment. The Southern Ocean is one of the most productive oceans (Smetacek & Nicol, 2005) and it has been shown that this circumpolar ocean has warmed more rapidly than the global ocean average (Gille, 2002). It has also been shown that winds over this ocean have strongly increased over the past few decades (Meredith & Hogg, 2006) causing an increase in eddy activity and number. This could have significant impacts on primary productivity 39 (Le Quéré et al., 2007) and hence on feeding opportunities for predators. Nonetheless, direct observations of how marine predators interact with their environment and their prey are very 41 scarce. Because of the Southern Ocean remoteness, it is particularly challenging to obtain information on diet and the distribution of prey for long-ranging migrating species in those waters. Acurate feeding indices are often difficult to obtain, and most studies instead use proxies such as changes in movement patterns and time spent within restricted areas (Weimerskirch et al., 2007; Aarts et al., 2008). Therefore, recent developments in animal-mounted loggers (Weimerskirch & Jouventin, 1990; Weimerskirch et al., 2002) and indirect diet analyses (Bradshaw et al., 2004) have significantly increased the amount of knowledge on cryptic marine 50 predators' ecology. Especially, the recordings of predators' movements, diving behaviour and in 51 situ oceanographic parameters have indirectly contributed in a better understanding of potential prey distribution otherwise difficult to observe. 53 By correlating movement patterns to environmental conditions, characteristics of the areas profitable for a predator can be revealed (Turchin, 1991). In various predator species, resource

```
acquisition has been linked to a type of free-ranging behaviour called the area-restricted search
   (ARS) (Kareiva & Odell, 1987). In a prey-aggregated environment, such as in the open ocean,
   an animal having already captured a first prey intensifies its foraging in the patch (Charnov,
   1976; Parker & Stuart, 1976). Therefore, an ARS is characterised by a decrease in displacement
   speed and an increase in the track sinuosity in areas with putative prey aggregation (Bovet &
   Benhamou, 1988). Between two patches, the animal, on the contrary, travels more linearly and
62
   at a faster pace. Natural environments are generally considered as hierarchical patch systems, in
   which patches at small scales are nested in patches at larger scales (Kotliar & Wiens, 1990).
64
   While foraging, predators often display movement patterns at multiple spatial and temporal
   scales that are assumed to match the spatial structure of the hierarchical aggregations of prey
   (Fauchald, 1999). Since predators likely adjust their foraging movements at small spatial scales,
   especially within a dense patch, prey encounter rate is supposed to play a major role in
   predator's foraging decisions. On the other hand, past experiences are expected to act mainly in
   large-scale movements at a scale where prey distribution is more predictable (Hunt et al., 1999).
   With the latest technical advances in wildlife telemetry, it is now possible to examine
71
   small-scale movements that are crucial to better understand scale-dependent adjustments of
   long-ranging predators. By using high-precision locating system (GPS, Weimerskirch et al.
73
   (2002)) together with high-resolution behavioural recorders (Time Depth Recorders (TDR)
   Charrassin et al. (2001), stomach temperature sensors Austin et al. (2006)), it is now possible to
   accurately study foraging decisions. However, to understand the effects of environmental
   variability on foraging success of marine predators and, ultimately their fitness increase,
   requires not only at-sea movement analyses, but also some method of identifying where and
   when the animals actually improve their body condition.
```

Considering diving predators, buoyancy has been proved to directly depend on the animals'

condition, the relative proportion of adipose tissue increases thereby increasing its buoyancy (Robinson et al., 2010). Therefore, a predator species that performs dives during which the 84 animals drift passively in the water column can be considered as an ideal study model to inform on in situ buoyancy in situ (Biuw et al., 2003). Travelling thousands of kilometres per year in the circumpolar waters of the Southern Ocean (McConnell et al., 1992), southern elephant seals, Mirounga leonina, are elusive marine predators that can spend as much as 85% of their lifetime at sea (McIntyre et al., 2010). They continuously dive during their extended stay at sea and display behaviours qualified of "drift dives" along their track (Crocker et al., 1997). They 90 regularly perform those dives during which they stop swimming and drift passively in the water column (Biuw et al., 2003; Mitani et al., 2010). Vertical movements during these dives were shown to be related to the seal's body condition (Webb et al., 1998): fat and positively buoyant 93 seals will follow an upward drift. Inversely, lean seals with negatively buoyant body condition will sink during a drift dive. An increase in the drift rate over time is therefore an index of a successful foraging activity (Biuw et al., 2007; Bailleul et al., 2007b; Thums et al., 2008; Robinson et al., 2010). Although there are potential errors in the estimation of foraging success from drift rate, they generally lead to an underestimation of the energy gain and foraging 98 success (Robinson et al., 2010). Southern elephant seals represent therefore a unique 90 opportunity for studying, in situ, links between the foraging behaviour and the individual's body 100 condition. 101

data, has been studied in detail (Bailleul *et al.*, 2008). However, southern elephant seals spend little time at the surface between each dive (Hindell *et al.*, 1991) and feed on deep-ranging prey (Cherel *et al.*, 2008). In addition, previous studies could only integrate the diving behaviour by

102

103

using indices estimated from low-resolution dive profiles (four depth-time points per dive, Biuw

Horizontal foraging behaviour, from track-based analyses of low-resolution surface tracking

et al. (2003); Bailleul et al. (2007a)). Recent studies have focused on the fine scale vertical

behaviour which is more likely to respond directly to prey abundance (Thums *et al.*, 2011).

However, fine scale vertical as well as horizontal foraging behaviour remain poorly known
which limits our understanding of the seals' responses to the variability in prey distribution.

112

In the Southern Ocean, mesoscale features, such as fronts and eddies, have been shown to have a significant impact in structuring and enhancing primary productivity (Bakun, 2006). They are 114 likely to influence the spatial structure of prey patches and play a key role in the formation of 115 profitable foraging areas for oceanic predators (Bost et al., 2009). The interfrontal zone, 116 between the Polar Front (PF) and the Subtropical Front (STF, see Figure 1), is especially dynamic with locally productive eddies that are rich in prey. Within the Kerguelen population, Bailleul et al. (2010a) work suggests that over two thirds of the southern elephant seal females 119 forage in the interfrontal zone. It is therefore likely to be a key habitat where those predators 120 interact with spatially and temporally heterogeneous oceanographic features (Dragon et al., 12 2010). In this study, we used high resolution tracking and diving data to investigate fine-scale 122 temporal and spatial changes in horizontal movements and diving patterns of female elephant 123 seals in the interfrontal zone. We expected a good correspondence between the areas of 124 intensive foraging identified from horizontal tracking data and the areas with high proportions 125 of foraging dives, as determined from TDR data. Finally, using drift rate as a physiological proxy of foraging success, we expected to monitor the gain or loss in the seals' body conditions 127 and to relate it with the observed diving behaviour. 128

## 29 **2** Material & Methods

## 2.1 Logger Deployment

In October 2009, nine post-breeding southern elephant seal females, all about the same mass  $(296 \pm 26 \text{ kg})$  and length  $(236 \pm 14 \text{ cm})$ , were captured on the Kerguelen Islands  $(49^{\circ}20^{\circ}\text{S})$ , 132 70°20'E). They were anaesthetised using a 1:1 combination of Tiletamine and Zolazepam 133 (Zoletil 100) which was injected intravenously (McMahon et al., 2000). Data loggers were 134 glued on the head of the seals, using quick-setting epoxy (Araldite AW 2101), after cleaning the 135 fur with acetone. Four seals were equipped with satellite-GPS loggers in combination with satellite-Argos and archival data loggers (MK10 Fast-Loc, Wildlife Computers, Washington, 137 USA). MK10 devices transmitted Argos location data and collected GPS location data. To save 138 battery life, the sampling interval of GPS locations was set to a minimum of 20 minutes, i.e. 139 slightly shorter than the average dive duration of the species (Hindell et al., 1991). The additional logger, Time-Depth Recorder (TDR), included in the MK10 devices collected and 141 archived pressure and temperature levels every two seconds. Five other seals were equipped 142 with Fluorometry - Conductivity - Temperature - Depth Satellite - Relayed Data Loggers 143 (termed Fluo-CTD-SRDLs, designed and manufactured by the Sea Mammal Research Unit, 144 University of St Andrews, Scotland) combined with MK9-TDR loggers (Wildlife Computers, Washington, USA). Fluo-CTD-SRDLs devices allowed the calculation and transmission of tag 146 positions estimates of Argos quality. The MK9 devices combined with each Fluo-CTD-SRDL 147 were set to sample and archive pressure and temperature levels every two seconds. After 148 locating their respective haulout beaches via Argos locations, returning females were recaptured, weighed and loggers were retrieved.

## 2.2 Tracking data and identification of horizontal foraging behaviour

151

The GPS and Argos seal tracking data were both analysed with state-space models in order to 152 detect areas of restricted search (Jonsen et al., 2003; Patterson et al., 2008; Schick et al., 2008; 153 Block et al., 2011). Argos locations were first estimated using the observation model of a 154 switching-state-space model in order to take into account measurement errors (Jonsen et al., 155 2003). Following preliminary studies based on the movement parameters distributions (not 156 displayed here), we used two behavioural modes for the analyses. The state-space models also 157 estimated the probability of being in a particular behavioural mode (intensive foraging, that is 158 when ARS behaviour is displayed, vs. extensive foraging, when the animal travels at a faster and more linear pace) along the animals' paths (for details see Jonsen et al. (2007); Block et al. 160 (2011)). GPS tracks were analysed the same way: the switching state-space models discerned 161 two behavioural modes within the location data. All models were fitted with freely available 162 software WinBUGS (Bayesian Analysis Using Gibbs Sampler, Spiegelhalter et al. (1999)) called 163 from R (R Development Core Team, 2009) with the package R2WinBUGS (Sturtz et al., 2005). As recommended by Dennis (1996), we used vague priors (Gamma and Uniform 165 distributions). Two Monte-Carlo Markov Chains (MCMC) were run for each model, with 166 50000 iterations following a 25000 burn-in (thin=2). 167 As female southern elephant seals from Kerguelen population are known to forage mostly in the pelagic waters of the interfrontal zone (Bailleul et al., 2010b; Dragon et al., 2010), we focused 169 on the pelagic part of the tracks after having applied a bathymetric mask (1000 m depth from 170 Etopo mask 2' (NGDC, 2001)) to exclude all locations on the Kerguelen and Crozet plateaux, 171 and hence all benthic dives.

### 2.3 Diving Behaviour and dive classification

The following diving variables were derived from MK9 and MK10 TDR data (Table 1):

maximum depth, descent and ascent speeds, bottom-time duration (where the bottom phase

starts at the end of the descending phase and finishes at the beginning of the final ascent to the

surface) and bottom-time residuals (residuals of multiple regression of

bottomtime  $\sim$  maximumdivedepth + diveduration Bailleul et al. (2008); calculated for each

dive within a path) and vertical sinuosity in the bottom phase (Equation 1, derived from

Weimerskirch et al. (2007)).

$$BottomSinuosity = \frac{BottomDistance_{observed}}{BottomDistance_{euclidean}}$$
(1)

where BottomDistance<sub>observed</sub> is the total vertical distance swum in the bottom of the dive, and BottomDistance<sub>euclidean</sub> is the sum of the Euclidean distances from the depth at the 182 beginning of the bottom to the maximum depth and from the maximum depth to the depth at the 183 end of the bottom phase. 184 Vertical sinuosity takes a value of 1.0 when the animals swims in a straight path at the bottom of its dive. Any deviation from a straight path increases the sinuosity value. The horizontal distance travelled during each dive was also estimated from linearly interpolated GPS tracking 187 data. Drift dive identification was processed from the complete time-depth (TDR) data in 3 188 steps. (1) Instantaneous vertical speed was calculated from the time-depth data. (2) Vertical 189 speed was then smoothed by using a moving average filter (10 seconds window) in order to compensate for abrupt changes in depth reading due to the sensor accuracy  $(\pm 1m)$ . (3) Within 191 dives, drift phases were isolated using a custom-made function under R software (R 192 Development Core Team, 2009). Drift phases were detected as periods of time of more than 3 193 minutes during which the vertical speed was bounded between  $[-0.6; 0.6]m.s^{-1}$  and with a low variance ( $s^2 < 0.005$ ) (for more details see the annotated R codes in the supplementary

material). For each drift dive, a drift rate was determined as the slope coefficient of a linear regression between depth and time (Biuw et al., 2003; Bailleul et al., 2007a; Mitani et al., 197 2010). Daily averaged drift rates were calculated for the 3-month tracks. 198 Following a preliminary analysis of diving behaviour (Table 1) and a literature review (Hindell et al., 1991; Schreer et al., 2001; Hassrick et al., 2007), four dive classes displayed by the seals 200 in pelagic waters were determined. A k-mean classification was then applied on the normalised 201 Principal Component Analysis (PCA, in this study with 4 principal components) scores from 202 the behavioural variables of all individuals in the pelagic part of their tracks (Forgy, 1965). 203 Transition matrices including the probabilities of dive class changing were then estimated. The daily proportions of each dive classes for each individual were also calculated. Linear mixed 205 models, with individual as random effect, were used to evaluate the daily proportions of dive 206 class in intensive foraging vs. extensive foraging areas detected from the tracking data (in R, 207 nlme library from Pinheiro & Bates (2000) with REML method). Models' assumptions were 208 verified and no autocorrelation nor heterogeneity of variance of within-group residuals was 209 noticed (Pinheiro & Bates, 2000). 210

# 2.4 Detection of successful foraging areas with drift rate increases and 212 mass gain models

Positive variations of drift rate are supposed to indicate an improvement of the seal's body

condition and buoyancy (Crocker *et al.*, 1997; Biuw *et al.*, 2003). We used increases in drift rate

as a physiological index of successful foraging activity along the seals' tracks. The overall drift

rate increase was calculated as the difference between the mean drift rate over the last 10% of

the track, hereafter referred as the final drift rate, and the one over the first 10% of the track.

Final drift rate before the animal's hauling out and percentage of time spent in intensive

foraging were also considered. Finally, we also calculated the respective proportions of the four

- dive classes while the animal was displaying intensive, or extensive, foraging behavioural mode.
- For all individuals, mass gain (kg) over the foraging trip was related, using linear models, to
- overall drift rate, final drift rate and the proportions of dive classes while in intensive foraging.
- 223 In the end, we used linear models to estimate the mass gain from multiple regressions of the
- variables listed above. Model selection was based on Akaike Information Criterion (AIC,
- Akaike (1973), with a correction for small sample sizes Burnham & Anderson (2002)) to find
- the best linear model (Venables & Ripley, 2002).

### 227 **Results**

### 3.1 Statistics of the horizontal tracking data

Argos tags transmitted in average (mean  $\pm s.d.$ ) 6.86  $\pm$  4.31 locations per day whereas GPS tags collected an average of  $38.28 \pm 10.57$  daily locations. The 9 animals equipped for this study 230 spent an average of  $79 \pm 6$  days at sea with  $69 \pm 9$  days in the pelagic area. They covered an 231 average of  $4399 \pm 622$  km, including  $3822 \pm 763$  km in pelagic waters (Figure 1). All but one 232 individual foraged exclusively within the interfrontal zone east of Kerguelen Island. The last 233 one went to the western interfrontal zone, near Crozet plateau. Individual seals dived on average 64 times per day which is consistent with the literature (Boyd & Arnbom, 1991). This provided 235  $5059 \pm 700$  dives, per seal, of which  $4529 \pm 909$  were in pelagic waters. From the state-space 236 model analysis, seals displayed two statistically distinct behavioural movement modes: 237 intensive, which corresponds to the display of ARS behaviour, and extensive foraging. Intensive foraging mode was estimated on average during 33 % of their time ( $33 \pm 12\%$ ;  $28 \pm 8$  days) 239 including in pelagic waters ( $23 \pm 9$  days). 240

### 3.2 Characterisation and localisation of the dive classes

For all individuals, four dive classes were detected and defined as: drift, exploratory,
shallow-active and deep-active dives. The biological meanings of the dive classes will be
discussed in detail in the first part of the discussion. Characteristics of the four dive classes are
illustrated in Figure 2 and Table 2. Although their relative proportions varied, with for instance
deep active dives being more numerous by day than by night, all dive classes were observed by
day and night time (Figure 2b). Drift dives were the least sinuous in the bottom (Figure 2d),
presented the longest bottom time durations (Figure 2a,c) and low horizontal distances (Figure
2f). While "drift-diving", the animals displayed low descent (Figure 2e) and ascent speeds
(Figure 2d) and performed this class of dive at average depths (Figure 2c and Table 2). On the

contrary, deep active and shallow active dive classes exhibited high sinuosity ratio during their 25 bottom phases (Figure 2d). The deep active dive class was the most sinuous of all dive classes. 252 Both shallow and deep active classes also exhibited high descent and ascent speeds (Figure 253 2d,e). Deep active dive presented also the lowest horizontal distance travelled between two dives of this class (Figure 2f). Finally deep active dive class was also characterised by negative 255 bottom-time residuals that is bottom times lower than expected. Considering the exploratory 256 dive class, they were characterised by large horizontal distance (Figure 2f), medium vertical 257 sinuosity at the bottom of the dives (Figure 2d) and low descent speed (Figure 2e). Figure 3a 258 presents the typical profiles of the four dive classes. 259 The proportions of dive classes along the pelagic part of the individual tracks are presented on 260 Table 3. Deep active dives represent the majority of the dives along the animal path (46.1 % in 261 average) while shallow active and exploratory dives are the second and third classes with 262 respectively 31.3% and 14.9% of the dives. Finally, drift dives are sparsely displayed (7.7%). 263 The combination of deep and shallow active classes (from now on referred as active dives) 264 represents over three quarters of the whole set of dives (77.4 %). All dive classes occurred all 265 along the tracks (Figure 3b). On the other hand, observed probabilities of dive class changing 266 from dive at time t to dive at time (t+1) revealed a high temporal persistence, i.e. temporal 267 auto-correlation, in the animals behaviour and a hierarchy in the dive classes activity (Table 4). An animal displaying a shallow active dive is more likely to continue displaying this class of 269 dive or to change most likely for a deep active dive or an exploratory dive. 270

## 3.3 Combining horizontal foraging behaviour identified from tracking data to fine scale vertical behaviour

The most parsimonious linear mixed model on the daily proportions of shallow active dives showed a positive intercept ( $intercept = 42.11 \pm 5.42$ , p.value = < 0.0001), a negative link with

the daily horizontal distance travelled ( $slope(Hor.Dist) = -0.26 \pm 0.03$ , p.value = < 0.0001) and a positive link with the intensive foraging mode ( $slope(ARS) = 5.32 \pm 2.35$ , p.value = 276 0.02). Furthermore, the most parsimonious linear mixed model on the daily proportions of drift 277 dives showed a positive intercept (intercept =  $5.91 \pm 1.28$ , p.value = < 0.0001), a positive link with the proportions of shallow dives ( $slope(Shallow.Active) = 0.03 \pm 0.01$ , p.value = 0.03) and with the intensive foraging mode ( $slope(ARS) = 1.37 \pm 0.73$ , p.value = 0.05). Figure 4(a, 280 b) confirm the variations of proportions of the four dive classes between the 2 behavioural 281 movement modes detected on the tracking data: extensive (a) and intensive (b) foraging. The 282 proportion of exploratory dives almost doubles in extensive foraging areas compared to 283 intensive ones. Meanwhile, drift dives number is reduced nearly 50% in extensive foraging 284 areas. The proportion of deep active dives remains identical while the proportion of shallow 285 active dives increases with the intensification of the foraging behaviour. Therefore, the 286 proportion of active dives, combination of deep and shallow active dives, is more important in 287 intensive foraging areas than in extensive ones. 288

### 289 3.4 Mass Gain related to an increase in drift rate and active dives

Mass gain ranged from -60 to 120 kg (Figure 5) and was positively related to four variables. The overall change in drift rate along the track, referred as the gain in drift rate 29  $(\rho = 0.83, p.value = 0.006, \text{ Figure 5a})$ , and the final drift rate  $(\rho = 0.78, p.value = 0.013, p.value$ 292 Figure 5a) were positively related to the mass gain. The proportion of time spent in intensive 293 foraging ( $\rho = 0.67$ , p.value = 0.049, Figure 5b) and the proportion of active dives realised while the animal was in intensive foraging ( $\rho = 0.80, p.value = 0.009$ , Figure 5b) were also positively related to the mass gain. The drift rate gain was the variable best correlated with mass 296 gain. The model selection, based on small sample size corrected AIC, that applied to the 297 multiple regressions (table 5) highlighted the most parsimonious model: Mass Gain ~ Drift 298 Rate Gain (AICc = 65.99,  $R^2 = 0.685$ , with  $slope = 708.26 \pm 181.54$  and

intercept =  $-110.75 \pm 42.82$ ). It is to be noted that the second most parsimonious is: Mass
Gain  $\sim$  Drift Rate Gain + Proportion Active Dives in ARS (AICc = 69.47 and  $R^2 = 0.728$ ).

## 4 Discussion & Perspectives

In this study, we showed that intensive foraging detected from surface tracking data is a good 303 predictor of the diving activity and foraging success occurring in the vertical dimension. 304 Previous studies have shown that southern elephant seals display several dive classes during the 305 pelagic parts of their foraging trips (Hindell et al., 1991; Schreer et al., 2001; Thums et al., 306 2008). However, only few studies linked the fine scale diving patterns with the horizontal 307 movements detected from high resolution tracking data e.g. Thums et al. (2011). Our results 308 suggest that proportions of active dives are more important when seals are displaying 309 area-restricted search behaviour than when they are extensively foraging. Our study also highlights that the mass gain over the animals' foraging trip is positively correlated to the gain 311 in drift rate and to the proportions of active dives and intensive foraging detected from tracking 312 data.

### 4.1 Characterisation and ecological role of dive classes

In the pelagic waters of the interfrontal zone, all individuals displayed four distinct dive classes.

For all individuals but one (09-78524, Table 3), the drift dives were the least abundant dives. As

first mentioned by Hindell *et al.* (1991), drift dives occurred in bouts generally in the early

hours of the morning and are thought to be resting and/or food processing dives (Crocker *et al.*,

1997; Mitani *et al.*, 2010). For some individuals, we also noticed a high occurrence of drift

dives after long sets of deep active dives (results not shown). Thums *et al.* (2008) observed a

tendency of positively buoyant seals to display upwards drift phases in their foraging dives

leading to their misclassification as drift dives. Because our study was based on post-breeding

foraging trips that are much shorter (ca. 2 months) than post-moulting ones (ca. 8 months), only one seal reached positive buoyancy. Therefore, misclassification of the dives was not 324 problematic in our study. 325 High sinuosity, corresponding to wiggle displays in the bottom phase, combined with a maximisation of the time spent at the bottom of the dive (i.e. high descent and ascent speeds) 327 can be associated with intensively active foraging (Fedak et al., 2001). Both deep and shallow 328 active dives are very abundant, occur in bouts or series and generally have a uniform depth 329 within a bout. Finally, deep active dives were characterised by negative bottom-time residuals 330 corresponding to dives with short bottom duration in regards to their maximum depths. Large vertical sinuosity, fast descending and ascending speeds combined to negative bottom-time 332 residuals highlight the very high energetic demand of this dive class. Shallow active dives 333 presented slightly positive bottom-time residuals that is a longer time than expected at the 334 bottom phase which was presented in previous studies as a proxy for intensive foraging 335 (Bailleul et al., 2007b). Considering the time spent at the bottom, female elephant seals seem to 336 display a trade-off between foraging intensity and depths at which foraging occurs. Since 337 bottom-time residuals are calculated with a linear multiple regression (Bailleul et al., 2007b, 338 2008), it seems plausible that at deep depths, where the deep active dives occur, the relation 339 between dive duration and maximum depth changes. The inflexion of this relation would therefore lead to the sign inversion observed in bottom-time residuals between the deep and shallow active dives. In shallow active dives, seals would optimise their efficient hunting time in 342 maximizing the proportion of time spent at the bottom of their dives where prey may be 343 encountered, hence displaying positive bottom-time residuals (Schreer et al. 2001). While deep-diving, the seals' abilities for bottom-time adjustment, on the contrary, are reduced by long descending and ascending durations. In the end, both active dive classes are likely to represent intensive foraging activity as square dives were described in previous studies on 347 various diving predators (LeBoeuf et al., 1988; Hindell et al., 1991; Schreer & Testa, 1996; 348

Fedak et al., 2001; Schreer et al., 2001; Hassrick et al., 2007). Therefore, the vertical sinuosity at the bottom was an important predictor of the dive class as speed and depth were in other 350 classification studies on southern elephant seals (Hindell et al., 1991; Thums et al., 2008). 351 Exploratory dives exhibited large horizontal distances and low bottom time residuals. These 352 dives are thought to be travelling dives because the seals dive at average depths, without displaying much wiggle activity (low sinuosity in the bottom), with low-speed descent and 354 ascent phases and potentially travelling in a straight direction (high horizontal distance). All 355 these characteristics also describe the V-shape dives detected in previous studies (Schreer et al., 356 2001). Although southern elephant seal females from Kerguelen forage mainly in pelagic waters 358 (Dragon et al., 2010; Bailleul et al., 2010b), it has been shown that females of this species can 350 dive and forage over continental shelves (Hindell et al., 1991). In this case, they can interact 360 with different oceanographic conditions and display other foraging behaviours resulting in 36 additional dive classes. As a result, our data correspond to a subset of the dive classes spectrum 362 displayed by foraging seals. All seals in this study were females, so additional work on the 363 fine-scale diving behaviour of males is needed. 364

# 4.2 Association of horizontal foraging patterns with vertical behaviour and overall successful foraging

Our results indicate that southern elephant seals display ARS over 30% of their time spent at sea and mainly within pelagic waters. From previous tracking studies, southern elephant seals are known to be predators that prospect continually within and between prey patches (Bailleul *et al.*, 2008; McIntyre *et al.*, 2011). This may be especially true for pregnant phocid females that exhibit a capital-breeding strategy. Phocids accumulate energy stores prior to fasting during month-long hauling-out for parturition or moult (Berta *et al.*, 2006). Between fasting periods

during parturition and moult, pregnant southern elephant seal females, on their 3-month post-breeding foraging trip, potentially optimise their foraging to recover from breeding and 374 prepare the next energetically demanding period of hauling-out. All seals in this study showed a 375 large proportion of active dives that occur all along the pelagic parts of the tracks by day and 376 night time. This confirms that seals are foraging and probably feeding all along their tracks and that the typical intensification of their search in a zone may therefore correspond to encounters 378 with high quality prey patches. Seals were also found to modify their proportions of dive classes 379 according to the movement behavioural mode: while intensively foraging, the active dive 380 classes were more represented, e.g. most energetically demanding dives (high vertical sinuosity and high ascent speed). The adjustment between intensive and extensive foraging behaviour 382 was not observed on the proportion of deep active dives but on the shallow active ones. From a 383 physiological point of view, numerous deep dives that require intense foraging activity could be 384 too demanding in terms of recovery time (Costa et al., 2004) as suggested by the fact that sets of 385 deep active dives are followed, for some individuals, by sets of drift dives. Therefore, the 386 proportion of deep active dives in intensive and extensive foraging areas (ca. 45%) could be an 387 average threshold of southern elephant seals' ability to dive deeply and actively without 388 energetic pay-off (Davis et al., 2001; Costa et al., 2004). 389 Regarding the existence of two active dive classes, differences in their proportions were observed between day and night. But since deep and shallow active dives are both displayed 39 during day and night time, a diel pattern cannot be the only explanation for their display. 392 Besides diving physiology, a combination of biologic and oceanographic reasons can explain the 393 existence of two distinct types of active dives. Previous studies have shown that female southern 394 elephant seals feed on myctophids in the interfrontal zone (Ducatez et al., 2008; Cherel et al., 2008). Myctophids are bioluminescent cryptic fish and their habitat is highly dependent on light 396 level (Widder, 2010). They adjust their habitat depth according to the light intensity and display 397 not only nycthemeral migrations but also migrations in the water column depending on the local 398

light attenuation (e.g. depending on the particles concentration in the surface water layers, cloud cover, moonlight intensity etc.). Furthermore, the pelagic waters of the interfrontal zone include 400 a variety of water masses (subtropical, subantarctic, polar water masses etc.) that host different 401 prey species for southern elephant seals. The variety in prey, and their respective habitats, 402 potentially drives different foraging behaviours. Interfrontal zones are major components in terms of biological production and are frequently populated with intense mesoscale eddies 404 (Bakun, 2006). Vertical movement of water masses associated with cold-core eddies can induce 405 isopycnal shoaling that is likely to influence prey behaviour, driving upward migrations to 406 remain at preferred densities and temperatures (Wiebe, 1982). Cold water and high biomass in the surface layers may cause a decrease of luminosity contributing to the presence of the cryptic 408 myctophids species at shallower depths (Flierl & McGillicuddy, 2002). Upward cold water 400 masses, often from cyclonic eddies' cores and anticyclonic eddies' edges (Bakun, 2006), have 410 been found to be preferential marine structures for foraging predators (Bost et al., 2009; Bailleul et al., 2010b; Dragon et al., 2010). Female southern elephant seals were shown to clearly intensify their diving effort and decrease their diving depth in rich upwelling areas (Dragon 413 et al., 2010). Therefore, the existence of two active dive classes can be interpreted as a direct 414 adaptation to the highly dynamic and heterogeneous pelagic waters where the seals forage. 415 On the other hand, the increase of shallow active dives in areas of intensive foraging likely highlight the increased accessibility of prey in the water column as observed in previous studies (Dragon et al., 2010). In cyclonic cores and anticyclonic edges where myctophids migrate to 418 shallower depths, we can therefore expect the seals to display higher proportions of shallow 419 active dives. Proportions of drift dives also varied accordingly: while intensively foraging, the 420 seals displayed more drift dives. This could highlight their need, after displaying numerous active dives, either for resting or for food processing (Biuw et al., 2003). In contrast, when the 422 seals are extensively foraging and abundantly displaying exploratory dives, the diminution of 423 drift dive proportions suggests either a low energy consumption prospective mode adopted

during the exploratory dives or, simply, less need for food processing. Either way, the ultimate proxy of the seals overall successful foraging, the mass gain, was significantly correlated with 426 the percentage of intensive foraging mode and of active dives while in intensive foraging: the 427 more numerous the active dives while intensive foraging, the more successful the foraging seals. 428 Although we worked on a 1-year sample, similar results were found on numerous post-moulting and post-breeding tracks of northern elephant seals by Robinson et al. (2010). It should finally 430 be noted that these significant correlations highlight the proxies' pertinence to predict, at the 431 track scale, the foraging success of seals. Our sample of post-breeding females was selected to 432 be homogeneous in mass and length so that the females could be supposed to have similar age and amount of experience. All went to forage in the interfrontal zone but displayed, in the end, a 434 variety of mass gain, ranging from a loss of 60 kg to the gain of more than 100 kg in only 3 435 months. This high inter-individual variability in mass gain probably drives a fitness variability 436 related to inter-individual variations in foraging behaviour and/or differences in prey selection 437 (Field et al., 2004, 2007). This confirms the importance of the individual foraging efficiency, 438 and past experiences, in this dynamic and unpredictable oceanographic environment (Hindell 439 et al., 1999; Bradshaw et al., 2004). 440

### 4.3 Methodological perspectives

Direct information on prey distribution remains very scarce in the Southern Ocean. Therefore,
identifying periods of intensive foraging appears to be an efficient way to investigate the prey
distribution of marine predators. Animal behaviour, in the horizontal and the vertical
dimension, can be modeled as a dynamic variable changing in relation to the animal's internal
state and/or its environment (Morales *et al.*, 2004; Jonsen *et al.*, 2007). Track-based analyses of
the fine scale vertical behaviour could be an interesting next step to investigate relationships
between seals behaviour and their environment. This could be used to systematically detect
behavioural transitions along the dive profiles, associate them with the animal's direct

surroundings and infer information on prey distribution.

On the other hand, there are difficulties of interpretation of 2-dimensional data (time and depth) 451 into a behaviour occurring in 4-dimensions (time-longitude-latitude-depth, Thums et al. 452 (2008)). Brillinger & Stewart (1997) have shown that a time-depth curve can actually 453 correspond to different possible 4D paths. We can therefore expect the same differences between the observed horizontal trajectory (longitude-latitude) and the actual path of a diving 455 animal. Other studies have also questioned the validity of behavioural interpretations based on 456 dataset with reduced dimensions (Harcourt et al., 2000; Davis et al., 2003). New technological 457 devices, such as 3D-accelerometers and video cameras, are promising to solve those issues. In free-ranging Weddell seals (Leptonychotes weddellii) for instance, studies using video 450 recordings have proved the encounter of prey within the foraging dives (Davis et al., 2003). In 460 Weddell seals and also in captive Steller sea lions (Eumetopias jubatus), accelerometers were 461 able to precisely detect the mouth opening events linked with prey capture attempts (Naito 462 et al., 2010; Viviant et al., 2010). Such in situ recording devices will indicate the real behavioural activity and also help to identify accurate 2-dimensional proxies of the foraging 464 effort. Uses of such new devices could therefore validate our findings on active dives being the 465 most successful foraging dives. It is our intention to examine this in future work. 466

### 5 Conclusion

Previous studies have shown that southern elephant seals display various behavioural modes
detected from tracking data (Bailleul *et al.*, 2008) and various dive classes during their foraging
trip (Hindell *et al.*, 1991; Thums *et al.*, 2008). Here we have shown that proportions of dive
classes displayed by southern elephant seal females varied according to their horizontal
behaviour. It is probable that by going to the polar frontal zone where resources are both
spatially and temporally highly variable, female elephant seals can concentrate their foraging

searching activity in the most productive parts of the zone and maximise feeding success. They repeatedly adapt their diving behaviour to prey accessibility in the water column and seem to 475 display a trade-off between diving depth and recovery time. Mass gain over the animals' 476 foraging trip was also highly correlated to the proportions of intensive foraging detected with track-based analyses. Improved body condition of seals was finally associated with the occurrence, within the vertical dimension, of sets of highly active dives. The classification of 479 diving behaviour is not an end in itself, but rather a tool that allowed us to conclude that 480 intensive foraging detected from surface tracking data is a good predictor of the diving activity 481 and foraging success occurring in the vertical dimension. However, in changing environments, the addition of fine-scale monitoring of in situ oceanographic conditions to high resolution 483 behavioural datasets is an interesting further step in research on foraging behaviour in relation 484 to prey distribution. 485

## 486 6 Acknowledgements

The authors wish to thank all fieldworkers of the 60<sup>ieme</sup> Mission for field work that helped to collect data. This study is part of a national research program (no. 109, H. Weimerskirch and 488 the observatory Mammifères Explorateurs du Milieu Océanique, MEMO SOERE CTD 02) 489 supported by the French Polar Institute (Institut Paul Emile Victor, IPEV). This work was 490 carried out in the framework of IPSOS-SEAL (ANR VMC 07) program and CNES-TOSCA 49 program ("Élephants de mer océanographes"). The authors wish also to thank the Total Fundation for financial support. All animals in this study were cared for in accordance with its 493 guidelines. We are grateful to three anonymous reviewers for very useful comments and to 494 Janos Hennicke for correction of the English. Special thanks go also to Matthieu Authier and 495 Frédéric Bailleul for very useful comments and discussions. Finally, the authors wish to thank Ian Jonsen that provided the state-space model scripts and a kind assistance for analysis of the tracking data (R and WinBUGS scripts are available on demand to Ian Jonsen). 498

Variable	Abbreviation	Definition	Source
Bottom-Time (mn)	Bott.Time	descent end to ascent start	TDR
Bottom-Time Residuals (mn)	Res.Bott.Time	residuals of multiple regression	TDR
Maximum diving depth (m)	Max.Depth	-	TDR
Sinuosity	-	derived from Weimerskirch et al. (2007)	TDR
Ascending Speed (m/s)	Asc.Speed	-	TDR
Descending Speed (m/s)	Des.Speed	-	TDR
Horizontal Distance (km)	Horiz.Dist	distance travelled between 2 dives	GPS

Table 1: Behavioural variables: unit, abbreviation name, definition and source.

	Drift	Exploratory	Shallow Active	Deep Active
N =	2846	6221	12482	17656
Bott.Time (mn)	$15.8 \pm 6.0$	$11.3 \pm 4.8$	$13.2 \pm 3.3$	$10.1 \pm 3.6$
Res.Bott.Time (mn)	$2.6 \pm 5.9$	$-0.6 \pm 4.7$	$0.7\pm2.8$	$-1.2 \pm 3.2$
Max.Depth (m)	$424\pm118$	$348\pm156$	$324\pm127$	$698 \pm 131$
Sinuosity	$0.29\pm0.05$	$0.35 \pm 0.08$	$0.41\pm0.06$	$0.52 \pm 0.04$
Asc.Speed (m/s)	$1.21\pm0.22$	$1.31 \pm 0.24$	$1.77 \pm 0.19$	$1.56 \pm 0.15$
Des.Speed (m/s)	$1.18 \pm 0.37$	$1.22\pm0.27$	$1.74\pm0.26$	$1.76 \pm 0.25$
Horiz.Dist (km)	$0.98\pm0.74$	$1.57 \pm 0.67$	$1.20 \pm 0.32$	$0.97 \pm 0.54$

Table 2: Characteristics of dive classes for all individuals. All differences, between the dive classes, are statistically significant (p < 0.001). Bott.Time stands for bottom time and Res.Bott.Time for bottom time residuals (both in minutes). Max.Depth corresponds to the maximal depth of the dive. Asc.Speed and Des.Speed stand respectively for ascent and descent speeds. Finally Horiz.Dist corresponds to the horizontal distance travelled by the animal during its dive estimated from the tracking data.

ind	N	%Drift	%Exploratory	%Shallow Active	%Deep Active	% Active
09-78524	2605	14.8	9.6	2.5	73.1	75.6
09-78525	4169	9.4	12.2	28.8	49.6	78.4
09-86372	5778	5.3	15.5	41.4	37.8	79.2

ft03-Cy5-09	5450	5.6	31.3	32.9	30.2	63.1
ft03-Cy11038-09	4485	8.1	9.8	10.2	71.9	82.1
all ind	40763	$7.7 \pm 3.2$	$14.9 \pm 7.9$	$31.3 \pm 15.4$	$46.1 \pm 16.1$	$77.4 \pm 7.0$

Table 3: Proportions of dive classes for all individuals (%) equipped in October 2009. Only dives located in the pelagic part of the tracks were classified. Overall, inter-individual variability can be noticed. But deep active dives tend to always be the most important dive class and active dives, combined deep and shallow classes, represent for each individual over two thirds of the whole dives. Drift dive class rarely reach 10% of the whole dives.

Dive Class (t)	Drift (t+1)	Exploratory (t+1)	Shallow Active (t+1)	Deep Active (t+1)
Drift	0.70	0.12	0.05	0.13
Exploratory	0.06	0.60	0.19	0.15
Shallow Active	0.01	0.09	0.76	0.14
Deep Active	0.02	0.05	0.11	0.82

Table 4: Observed probabilities of dive class changing from dive at time t to dive at time (t+1). High temporal persistence in the dive classes can be noticed and the second highest probabilities of dive class changing always correspond to the nearest dive class in terms of activity. Probabilities of changing reveal thus the hierarchy in the dive classes activity: an animal displaying a deep active dive is more likely to continue displaying this class of dive or to change for a shallow active dive and vice versa.

Model Formula	AICc
$MassGain \sim MassStart + DriftRateGain + FinalDriftRate + PropARS + PropActiveARS$	111.25
${\it MassGain} \sim {\it MassStart} + {\it DriftRateGain} + {\it PropARS} + {\it PropActiveARS}$	87.27
$MassGain \sim MassStart + DriftRateGain + PropActiveARS$	75.61
$MassGain \sim DriftRateGain + PropActiveARS$	69.47
$MassGain \sim DriftRateGain$	65.99

Table 5: Model selection based on small sample sizes corrected AIC. The model with the smallest AICc is considered the best. The variable to explain is the gain in mass over the animal's foraging trip and the tested variables are: the animal mass when equipped before the post-breeding foragfing trip (MassStart), the gain in drift rate over this trip (DriftRateGain), the final drift rate (FinalDriftRate), the percentage of intensive foraging mode in pelagic waters (PropARS) and the percentage of active dives displayed while the animal was in intensive foraging (PropActiveARS).

Figure 1: Physical oceanography in the Southern Indian Ocean and post-breeding foraging trips
of 9 female southern elephant seals equipped in October 2009 (solid black lines). Light grey
shading indicates depths less than 1,000 meters and depicts Kerguelen and Crozet plateaux. Îles
Kerguelen and îles Crozet coastline's contour are also indicated in white over the plateaux.

Dotted lines symbolized fronts (Orsi *et al.*, 1995), within the Southern Ocean: Southern
SubTropical Front (SSTF), Sub-Antarctic Front (SAF), Polar Front (PF) and Southern Antarctic
Circum-Polar Front (SACCF). In this study, we refer to the interfrontal zone as the area between
the STF and the PF. Locations of intensive foraging behaviour displayed by the seals are
indicated in dark grey dots over the tracks.

Figure 2: Characteristics of dive classes for all individuals: drift dives (dark green), exploratory 717 dives (light green), shallow active dives (yellow) and deep active dives (orange). (a) Variations 718 of bottom time residuals: drift dives are the longest dives while deep active present negative bottom time residuals. (b) Proportion of dive classes by day and night times: all classes occur 720 by day and by night time. (c) Variations of maximum diving depth in function of bottom time: 72 depending on maximum depth distribution, time spent at the bottom of the dives varies from 722 one dive class to another. (d) Variations of sinuosity at the bottom of the dive in function of the 723 ascending speed: the higher the sinuosity, the more important the ascending speed.(e) For each dive class, the density distribution of the descending speeds. The distribution similarity of 725 descending speed for the two active dive classes can be noticed meanwhile exploratory and drift 726 dives present low descending speeds. Finally, (f) distributions of the horizontal distance 727 travelled during the dives: in exploratory dives, seals tend to swim more rapidly in the 728 horizontal dimension than for the other dive classes. The dashed vertical lines indicate, for each dive class, the average horizontal distance. 730

#### Figure 3:

731

(a) Typical Depth-Time profiles of the four dive classes. (b) Locations of the dives along the
 seals' tracks. Orange dots correspond to deep active dives, yellow to shallow active, light green
 to exploratory dives and finally dark green to drift dives. All dive classes occurred all along the
 tracks, by day as well as by night.

737

Figure 4: (a) and (b) Proportions of dive classes in extensive parts (N = 15,081 dives) vs.

intensive foraging parts of the tracks (N = 11,463 dives). Combination of deep and shallow

active (hereafter referred as active classes) is more important in intensive foraging areas than in

742

extensive ones.

Figure 5: For all individuals, mass gain presented with (a): overall drift rate, final drift rate and
(b): percentage of time spent in intensive foraging and proportion of active dives realised in
intensive foraging. Lines correspond to the significant linear regressions between variables.
