Abstract

We synthesise traditional unstructured food webs, allometric body size scaling, trait-based modelling, and physiologically structured modelling to provide a novel and ecologically relevant tool for size-structured food webs. The framework allows food web models to include ontogenetic growth and life-history omnivory at the individual level by resolving the population structure of each species as a size-spectrum. Each species is characterised by the trait 'size at maturation', and all model parameters are made species independent through scaling with individual body size and size at maturation. Parameter values are determined from cross-species analysis of fish communities as life-history omnivory is widespread in aquatic systems, but may be reparameterised for other systems. An ensemble of food webs is generated and the resulting communities are analysed at four levels of organisation: community level, species level, trait level, and individual level. The model may be solved analytically by assuming that the community spectrum follows a power law. The analytical solution provides a baseline expectation of the results of complex food web simulations, and agrees well with the predictions of the full model on 1) biomass distribution as a function of individual size, 2) biomass distribution as a function of size at maturation, and 3) relation between predator-prey mass ratio of preferred and eaten food. The full model additionally predicts the diversity distribution as a function of size at maturation.

Keywords: community ecology, trait based model, life-history omnivory, ontogeny, size-spectrum

1. Introduction

Food webs are typically modelled using unstructured species populations based on generalised Lotka-Volterra equations. This unstructured formulation ignores individual life-history by assigning a fixed trophic position to all individuals within a species. In aquatic ecosystems this assumption is violated as fish offspring reside at a low trophic level and grow during ontogeny through multiple trophic levels before reaching maturation (Werner and Gilliam, 1984). Along this journey, from the milligram range and up to several kilogram, fish change diet (as well as enemies) and consequently exhibit life-history omnivory through preying on different trophic levels in different life-stages (Pimm and Rice, 1987). Thus the assignment of a unique trophic level and role (resource, consumer, predator, etc.) for species in unstructured models is incompatible with systems where ontogenetic growth and life-history omnivory are pronounced. In the cases where

trophic level of individuals within a species is positively correlated with body size (Jennings et al., 2002), individual size may be used as a proxy for trophic level. Models may therefore account for ontogenetic growth and life-history omnivory by resolving the size-structure within each species.

A general framework for large food webs that includes the size-structure for all species must fulfil a set of requirements. It should: 1) be generic in the sense that large species-specific parameter sets are not necessary, 2) be based on mechanistic physiological individual-level processes, where parameters represent measurable biological quantities, 3) resolve food dependent growth of individuals (Werner and Gilliam, 1984), 4) be practically solvable for species-rich systems over many generations, and 5) comply with empirical data on size-structured communities. In this work we develop a food web framework complying with these requirements by resolving the life-history of individuals within species by a continuous size-spectrum. We parameterise the model for aquatic systems as an example of a size-structured community with widespread life-history omnivory, but the framework may be parameterised for other system types (cf. Discussion). In fish communities the most prominent empirical patterns, which the model framework should comply with, are that individuals exhibit biphasic growth (Lester et al., 2004), and the Sheldon community spectrum. Sheldon et al. (1972) hypothesised that the community biomass spectrum, from bacteria to whales, as a function of body mass is close to constant. Empirical studies later showed that the biomass for fish indeed is close to constant or slightly declining as a function of body mass (Ursin, 1982; Boudreau and Dickie, 1992) with the complication that heavily fished systems have a steeper decline in biomass (Jennings et al., 2002; Daan et al., 2005).

The importance of resolving ontogenetic growth and life-history omnivory has long been realised in fisheries science, where mechanistic individual-level size-structured food web models of fish communities were pioneered (Andersen and Ursin, 1977). Independently, the physiologically structured population model (PSPM) framework (Metz and Diekmann, 1986; de Roos and Persson, 2001) has been developed in the field of ecology. While providing the ecological realism needed for a size-structured food web framework these approaches typically rely on large species-dependent parameter sets, which must be reduced for the approaches to be useful as generic frameworks.

Reduction to species-independent parameter sets has been achieved in unstructured models of interacting populations by scaling of physiological and demographic rates with body size (Yodzis and Innes, 1992). By using body size as a trait this approach has resulted in several simple generic food web models for unstructured populations (Loeuille and Loreau, 2005; Virgo et al., 2006; Brose et al., 2006b; Lewis and Law, 2007).

In this work we combine the two approaches into one unified framework: We 1) use a physiological based description of individual life-history, and 2) use a single trait (size at maturation) to characterise each species while using trait and body size scaling to get one condensed species-independent parameter set. All processes are based on descriptions at the level of individuals, and interaction strengths among individuals are dynamic through the prescription of size-dependent food selection. This leads to a realised effective food web structure which depends on the emergent

size-spectrum composition of all species. In this manner we synthesise a general framework that in a conceptually simple yet ecologically realistic way can be used to model food webs where the life cycle of individuals in each species is explicitly modelled from birth to reproduction and death.

Our primary objective is the formulation and parametrisation of the food web framework. Food webs generated by unstructured food web models may be analysed at the community level in terms of distributions of biomass across species and trophic levels. Trait-based size-structured food webs allow a more detailed analysis of the community level as well as enabling analysis on three additional levels of organisation: 1) at the community level, i.e., the distribution of total biomass as a function of body size of individuals regardless of their species identity, and the distribution of biomass and diversity as a function of the trait size at maturation, 2) at the species level, i.e., distribution of biomass as a function of size within a given species, 3) at the trait level, which in the case of a single trait equals the species level, and 4) at the individual level, i.e., distribution of size of food in the stomachs. Due to this added complexity of size-structured food webs, our secondary objective is to illustrate diversity and biomass distributions at different levels of organisation. To this end we generate an ensemble of food webs and analyse them in terms of distributions of average community size-spectra, species size-spectra, trait biomass distributions, and trait diversity distributions. Finally, we develop an analytical solution of the model framework, basically by assuming that the community spectrum follows a power-law (equilibrium size-spectrum theory, EQT). All distributions, except the diversity distribution, may be calculated from EQT, and we demonstrate general accordance between EQT and the results from the full food web simulations. The accordance between EQT and the food web simulations validates the simplifying assumptions behind EQT. EQT provides a “null-solution” to the size- and trait-distributions which may be used as a baseline expectation of the results of large size-structured food web simulations.

[Figure 1 about here.]

2. Food web model

The model is based on a description of the processes of food encounter, growth, reproduction, and mortality at the level of an individual with body mass m (Fig. 1). The model is based on two central assumptions: 1) Prey selection is determined at the individual level where individual predators select prey from the rule “big individuals eat smaller individuals”, and at the species level through introduction of species-specific size-independent coupling strengths (Andersen and Ursin, 1977; Werner and Gilliam, 1984; Emmerson and Raffaelli, 2004). 2) In addition to species-specific coupling strengths, species identity is characterised by a single trait: size at maturation m_* . Interactions among individuals are described by a food encounter process which leads to consumption by predators and mortality on their prey. Food consumption leads to growth in body mass, and when an individual reaches size at maturation m_* it starts allocating energy for

92 reproduction, as well as producing new offspring. Thus the model encapsulates the life-cycle of
individuals from birth to maturity and death.

94 Population dynamics of species i is obtained from individual growth $g_i(m)$ and mortality $\mu_i(m)$
by solving the number conservation equation (McKendrick, 1926; von Foerster, 1959):

$$\frac{\partial N_i}{\partial t} + \frac{\partial}{\partial m} (g_i N_i) = -\mu_i N_i. \quad (1)$$

96 The population structure of species i is described by the size-spectrum $N_i(m, t)$, denoted $N_i(m)$
to ease notation. The size-spectrum represents the volumetric abundance density distribution
98 of individuals such that $N_i(m) dm$ is the number of individuals per unit volume in the mass
range $[m; m + dm]$. Similarly $B_i(m) = mN_i(m)$ denotes the biomass spectrum (biomass density
100 distribution), and $B_i(m) dm$ the biomass per unit volume in the range $[m; m + dm]$. The sum of
all species' size-spectra plus a resource spectrum $N_R(m)$ is the community spectrum (Fig. 1):

$$N_c(m) = N_R(m) + \sum_i N_i(m). \quad (2)$$

102 The community spectrum represents the entire biotic environment providing individuals with food
(from smaller individuals) as well as their predation risk from larger individuals. To include
104 species-specific preferences each species i has its own *experienced* community spectrum:

$$\mathcal{N}_i(m) = \theta_{i,R} N_R(m) + \sum_j \theta_{i,j} N_j(m), \quad (3)$$

where $\theta_{i,j} \in [0; 1]$ is the coupling strength of species i to species j . Coupling strengths are
106 independent of body size (cf. Discussion) since size-dependent food intake is described with a
feeding kernel (below).

108 2.1. Food consumption

The consumption of food by an individual depends on the available food from the experienced
110 community spectrum, on the volume searched per time, and on its functional response. The
consumed food is assimilated and used to cover respiratory costs. Remaining available energy is
112 used for somatic growth by immature individuals and for a combination of somatic growth and
reproduction by mature individuals.

114 We incorporate the rule of “big ones eat smaller ones” by assuming that predators have a
preferred predator-prey mass ratio (PPMR). This assumption is inspired by stomach analyses of
116 marine fish (Ursin, 1973, 1974), and supported by stable isotope analyses (Jennings et al., 2001).
The feeding kernel describing the size preference for prey is prescribed with a normalised log-normal
118 function (Fig. 1, Ursin, 1973):

$$s(m_p, m) = \exp \left[- \left(\ln \left(\frac{\beta m_p}{m} \right) \right)^2 / (2\sigma^2) \right], \quad (4)$$

where m_p is prey mass, m predator mass, β the preferred PPMR, and σ the width of the function.

120 The food available (mass per volume) for a predator of size m is:

$$\phi_i(m) = \int m_p \mathcal{N}_i(m_p) s(m_p, m) dm_p. \quad (5)$$

Encountered food (mass per time) is the available food multiplied by the volumetric search rate
 122 $v(m) = \gamma m^q$, where q is a positive exponent signifying that larger individuals search a larger
 volume per unit time (Ware, 1978). Satiation is described using a feeding level (number between
 124 0 and 1, Kitchell and Stewart, 1977; Andersen and Ursin, 1977):

$$f_i(m) = \frac{v(m)\phi_i(m)}{v(m)\phi_i(m) + hm^n}, \quad (6)$$

where hm^n is the maximum food intake. Feeding level times hm^n corresponds to a type II func-
 126 tional response.

2.2. Somatic growth

128 Ingested food $f(m)hm^n$ is assimilated with an efficiency α accounting for waste products and
 specific dynamic action. From the assimilated energy an individual has to pay the metabolic costs
 130 of standard metabolism and activity, km^p . Thus the energy available for growth and reproduction
 is:

$$E_i(m) = \alpha f_i(m)hm^n - km^p. \quad (7)$$

132 Of the available energy a fraction $\psi(m, m_*)$ is used for reproduction, and the rest for somatic
 growth:

$$g_i(m, m_*) = \begin{cases} (1 - \psi(m, m_*))E_i(m) & E_i(m) > 0 \\ 0 & \text{otherwise} \end{cases}. \quad (8)$$

134 If the intake is insufficient to cover respiratory costs ($E_i(m) < 0$) growth is halted. Body size does
 not shrink when costs cannot be covered, instead starving individuals are exposed to a starvation
 136 mortality (see section 2.4). The maximum asymptotic size M an individual can obtain is reached
 when all available energy is used for reproduction ($\psi(M, m_*) = 1$).

2.3. Reproduction

In order to generate growth trajectories with biphasic growth the allocation rule $\psi(m, m_*)$ has
 140 to change smoothly from 0 around size at maturation to 1 at the theoretical maximum asymptotic
 size M . The allocation rule $\psi(m, m_*)$ is derived using two requirements: 1) that the size of
 142 gonads is proportional to individual mass (Blueweiss et al., 1978), and 2) that size at maturation is
 proportional to asymptotic size (Beverton, 1992; Froese and Binohlan, 2000; He and Stewart, 2001).
 144 To obtain an analytical solution as to how individuals allocate available energy to growth and
 reproduction we assume that the allocation rule is based on a constant feeding level \bar{f} . Requiring
 146 allocation to reproduction to be proportional to individual mass, $\psi(m, m_*)\bar{E}(m) = k_r m$, gives
 $\psi(m, m_*) = k_r m / \bar{E}(m)$, where $\bar{E}(m) = \alpha \bar{f} h m^n - k m^p$ denotes the available energy when feeding

148 level is constant. The factor k_r is found by the second requirement through $\psi(M, m_*) = 1$:
 $k_r = \overline{E}(M)/M$ where $M = m_*/\eta_*$. The allocation can thus be described as:

$$\psi(m, m_*) = \left[1 + \left(\frac{m}{m_*} \right)^{-u} \right]^{-1} \frac{\overline{E}(m_*/\eta_*)}{\overline{E}(m)} \frac{m}{m_*/\eta_*}, \quad (9)$$

150 where the term in the square brackets is a smooth step function switching from zero to one around
the size at maturation (u determines transition width).

152 The exponents of maximum consumption and standard metabolism are close to equal (cf. Ap-
pendix E and Discussion). In the limit of $n = p$ the available energy for growth and reproduction
154 becomes $\overline{E}(m) = \hbar m^n$ where $\hbar = \alpha \overline{f}h - k$. This gives: $\psi(m, m_*) = [1 + (m/m_*)^{-u}]^{-1} (\eta_* m/m_*)^{1-n}$,
meaning that the juvenile growth pattern is $g = \hbar m^n$ whereas adults grow according to $g =$
156 $\hbar m^n - \hbar (m_*/\eta_*)^{n-1} m$. Thus the growth model is a biphasic growth model where adults follow von
Bertalanffy growth curves as advocated by Lester et al. (2004).

158 The total flux of offspring is found by integrating the energy allocated to reproduction $\psi(m, m_*)E_i(m)$
over all individual sizes:

$$R_i = \frac{\epsilon}{2m_0} \int N_i(m) \psi(m, m_*) E_i(m) dm, \quad (10)$$

160 where m_0 is the egg size, ϵ the efficiency of offspring production (Appendix C), and $1/2$ takes into
account that only females spawn (assuming equal sex distribution). Reproduction determines the
162 lower boundary condition of (1) for the size-spectrum of the species:

$$g_i(m_0, m_*) N_i(m_0) = R_i. \quad (11)$$

2.4. Mortality

164 The mortality rate $\mu(m)$ of an individual has three sources: predation mortality $\mu_p(m)$, star-
vation mortality $\mu_s(m)$, and a small constant background mortality $\mu_b(m_*)$. The background
166 mortality is needed to ensure that the largest individuals in the community also experience mor-
tality as they are not predated upon by any individuals from the community spectrum.

168 Predation mortality is calculated such that all that is eaten translates into predation mortalities
on the ingested prey individuals (Appendix A):

$$\mu_{p,i}(m_p) = \sum_j \int s(m_p, m) (1 - f_j(m)) v(m) \theta_{j,i} N_j(m) dm. \quad (12)$$

170 When food supply does not cover metabolic requirements km^p starvation mortality kicks in.
Starvation mortality is proportional to the energy deficiency $km^p - \alpha f(m) \hbar m^n$, and inversely
172 proportional to lipid reserves, which are assumed proportional to body mass:

$$\mu_s(m) = \begin{cases} 0 & E_i(m) > 0 \\ \frac{-E_i(m)}{\xi m} & \text{otherwise} \end{cases}. \quad (13)$$

Mortality from other sources than predation and starvation is assumed constant within a species
174 and inversely proportional to generation time (Peters, 1983):

$$\mu_b = \mu_0 m_*^{n-1}. \quad (14)$$

2.5. Resource spectrum

176 The resource spectrum $N_R(m)$ represents food items which are needed for the smallest individuals (smaller than βm_0). The dynamics of each size group in the resource spectrum is described
178 using semi-chemostatic growth:

$$\frac{\partial N_R(m, t)}{\partial t} = r_0 m^{p-1} [\kappa m^{-\lambda} - N_R(m, t)] - \mu_p(m) N_R(m, t), \quad (15)$$

where $r_0 m^{p-1}$ is the population regeneration rate (Fenchel, 1974; Savage et al., 2004) and $\kappa m^{-\lambda}$
180 the carrying capacity. We prefer semi-chemostatic to logistic growth since planktonic resources rebuild from depletion locally due to both population growth and invasions.

182 [Table 1 about here.]

2.6. Derivation of parameters

184 Each species is characterised by a single trait, size at maturation m_* , and a species-independent parameter set is achieved through scaling with body size m and m_* . The model is parameterised
186 for marine ecosystems using cross-species analyses of fish communities (Appendix E and Table 1).

The constant γ for the volumetric search rate is difficult to assess (Appendix E). However,
188 since the feeding level $f(m)$ of small individuals is determined solely by the amount of encountered food from the resource spectrum, we may use *initial feeding level* f_0 as a physiological measure of
190 food encounter; f_0 is defined as the feeding level resulting from a resource spectrum at carrying capacity. The initial feeding level is used as a control parameter for food availability (enrichment),
192 through which the value of γ can be calculated (Appendix D):

$$\gamma_i(f_0) = \frac{f_0 h \beta^{2-\lambda}}{(1 - f_0) \sqrt{2\pi} \theta_{i,R} \kappa \sigma}, \quad (16)$$

194 where it is noted that γ will be species dependent if species have different coupling strengths to the resource.

A *critical feeding level* f_c can be formulated as the feeding level where all assimilated food is
196 used for metabolic costs (using values from Table 1):

$$f_c = \frac{k}{\alpha h} m^{p-n} = \frac{k}{\alpha h} \approx 0.2. \quad (17)$$

Individuals can only grow and reproduce if $f > f_c$. Assuming that individuals experience an average feeding level \bar{f} , the growth (8) of juveniles is $g = \bar{h} m^n$ (for $n = p$). The parameter $\bar{h} = \alpha h \bar{f} - k$ can be estimated through the relation between observed von Bertalanffy growth rate and asymptotic size yielding $\bar{h} \approx 10 \text{ g}^{0.25}/\text{year}$ (Andersen et al., 2008). This allows an estimation of the expected average feeding level of individuals in the field (Table 1):

$$\bar{f} = \frac{\bar{h} + k}{\alpha h} \approx 0.4, \quad (18)$$

198 i.e. around twice the critical feeding level. As the initial feeding level f_0 is calculated from a resource spectrum at carrying capacity, the realised feeding level in the model will be smaller than f_0 . A value of $f_0 = 0.6$ was seen to give realised feeding levels around 0.4.

200 3. Methods

202 Stable food webs are constructed using the full dynamic food web model with random coupling strengths $\theta_{i,j}$. For each run, 30 species are assigned with m_* evenly distributed on a logarithmic size axis ($m_* \in [0.25 \text{ g}; 20 \text{ kg}]$), random $\theta_{i,j}$ matrices (mean 0.5), and a common $\theta_{i,R} = 0.5$ coupling to the resource spectrum. Numerical integration is performed by standard finite difference techniques (Appendix G). Food webs are simulated in 10 consecutive intervals covering 300 years each, where 204 species with a biomass less than 10^{-30} g/m^3 are eliminated after each interval. To eliminate food webs that still have not reached the final state each community is integrated for additional 500 208 years and discarded if any species has an absolute population growth rate larger than 1 logarithmic decade per 100 years. To ensure that each food web in the final ensemble spans multiple trophic levels we only retain food webs where at least one species has m_* larger than 2.5 kg. For statistics we use the mean of the last 250 years of the simulation with time steps saved in 0.1 year increments. 212 In this manner 204 food webs having a total number of 1016 species were collected. Each web contained between 2 and 9 species with a mean of 4.98 species.

214 We analyse the generated food webs in terms of distributions of average community size-spectrum, species size-spectra, trait biomass distributions, and trait diversity distributions. Additionally we demonstrate the importance of distinguishing between what an individual prefers to eat and what is actually ingested (i.e. found in its stomach) by showing how emerging PPMRs vary with food availability and differ from preferred PPMRs. 218

An approximate steady-state solution to the food web model which neglects the dynamics of 220 reproduction can be found using two assumptions: 1) all species consume food and experience mortality from a scaling community size-spectrum $N_c = \kappa_c m^{-\lambda}$, and 2) constant feeding level \bar{f} , which implies equal species coupling strengths $\theta_{i,j} = \bar{\theta}$. Whereas the food webs in the full model are based on a discrete set of m_* , the analytical solution considers m_* as a continuous distribution. 224 The procedure for deriving the analytical solution is similar to the derivation of equilibrium size-spectrum theory (Andersen and Beyer, 2006), but the results are slightly different as standard 226 metabolism is taken explicitly into account here. The food encountered by an individual is found using assumption 1): $v(m)\phi(m) = \gamma m^q \int N_c s(m_p, m) m_p dm_p \propto m^{2-\lambda+q}$. The feeding level is 228 calculated from (6), and the requirement that it is constant (assumption 2) leads to a constraint on the exponent of the community spectrum: $\lambda = 2 + q - n$. Feeding with a constant feeding 230 level generates a predation mortality of $\mu_p = \alpha_p m^{n-1}$ (Appendix A). The size-spectrum of juvenile individuals is found as the steady state solution of (1) using the above predation mortality and $g = \hbar m^n$ (cf. (F.1)): $N(m, m_*) = \kappa(m_*) m^{-n-a}$, where $a = \alpha_p / \hbar$ is the physiological level of predation (Beyer, 1989; Andersen and Beyer, 2006), which can be calculated as $a \approx \bar{f} / (\bar{f} - f_c) \beta^{2n-q-1} / \alpha = 0.86$ (Appendix B). The constant $\kappa(m_*)$ is found from the requirement that the 234 sum of all species spectra should equal the community spectrum. Assuming a continuum of species the requirement can be written as $\int N(m, m_*) dm_* = N_c(m)$ which leads to $\kappa(m_*) \propto m_*^{2n-q-3+a}$ (Fig. 1). This approximate solution of the model will be referred to as equilibrium size-spectrum

theory (EQT), and it will be compared to the output of the complete dynamic food web model.

In dynamic models, as in nature, the lifetime reproductive success (fitness) has to be $R_0 = 1$ for all coexisting species. Since EQT does not consider the boundary condition (11) life-time reproductive success becomes a function of size at maturation: $R_0 \propto m_*^{1-a}$ (Andersen et al., 2008). One solution to making R_0 independent of m_* is to set $a = 1$, but that breaks the above employed mass balance between growth and mortality used to calculate a . Due to the $R_0 \neq 1$ inconsistency in EQT we have a specific focus on the realised values of a when comparing food web simulations with EQT predictions. To examine how the regulation of R_0 occurs in the full food web model R_0 is split into two factors: 1) the probability of surviving to become adult, and 2) lifetime reproduction per adult (Appendix F):

$$p_{m_0 \rightarrow m} = \frac{N(m)g(m, m_*)}{N(m_0)g(m_0, m_*)}, \quad (19)$$

$$R_{\text{adult}}(m_*) = \int_{m_*}^M p_{m_* \rightarrow m} \frac{\psi(m, m_*)E(m)}{g(m, m_*)} dm. \quad (20)$$

Survival probabilities and reproductive outputs in the food web simulations are compared with EQT predictions, which are calculated by inserting the EQT size-spectra into (19) and (20). Juvenile growth is $g \propto m^n$, which gives $p_{m_0 \rightarrow m_*} \propto m_*^{-n-a} m_*^n = m_*^{-a}$ and $R_{\text{adult}} \propto m_*$.

[Figure 2 about here.]

4. Model predictions

4.1. Growth trajectories

In unstructured models fluctuations are manifested as oscillations in the biomass of species, whereas the oscillations in structured models stem from oscillations in the size-spectrum composition. Such oscillations give rise to fluctuating feeding levels as individuals encounter different levels of food in different life-stages (Fig. 2.a). Variations in feeding levels between species and as a function of individual size lead to different emergent growth trajectories (Fig. 2.b). The growth trajectories roughly follow the biphasic growth curve that is obtained if the feeding level is assumed to be constant.

[Figure 3 about here.]

[Figure 4 about here.]

4.2. Biomass structure

By pooling species from each food web into logarithmic evenly distributed m_* groups, and summing the size-spectra in each group, a size-spectrum is obtained for each m_* group. Next, the logarithmic average of m_* groups across all food webs is performed to produce the average size-spectra of a m_* group (Fig. 3). Average community biomass spectrum $N_c(m)m$ follows the

EQT prediction of a slope of $1 + q - n = 1.05$, meaning that the biomass in logarithmically
 270 evenly sized size-groups, $\int_m^{cm} N_c(m)mdm$, is a slightly declining function of body mass. The
 community spectrum oscillates around the EQT prediction due to a trophic cascade initiated
 272 by a superabundance of the largest predators which do not experience any predation mortality
 (Andersen and Pedersen, 2010). The peaks of the oscillating pattern are roughly spaced by the
 274 preferred PPMR. Biomass density within species is constant until individuals reach the end of the
 resource spectrum, and larger individuals, $\gtrsim 0.1$ g, have a biomass spectrum slope flatter than
 276 that of the community spectrum (Fig. 3). Thus, in contrast to EQT, the dynamic model produces
 species size-spectra that cannot be described as power laws. The number of small individuals
 278 is inversely related to size at maturation. The scaling of offspring abundance can be calculated
 using EQT as $N_0 \propto \int_{m_*}^{cm_*} \kappa(m'_*)dm'_* \propto m_*^{2n-q-2+a}$, which fits the simulated results well for $a = 1$
 280 (Fig. 3, inset).

The distribution of species biomass as a function m_* can be calculated from EQT as:

$$B(m_*) = \int_{m_*}^{cm_*} \int_{m_0}^M N(m, m'_*)mdm dm'_* \propto m_*^{n-q}. \quad (21)$$

282 As n and q are almost equal the biomass distribution $B(m_*)$ as a function of m_* is almost constant.
 This result is also borne out by the dynamical simulations (Fig. 4.a) with some variation due to
 284 uneven species distribution along the m_* axis: peaks occur in species diversity separated by the
 preferred PPMR β (Fig. 4.b).

286 [Figure 5 about here.]

4.3. PPMR and feeding level

288 The realised mean PPMR can be derived when prey concentrations are known: $\mathcal{N}(m_p)s(m_p, m)$
 is the prey size distribution encountered by a m sized predator. Mean prey size encountered by a
 290 m sized predator is $\frac{\int_0^\infty m_p \mathcal{N}(m_p)s(m_p, m)dm_p}{\int_0^\infty \mathcal{N}(m_p)s(m_p, m)dm_p}$. The realised mean PPMR is calculated as the predator
 size m divided by the mean prey size:

$$PPMR(m) = \frac{m \int_0^\infty \mathcal{N}(m_p)s(m_p, m)dm_p}{\int_0^\infty m_p \mathcal{N}(m_p)s(m_p, m)dm_p}. \quad (22)$$

292 Realised mean PPMR is always larger than the preferred PPMR β , due to higher abundance of
 smaller prey items (Fig. 5.a). The realised mean PPMR calculated from EQT (using $\mathcal{N} \propto m_p^{-\lambda}$)
 294 is $\exp[(\lambda - 3/2)\sigma^2]\beta \approx 1.7\beta$. Realised PPMR from the simulations oscillate around this value due
 to the fluctuations in the community spectrum (Fig. 3).

296 As individuals grow to a size larger than βm_0 they switch from eating food in the resource
 spectrum to feeding on other species. This leads to a decrease in the feeding level from $f_0 = 0.6$
 298 to about 0.45. The oscillations in feeding level increase in magnitude as body size increases due
 to larger fluctuations in prey availability (Fig. 5.b). Many large individuals periodically have a
 300 feeding level below the critical feeding level f_c (where starvation kicks in) since prey items in the

preferred size range become scarce, which results in ingestion of smaller food items and therefore
 302 increasing PPMR.

[Figure 6 about here.]

304 4.4. *Reproduction and survival*

Lifetime adult reproduction calculated from the simulated food webs fit the EQT prediction
 306 since it scales linearly with m_* (Fig. 6.b). The probability of surviving to a given size is independent
 of m_* , as the survival curves of the different m_* groups lie on top of one another (Fig. 6.a). Survival
 308 to m_* scales inversely with m_* (i.e. $a = 1$, crosses in Fig. 6.a), which ensures that R_0 is constant.
 However, if the $a = 1$ scaling of survival to m_* is extrapolated to m_0 it is seen that it does not
 310 intersect $p_{m_0 \rightarrow m_0} = 1$. Instead the survival curves change slope between m_0 and around 10^{-1} g
 where predation mortality starts to dominate due to an abundance of fish individuals in the same
 312 order of magnitude as the resource spectrum, which is intensified by reduced growth stemming
 from food competition (Fig. 3). In summary survival does not scale with m_*^{-a} as predicted by
 314 EQT. Instead adult survival scales with m_*^{-1} (i.e. $a = 1$) whereas individuals smaller than ≈ 0.1 g
 have a higher survival (i.e. a smaller scaling exponent).

316 5. Discussion

We have developed a generic food web framework suitable for analysing systems of interacting
 318 size-structured populations. The framework increases ecological realism compared to traditional
 unstructured food web models by explicitly resolving the whole life-history of individuals, but
 320 maintains simplicity by describing species with only one trait: maturation size m_* . Remaining
 parameters are made species-independent through inter- and intraspecies scaling with m_* and
 322 body mass m . The productivity of the system is characterised by one parameter, the initial
 feeding level f_0 . Feeding behaviour is assumed to be determined by a feeding kernel with a fixed
 324 preferred PPMR (big individuals eat small individuals), multiplied by a species-specific coupling
 strength.

326 Only characterising the life-history and feeding preference of individuals of a species by body
 mass m and trait m_* is clearly a simplification, but contemporary knowledge suggests that a large
 328 part of the individual bioenergetics related to growth (Peters, 1983) and reproduction (Blueweiss
 et al., 1978) indeed can be described by such scaling. Additionally it is well-known that predators
 330 often outsize their prey (Brose et al., 2006a) which justifies the use of the generalisation “big ones
 eat small ones”.

332 5.1. *Model architecture*

The model was parameterised from cross-species analyses of fish communities, since aquatic sys-
 334 tems constitute a group of strongly size-structured ecosystems. Other less strongly size-structured

taxa can be modelled as well through reparametrisation and by allowing each species to have
 336 its own offspring size $m_{0,i}$. Additionally, the description of how available energy energy is divided
 between growth and reproduction may have to be reformulated since animals in other taxa may ex-
 338 hibit determinate growth. Determinate growth can be modelled simply by replacing the allocation
 function (9) with only the part within the square brackets.

340 The proposed modelling framework is similar to physiologically structured models (Andersen
 and Ursin, 1977; Metz and Diekmann, 1986; de Roos and Persson, 2001), and as these based on
 342 mechanistic individual-level processes. Our contribution is to employ a trait-based description
 of species identity, and a formulation of food preference which is split into a size- and a species-
 344 based contribution, which renders the developed framework useful as a generic food web framework.
 Recently the PSPM approach has been reduced to a stage-structured model which facilitates multi-
 346 species studies (de Roos et al., 2008a); however this is achieved at the cost of collapsing continuous
 size-structure to a discrete stage-structure. A first step towards multi-species PSPMs was carried
 348 out with an intra-guild predation model, which showed that obtaining species coexistence between
 two size-structured populations is a difficult task (van de Wolfshaar et al., 2006); a result which is
 350 probably due to insufficient ecological differentiation of the two species. In the proposed framework
 the trait maturation size provides a simple and logical way of representing ecological differentiation
 352 of species, whereas this differentiation in PSPMs is less clear due to large species-specific parameter
 sets. Additional ecological differentiation and heterogeneity are obtained by also including food
 354 web structure in the form of species coupling strengths.

An alternative approach to model a size-structured community is the community size-spectrum
 356 models (Silvert and Platt, 1980; Benoît and Rochet, 2004). In these models the community is
 represented by a community size-spectrum of all individuals irrespective of species identity (Sheldon
 358 and Parsons, 1967). As with the physiologically structured models these are based on individual-
 level descriptions of life-history. The community spectrum approach has the drawback that species
 360 are not resolved, as all individuals are lumped together into one spectrum. Their advantage is their
 ability to make community-wide predictions with simple means (Blanchard et al., 2009) similarly
 362 to the mean-field theory in unstructured food webs (McKane et al., 2000; Wilson et al., 2003).

A central element in the model is the division of energy between somatic growth and repro-
 364 duction through the allocation function $\psi(m, m_*)$. As in PSPMs our bioenergetic model is a
 net-production model where it is assumed that metabolic costs are covered with highest priority
 366 after which the remaining energy can be used for growth and reproduction. PSPMs are formu-
 lated either with one state variable: individual body weight (Kooijman and Metz, 1984; Claessen
 368 and de Roos, 2003), or with two state variables: somatic weight and reserve weight (de Roos and
 Persson, 2001). In the latter case energy is divided between the two states such that the ratio
 370 between the two state variables is aimed to be constant, and accumulated reserves are used for
 reproduction at the end of the growing season. In the case with only one state variable surplus
 372 energy is divided between somatic growth and reproduction with a fixed ratio (κ -rule). When us-

ing the κ -rule the maximum asymptotic size any species individual can obtain is M_+ where intake
 374 $\alpha h f(M_+) M_+^n$ equals the metabolic costs $k M_+^p$ – meaning that all species would obtain the same
 asymptotic size if parameters are species independent as in our formulation. M_+ is very sensitive
 376 to the precise values of n and p , and they can therefore only be regarded as poor determinators for
 asymptotic size (Andersen et al., 2008). Our model deviates from the single-state PSPMs in this
 378 partitioning of energy, as we assume that mature individuals allocate an amount proportional to
 their body size for reproduction (Blueweiss et al., 1978), and that asymptotic size depends on the
 380 trait size at maturation (Beverton, 1992; Froese and Binohlan, 2000; He and Stewart, 2001). This
 ensures that the ratio between gonad size and somatic weight is constant within a species, which
 382 is similar to the partitioning rule used in two-state PSPMs. The allocation function is derived
 under the assumption of a constant feeding level throughout adult life. Even though the feeding
 384 level is assumed constant, the actual allocation still vary depending on the actual food availabil-
 ity, as $\psi(m, m_*)$ only determines the fraction of available energy allocated to reproduction. An
 386 alternative way to derive $\psi(m, m_*)$ is to let it depend on actual feeding levels. This assumption,
 however, would imply that individuals adjust their allocation to reproduction such that asymptotic
 388 size is always reached. This does not seem plausible as individuals in resource scarce environments
 probably obtain smaller maximum sizes, and therefore we find the most reasonable assumption to
 390 be that of a constant feeding level. The exponents n and p are close to equal in nature, and for
 $n = p$ the energy allocation function leads to biphasic growth where adults follow von Bertalanffy
 392 growth curves (Lester et al., 2004). We fixed the yearly mass-specific allocation to reproduction
 (yearly gonado-somatic index, GSI) to be independent of individual body size within a species. The
 394 obtained form of $\psi(m, m_*)$, however, yields a m_*^{n-1} scaling of yearly GSI across species, which is
 consistent with empiric evidence (Gunderson, 1997). This means that the form of $\psi(m, m_*)$ implies
 396 a trade-off between m_* and the mass-specific reproduction: large m_* species can escape predation
 mortality via growth by paying the price of a lower mass-specific reproduction (Charnov et al.,
 398 2001). When the exponents n and p differ, growth will still be biphasic and adult growth curves
 will be similar to von Bertalanffy curves (see also Andersen and Pedersen, 2010). In conclusion
 400 the derived allocation rule leads to realistic growth patterns.

5.2. Food web structure

402 Food web structure is the most essential part of a food web model, and in principle two ap-
 proaches can be taken to obtain a structure for a dynamic food web model: a top-down and a
 404 bottom-up approach.

The top-down method generates food web matrices from the desired number of species and
 406 connectance using a static model (stochastic phenomenological models: Cohen and Newman (1985);
 Williams and Martinez (2000); Cattin et al. (2004); Allesina et al. (2008), or more mechanistic
 408 approaches involving phylogenetic correlations (Rossberg et al., 2006) or foraging theory (Petchey
 et al., 2008)). Next, the food web matrix is used to drive a dynamic model, which is simulated

410 forward in time where some of the initial species will go extinct, and the remaining species set can
be used for analysis. Note that in addition to a decreased species richness in the final community
412 other food web statistics as e.g. the final connectance may differ as well (Uchida and Drossel, 2007).

In the bottom-up approach link strengths are determined from ecological relations, such as
414 e.g. a predator-prey feeding kernel: if the prey fits into a certain size range relative to the predator
size, then interaction occurs between the nodes with a strength determined by the feeding kernel
416 (Loeuille and Loreau, 2005; Virgo et al., 2006; Lewis and Law, 2007). Predator preferences de-
pend, in addition to ecological characters, on evolutionary history and recent approaches add this
418 component of phylogenetic correlations (Rossberg et al., 2008).

For size-structured food webs a top-down algorithm for generating realistic food web matrices
420 does not exist. This is due to lack of data describing the three dimensional interaction matrix
– dimension one and two is respectively predator and prey identity as in the classic interaction
422 matrix, and the third dimension is predator/prey body size. Thus one is confined to the bottom-up
approach and/or random interaction matrices. In this study we use the bottom-up approach to
424 prescribe interactions to obey the pattern of “big ones eat smaller ones”. Life-history omnivory
(Pimm and Rice, 1987) is therefore naturally incorporated in size-structured food webs through
426 the use of a feeding kernel. To obtain an ensemble of different communities we use the top-
down approach of a classical two-dimensional predator-prey interaction matrix – that is we assume
428 that regardless of size individuals within a species have equal potential maximum link strength
(coupling strengths in our model) to another species. As no top-down method exists for generating
430 this matrix we use random matrices. The actual link strength is the product of the coupling
strength and the feeding kernel, meaning that link strengths indeed are dynamic as they depend
432 on the size-structure of both prey and predator.

As we generate food webs from a fixed initial pool of only 30 species and use a random matrix
434 as coupling matrix we only obtain small food webs (maximum: 9 species). However, it should be
noted that the number of resource species the resource spectrum represents is not included. To
436 obtain larger food webs a larger species pool is needed along with a sequential assembly algorithm
(Post and Pimm, 1983), and a better method for obtaining coupling strengths between species.
438 Our primary interest in the food web analyses has been the size- and trait-structure of food webs
with a finite number of species, and how these compare with EQT predictions, which are based
440 on the premise of a continuum of species. The general correspondence with EQT indicates that
the broad-scale patterns are relatively insensitive to how the species-specific coupling strengths
442 (i.e. food web structure) are specified. Still, an interesting follow-up study would be focused on
the coupling matrix structure, which may more generally be size-dependent, and how the effective
444 food web structure that emerges from the coupling strengths and feeding kernel compares with
empiric food webs.

446 5.3. Community structure

We generated an ensemble of size-structured food webs and used averages over these to make
 448 general predictions of the structure of fish communities, in particular the size-structure of individual
 populations, and how these spectra “stack” to form the community size-spectrum. In accordance
 450 with EQT we find the community spectrum to scale with $\lambda = 2 + q - n \approx 2$ meaning that the
 distribution of biomass as a function of individual body size is close to constant when individuals are
 452 sorted into logarithmically evenly sized bins. This prediction means that the biomass of individuals
 between e.g. 1 g and 10 g is the same as those present with body sizes between 1 kg and 10 kg, in
 454 accordance with the Sheldon hypothesis (Sheldon et al., 1972).

The distribution of biomass as a function of m_* is predicted to be almost independent of
 456 m_* in accordance with EQT. The result is reminiscent of the Sheldon hypothesis, and it can be
 formulated as an extension of the Sheldon hypothesis: “*The total biomass of individuals ordered*
 458 *in logarithmically spaced groups of their maturation size is approximately constant*”. This means
 that the total biomass of all species with m_* between 1 and 10 g is approximately the same as
 460 that of species with m_* within 1 to 10 kg. This prediction is a novel extension and could be tested
 by size-based field data. In contrast to EQT the dynamic framework also provides predictions on
 462 the distribution of the number of species as a function of m_* . Species tend to cluster in groups on
 the m_* axis separated by a distance corresponding to the preferred PPMR β . This clustering is
 464 partly a reflection of the use of a fixed value of β ; more diversity in feeding strategies (i.e. different
 β) would probably smoothen the species distribution as well as making the feeding level more
 466 constant.

The size-spectra of individual species do not to follow power laws as predicted by EQT since
 468 there is a change in spectrum slopes from small to medium sized individuals. This difference stems
 from different scaling relationships for the survival probability of small and larger individuals. The
 470 less steep slope in survival for small individuals is due to a proportionally low mortality rate caused
 by their low abundance relative to similarly sized resource items. Incorporating mortality from
 472 the resource spectrum on the smallest individuals may thus result in a single survival probability
 scaling. The probability of surviving to m_* scale as m_*^{-a} for a physiological predation constant
 474 value of $a = 1$, which is conflicting with the value $a = 0.86$ predicted by EQT. The discrepancy
 about the value of a highlights an inconsistency within EQT: Enforcement of mass-balance between
 476 growth and predation leads to $a = 0.86$, while the reproductive boundary condition can only be
 fulfilled if $a = 1$. The full food web simulations demonstrate that both the scaling of surviving to
 478 m_* and the scaling of the number of offspring are best predicted by a value of $a = 1$. This indicates
 that when EQT predictions depend on a , the value $a = 1$ should be used even though that breaks
 480 mass conservation in EQT.

Lastly we demonstrate that realised PPMRs (i.e. PPMRs based on ingested prey) emerge in
 482 the model. Average realised PPMR is always larger than the preferred PPMR β since smaller prey
 items are more abundant than larger ones. It is found that the realised PPMR is proportional

484 to the preferred ratio ($PPMR = 1.7\beta$). Model predictions show that realised PPMR oscillates
 486 around this value due to fluctuations in the average community spectrum. PPMR displays large
 488 fluctuations with size demonstrating that determination of PPMR from single measurements is
 490 problematic due to high prey abundance sensitivity. Empirical findings show that realised PPMRs
 492 increase with body size (Barnes et al., 2010), but one should be careful about concluding that the
 preferred PPMR (which we put into models) shares this size scaling, since relative abundances
 may cause the increase rather than actual behavioural prey preferences: even though we have a
 fixed preferred PPMR our model predicts that realised PPMR is an increasing function of body
 size.

5.4. Conclusion and outlook

494 The proposed food web framework increases ecological realism in food web models as it resolves
 the complete life-history of individuals by representing the size-structure of each species with a size-
 496 spectrum. More specifically the framework complies with five requirements of (cf. Introduction):
 1) being generic with few parameters, 2) being mechanistic and utilising individual-level processes,
 498 3) including food dependent growth, 4) being practically solvable for species-rich communities, and
 5) complying with data on community structure and individual growth curves.

500 Trait-based size-structured food webs can be examined at four levels of organisation: at com-
 munity level, at species level, at trait level, and at the individual level. We generated empirically
 502 testable hypotheses of mainly biomass distributions at different levels of organisation.

By assuming a power law community spectrum and a constant feeding level the full dynamic
 504 model can be simplified to an EQT model (Andersen and Beyer, 2006). Correspondence of pre-
 dictions by EQT and the full model justifies the use of the simplifying assumptions. EQT is a
 506 powerful analytical tool that in a simple manner yields insight to e.g. the biomass distributions
 within and across species in size-structured food webs. However, as EQT assumes steady-state,
 508 the study of emerging effects, e.g. diversity and responses to perturbations, has to be conducted
 with the full model.

510 The PSPM framework has showed existence of alternative stable states where single populations
 can exist with different size-structure compositions (de Roos and Persson, 2002; Persson et al.,
 512 2007; de Roos et al., 2008b). It is an open question whether such alternative states become more
 widespread or if they disappear when more species interact with each other. This question is
 514 important since it tells whether such alternative states are expected to occur frequently or rarely
 in nature, and consequently whether exploitation can easily induce shifts between states. An
 516 important future challenge is thus to study the possibilities of multiple states in complex food
 webs – not only of single individual populations, but of the ecosystem as a whole. The proposed
 518 framework allows exactly this kind of studies since it provides a full ecologically realistic but
 conceptually simple model of size-structured ecosystems.

520 Natural future extensions of the model could be to allow the species coupling strengths to

be size-dependent and make coupling strengths depend on vulnerability and forageability of prey
522 and predators (Rossberg et al., 2008) as well as on the spatial overlaps of the interacting species.
Adding this extra level of mechanistic realism would allow the framework to be useful for studying
524 ecosystem consequences of spatial changes of species populations, which could be driven by climatic
changes.

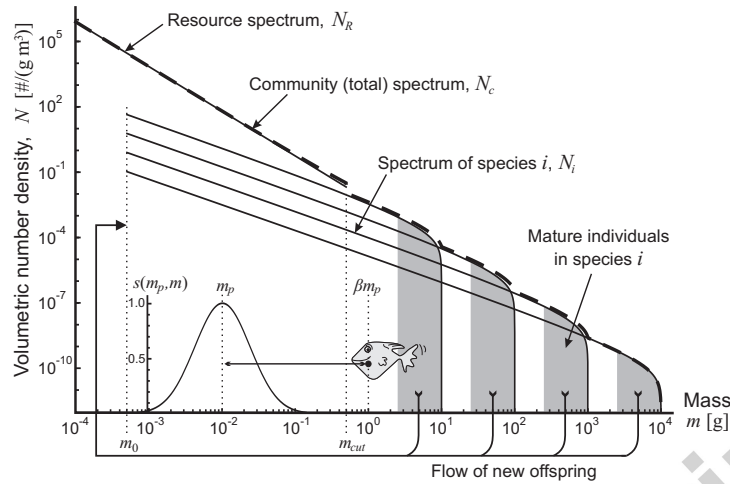

Figure 1: Illustration of the community model: resource spectrum (with cut-off m_{cut}) and four species size-spectra ($m_* = 2.5, 25, 250,$ and 2500 g) having off-spring of size m_0 . Shaded regions mark the spawning stock from maturation size m_* to maximum asymptotic size M . The sum of all spectra gives the community spectrum. The spectra shown are the steady-state solutions from Andersen and Beyer (2006). Inset shows how individuals feed on smaller prey using a feeding kernel with a preferred PPMR of β .

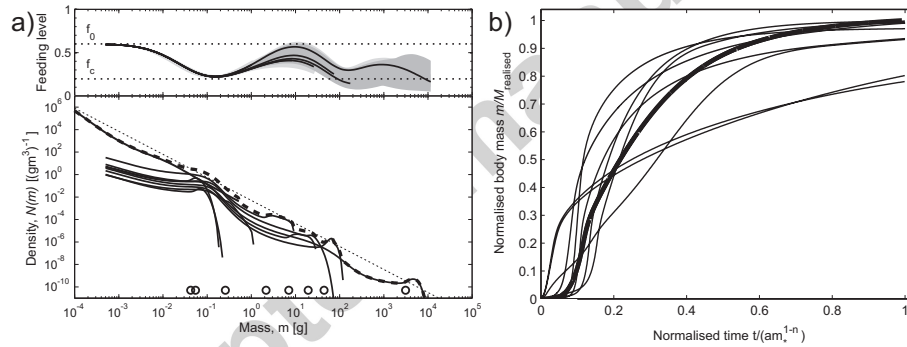

Figure 2: Example of an eight species cyclic state. a) Top: Feeding levels of the species along with the min/max (light grey) and the 25%/75% (dark grey) percentile values of the time-series. Dashed lines indicate initial f_0 and critical f_c feeding level. Bottom: The time-average of the resource and species spectra along with the community spectra (thick dashed). The idealised community spectrum $\kappa_c m^{-\lambda}$ (thin dashed) and the species maturation sizes m_* (circles). b) Time averaged growth curves for the species (thin lines) along with the biphasic growth curve (8) for a fixed feeding level that equals 75% of the time and size averaged feeding level experienced by the species (thick line). Growth curves are normalised with realised asymptotic size (y -axis) and generation time (x -axis) to enable comparison.

Figure 3: Mean species biomass spectra (grey lines) when species are divided into 5 logarithmic evenly distributed m_* groups. Also shown is the total mean community biomass spectrum (thick line), and the EQT community biomass spectrum $\kappa_c m^{1-\lambda}$ (dashed). Inset shows how offspring abundance (N_0) scales with m_* (data pooled in 25 log groups). Expected EQT scaling of N_0 is shown for $a = 0.86$ (dashed) and $a = 1$ (solid).

Figure 4: a) Distribution of biomass in different m_* groups. The expected distribution $B(m_*) \propto m_*^{n-q}$ is illustrated with the solid line. Dashed line shows biomass per species (bar values divided with bar values in b)). b) Mean no of species as a function of m_* . Species are pooled into 16 logarithmic groups.

Figure 5: a) Realised PPMR from each food web (grey), mean realised PPMR across all simulations (thick black), realised PPMR prediction from equilibrium theory (thin black), and preferred PPMR β (thin dashed). b) Feeding level from each species (grey), and mean feeding level (thick black).

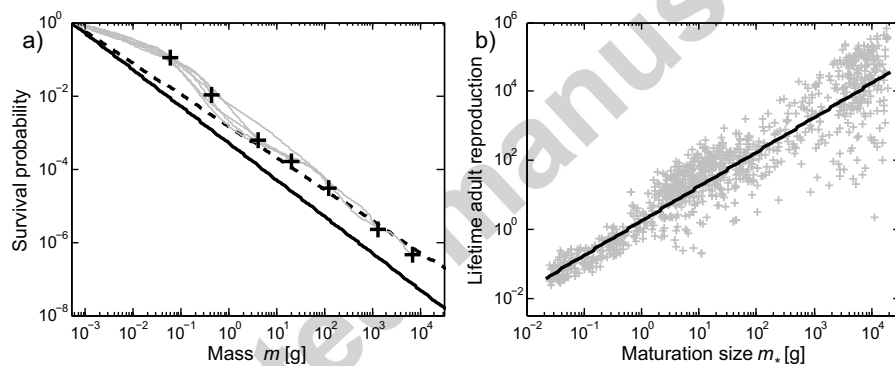

Figure 6: The components of the expected lifetime reproductive output. a) Probability of surviving to maturation size m_* (crosses) along with survival curves throughout life (grey line) for data pooled into 7 logarithmic groups. Expected $p \propto m_*^{-a}$ scaling from EQT is shown for $a = 0.86$ (dashed) and $a = 1$ (solid). b) Lifetime adult reproduction for all species (crosses) along with EQT $R_{\text{adult}} \propto m_*$ expectation (line).

Table 1: Default parameter values for a temperature of 10°C (Appendix E).

Symbol	Value	Units	Parameter
Individual growth			
f_0	0.6	-	Initial feeding level
α	0.6	-	Assimilation efficiency
h	85	g^{1-n}/year	Maximum food intake
n	0.75	-	Exponent for max. food intake
k	10	g^{1-p}/year	Std. metabolism and activity
p	0.75	-	Exponent of std. metabolism
β	100	-	Preferred PPMR
σ	1	-	Width of feeding kernel
q	0.8	-	Exponent for search volume
Reproduction			
m_0	0.5	mg	Offspring mass
η_*	0.25	-	m_* rel. to asymptotic mass M
ϵ	0.1	-	Efficiency of offspring production
u	10	-	Width of maturation transition
Mortality			
ξ	0.1	-	Fraction of energy reserves
μ_0	0.84	g^{1-n}/year	Background mortality
Resource spectrum			
κ	$5 \cdot 10^{-3}$	$g^{\lambda-1}/m^3$	Magnitude of resource spectrum
λ	$2 - n + q$	-	Slope of resource spectrum
r_0	4	g^{1-p}/year	Regeneration rate of resources
m_{cut}	0.5	g	Upper limit of resource spectrum

670 *Appendix should be available as online material.*

Appendix A. Derivation of predation mortality

672 Predators with a size between m and $m + dm$ have a food intake rate of $s(m_p, m)f(m)hm^n\theta N(m)dm$
for m_p sized prey. The total density of food available from all prey sizes to the predators in $[m; m + dm]$
674 is $\phi(m)$ (5), meaning that the mortality experienced by a m_p sized individual is:

$$\mu_{p,i}(m_p) = \sum_j \int \frac{s(m_p, m)f_j(m)hm^n\theta_{j,i}N_j(m)}{\phi_j(m)} dm. \quad (\text{A.1})$$

The maximum food intake may be expressed as a function of $f(m)$, $v(m)$, and $\phi(m)$ via (6), such that
676 the predation mortality can be written as:

$$\mu_{p,i}(m_p) = \sum_j \int s(m_p, m)(1 - f_j(m))v(m)\theta_{j,i}N_j(m) dm. \quad (\text{A.2})$$

By using the EQT assumptions of constant feeding level and a power law community spectrum (cf.
678 section 3) the mortality reduces to $\mu_p(m_p) = \bar{\theta}(1 - \bar{f}) \int s(m_p, m)v(m)\kappa_c m^{-\lambda} dm$, which can be solved
analytically:

$$\mu_p(m_p) = \alpha_p m_p^{n-1}, \quad (\text{A.3})$$

680 where $\alpha_p = \bar{\theta}(1 - \bar{f})\sqrt{2\pi}\kappa_c\gamma\sigma\beta^{1+q-\lambda} \exp\left[\frac{1}{2}\sigma^2(1+q-\lambda)^2\right]$.

Appendix B. Available food and the physiological level of predation a

682 Using the EQT assumption of a power law community spectrum allows calculation of the available
food density $\phi(m) = \bar{\theta} \int s(m_p, m)\kappa_c m_p^{-\lambda} m_p dm_p$:

$$\phi(m) = \alpha_\phi \bar{\theta} \kappa_c m^{2-\lambda}, \quad (\text{B.1})$$

684 where $\alpha_\phi = \sqrt{2\pi}\sigma\beta^{\lambda-2} \exp\left[\frac{1}{2}\sigma^2(2-\lambda)^2\right]$.

Using the EQT assumption of constant feeding level yielding $\lambda = 2 + q - n$ allows us to write $\bar{\theta}\kappa_c =$
686 $\bar{f}h/(\alpha_\phi\gamma(1 - \bar{f}))$ by rearranging the expression of the feeding level (6). Using this and the definition
of \hbar allows writing $\alpha_p = c(\hbar + k)\beta^{2n-q-1}/\alpha$ where $c = \exp\left[\frac{1}{2}\sigma^2((1+q-\lambda)^2 - (2-\lambda)^2)\right] = 1.03 \approx 1$.
688 Ultimately using the definition of f_c allows writing the physiological level of predation $a = \alpha_p/\hbar$ as:

$$a = c \frac{\bar{f}}{\bar{f} - f_c} \beta^{2n-q-1} / \alpha. \quad (\text{B.2})$$

Appendix C. Calculating efficiency ϵ of offspring production

690 The efficiency of turning energy into offspring is denoted ϵ . It includes losses due to behavioural aspects,
pre-hatching mortality, and that the energy contents in gonadic tissue is higher than in somatic tissue. It
692 is a quantity that is difficult to measure, but for $n = p$ its value can be derived.

The energy (in units of mass) routed into reproduction (for $n = p$) is $\psi(m, m_*)\hbar m^n$ where $\hbar = \alpha\bar{f}h - k$.
694 The energy of the produced offspring is then, $E_o(m) = \epsilon\psi(m, m_*)\hbar m^n$:

$$E_o(m) = \epsilon\hbar\eta_*^{1-n}m_*^{n-1}m. \quad (\text{C.1})$$

From Gunderson (1997) we have the yearly mass-specific allocation to reproduction:

$$\varrho(m_*) = \varrho_0 \eta_*^{1-n} m_*^{n-1}, \quad (\text{C.2})$$

696 where $\varrho_0 = 1.2 \text{ g}^{1-n}/\text{year}$ is obtained using least sum of squares in fitting the curve to the data for
oviparous fish in Gunderson (1997). Equalling (C.2) and E_o/m allow us to determine the efficiency of
698 offspring production ϵ :

$$\epsilon = \frac{\varrho_0}{h} \approx 0.12. \quad (\text{C.3})$$

Appendix D. Setting the search rate prefactor γ from initial feeding level f_0

700 Food for the smallest individuals in the spectra will be supplied by the background spectrum. If we
assume that the resource spectrum is at carrying capacity κ then an equilibrium initial feeding level f_0 for
702 the small individuals can be calculated using (6).

Alternatively we may specify an initial feeding level f_0 and derive one other parameter. By solving
704 the feeding level for γ by using the analytical solution for the density of food $\phi(m)$ (B.1) we find γ as a
function of f_0 :

$$\gamma = \frac{f_0 h}{(1-f_0)\alpha_\phi \theta_{i,R} \kappa} \approx \frac{f_0 h \beta^{2-\lambda}}{(1-f_0)\sqrt{2\pi} \sigma \theta_{i,R} \kappa}. \quad (\text{D.1})$$

706 Appendix E. Parameter estimation

Individual growth: From Kitchell and Stewart (1977) we obtain an estimate of specific dynamic action
708 on 15 % of food consumption, and conservative estimates of egestion and excretion on 15 % and 10 %
respectively. This results in an assimilation efficiency of $\alpha = 0.6$.

710 The maximum intake scales with a 0.6–0.8 exponent, with $n = 0.75$ being an approximate average
value (Jobling, 1994). Andersen and Riis-Vestergaard (2004) provides a length-based relationship for the
712 maximum intake rate based on a whiting study adopted for saithe. Using $m = 0.01l^3$ (m in g and l in cm)
(Peters, 1983), and an energy content of 5.8 kJ/g (fish) or 4.2 kJ/g (invertebrates) (Boudreau and Dickie,
714 1992) yields a prefactor h for the maximal food intake on $83 \text{ g}^{1-n}/\text{year}$ or $114 \text{ g}^{1-n}/\text{year}$ (at 10°C). These
intake values overestimate the intake of large individuals since Andersen and Riis-Vestergaard (2004) use
716 an intake exponent of 0.67 instead of $n = 0.75$. Due to this a value of $h = 85 \text{ g}^{1-n}/\text{year}$ is selected, which
also provides reasonable fits to 'cod-like' growth curves ($m_* = 5 \text{ kg}$).

718 The standard metabolism scaling exponent p for fish is slightly higher than for other taxa, around
0.8 from intra- and interspecies measurements (Winberg, 1956; Killen et al., 2007). For simplicity we
720 assume $p = n$. The first term (acquired energy) in the growth model (8) is $\alpha f(m) h m^n$ where the feeding
level $f(m)$ is a decreasing function of body size (see *Results*). This has the effect that even when $n = p$ is
722 assumed the acquired energy term still effectively scale with a smaller exponent than the maintenance term
 $k m^p$ in accordance with the experimental data on food intake and standard metabolism. Furthermore it
724 is noted that this clearly makes the individuals in each functional species non-neutral. The bioenergetic
consequences of $n \neq p$ has been explored in detail by Andersen et al. (2008).

726 The prefactor for standard metabolism can from Peters (1983) be determined to $6.5 \text{ g}^{1-n}/\text{year}$ if the
diet is composed of only invertebrates and $4.7 \text{ g}^{1-n}/\text{year}$ if all the energy is from fish. Both values were
728 corrected to 10°C using $Q_{10} = 1.83$ (Clarke and Johnston, 1999). It is assumed that energy costs due

to activity can be described with an activity multiplier on the standard metabolic rate. Estimations of
 730 activity costs are difficult to obtain, but activity multipliers are often reported in the range 1 to 3; e.g. 1.25
 for North Sea cod (Hansson et al., 1996), 1.7 for dace (Trudel and Boisclair, 1996), and 1.44-3.27 for saithe
 732 (Andersen and Riis-Vestergaard, 2004) (however see also Rowan and Rasmussen (1996); He and Stewart
 (1997)). A reasonable value of the prefactor for the standard metabolism and activity costs is assumed to
 734 be $k = 10 \text{ g}^{1-n}/\text{year}$ corresponding to an activity multiplier in the range 1.5 to 2.1.

Food encounter: The preferred predator-prey mass ratio is set to $\beta = 100$ (Jennings et al., 2002)
 736 and the width of the selection function to $\sigma = 1$, which catches the general picture for at least cod and
 dab (Ursin, 1973). It should be noted that small organisms such as copepods have a larger σ of 3–4.5
 738 (Ursin, 1974), but for simplicity and since focus is on species with rather large m_* the width σ will be held
 constant.

The exponent for swimming speed is $q = 0.8$ (Andersen and Beyer, 2006). The prefactor γ for the
 volumetric search rate is difficult to assess from the literature. An alternative approach is to determine it
 742 as a function of initial feeding level f_0 via (D.1). Experience with the model shows that feeding level is
 a decreasing function of body size. This means that it is sensible to use an initial feeding level f_0 that is
 744 larger than the expected average feeding level \bar{f} . In this study a default value of $f_0 = 0.6$ is used. This
 along with default parameters yields $\gamma = 0.8 \cdot 10^4 \text{ m}^3 \text{ g}^{-q}/\text{year}$ (Table 1). An alternative estimate of γ
 746 is possible by multiplying the prefactors for swimming speed (Ware, 1978) and swept reactive field area
 (reactive radius assumed equal to body length): $\gamma = 20.3 \cdot \pi \cdot 0.01^{-2/3} \text{ cm}^3 \text{ g}^{-q}/\text{s} \approx 4.3 \cdot 10^4 \text{ m}^3 \text{ g}^{-q}/\text{year}$,
 748 which indeed justifies the use of $f_0 = 0.6$.

Mortality: Realistic energy reserve sizes may be $\xi \in [5\%; 20\%]$, and in the present study $\xi = 0.1$ is
 750 used. A widely used background mortality for 'cod-like' $m_* = 5 \text{ kg}$ fishes is $\mu_b = 0.1 \text{ year}^{-1}$, which yields
 $\mu_0 = 0.84 \text{ g}^{1-n}/\text{year}$.

Reproduction: The efficiency of offspring production was not found in the literature. However, an
 analytical expression may be obtained (for $n = p$) by combining the calculation of yearly mass-specific
 754 allocation to reproduction from the bioenergetic model (Appendix C) with empirical measurements (Gun-
 derson, 1997), which yields $\epsilon = \rho_0/\bar{h} \approx 0.1$. The fraction of asymptotic size to mature at is $\eta_* = 0.25$
 756 (Andersen et al., 2008). Offspring mass is $m_0 = 0.5 \text{ mg}$ which corresponds to an egg diameter of 1 mm
 (Wootton, 1979; Chambers, 1997).

Resource spectrum: The carrying capacity of the resource spectrum should equal the magnitude of the
 community spectrum: $\kappa m^{-\lambda}$, with an exponent $\lambda = 2 - n + q = 2.05$ (Andersen and Beyer, 2006). The
 760 magnitude of the resource spectrum is set to $\kappa = 5 \cdot 10^{-3} \text{ g}^{\lambda-1}/\text{m}^3$, which is comparable with findings
 from empirical studies (Rodriguez and Mullin, 1986). The constant for resource regeneration rate is $r_0 = 4$
 762 $\text{g}^{1-p}/\text{year}$ at 10°C (Savage et al., 2004). The cut-off of the resource spectrum is set to include mesoplankton,
 $m_{cut} = 0.5 \text{ g}$.

764 Appendix F. Expected Lifetime Reproductive Success

The expected lifetime reproductive success can be split into two components: 1) the probability of
 766 surviving to become adult, and 2) lifetime reproduction per adult.

Appendix F.1. Survival probability

768 If we set $\frac{\partial N}{\partial t} = 0$ in (1) we may obtain the steady-state solution as:

$$N(m) = \frac{K(m_*)}{g(m, m_*)} \exp\left(-\int \frac{\mu(m)}{g(m, m_*)} dm\right), \quad (\text{F.1})$$

where $K(m_*)$ is the constant from the integration along m . We notice that the probability of surviving
770 from size m_0 to size m is $p_{m_0 \rightarrow m} = \exp\left(-\int_{m_0}^m \frac{\mu(m')}{g(m', m_*)} dm'\right)$, which along with $p_{m_0 \rightarrow m_0} = 1$ allow us to write the survival probability as:

$$p_{m_0 \rightarrow m} = \frac{N(m)g(m, m_*)}{N(m_0)g(m_0, m_*)}. \quad (\text{F.2})$$

772 Appendix F.2. Lifetime adult reproduction

The amount of energy an adult belonging to a m_* population will spend on reproduction throughout
774 its life is:

$$R_{life}(m_*) = \int_{t_*}^{\infty} p_{t_* \rightarrow t} \psi(m, m_*) E(m) dt,$$

where t_* is maturation age, and $\psi(m, m_*) E_i(m)$ the rate at which energy is allocated to reproduction.

776 Noting that $g(m, m_*) = \frac{dm}{dt}$ allows us to write this as:

$$R_{life}(m_*) = \int_{m_*}^M p_{m_* \rightarrow m} \frac{\psi(m, m_*) E(m)}{g(m, m_*)} dm. \quad (\text{F.3})$$

Appendix G. Details of Numerical Methods

778 The model is in the form of a series of coupled partial-integro-differential equations (1), one for each species with the size preference function (4) being the integral kernel. The equations are of the first order
780 in mass (i.e. hyperbolic) in which case shocks could be formed in the solutions. However the integral kernel smooths out any discontinuities and the equations can be solved effectively and accurately using a standard
782 semi-implicit upwind finite-difference scheme for solving PDEs (Press et al., 1992). The McKendrick-von Foerster PDE (1) is discretised by calculating $g(m, m_*)$ and $\mu(m)$ explicitly and making the time update
784 implicit, to yield:

$$\frac{N_w^{i+1} - N_w^i}{\Delta t} + \frac{g_w^i N_w^{i+1} - g_{w-1}^i N_{w-1}^{i+1}}{\Delta m_w} = -\mu_w^i N_w^{i+1}, \quad (\text{G.1})$$

where i denotes the time step, and w the grid index on the mass axis ($i, w \in \mathbb{N}^+$). First order approximations
786 have been used for both the time and mass derivatives. The discretisation in mass is known as the upwind approximation since the derivative is calculated from w and $w - 1$, which is possible since the growth
788 function is non-negative. It is further noted that the ∂m approximation is semi-implicit since densities at time step $i + 1$ are used. Equation (G.1) may be written as:

$$N_{w-1}^{i+1} \underbrace{\left(-\frac{\Delta t}{\Delta w_w} g_{w-1}^i\right)}_{A_w} + N_w^{i+1} \underbrace{\left(1 + \frac{\Delta t}{\Delta w_w} g_w^i + \Delta t \mu_w^i\right)}_{B_w} = \underbrace{N_w^i}_{C_w}, \quad (\text{G.2})$$

790 which allows us to write an explicit solution for the density spectrum at the $i + 1$ time step:

$$N_w^{i+1} = \frac{C_w - A_w N_{w-1}^{i+1}}{B_w}, \quad (\text{G.3})$$

which can be solved iteratively since N_1^{i+1} is given by the boundary condition. The flux in the boundary
792 $g(m_0, m_*) N(m_0, t)$ is equal to the reproduction flux of new recruits R (11) such that $g_0^i N_0^{i+1} = R$, which yields: $A_1 = 0$, and $C_1 = N_1^i + \frac{\Delta t}{\Delta m_1} R$.

794 This semi-implicit upwind scheme is very stable but diffusive. The third order QUICK (Quadratic
 Upwind Interpolation for Convective Kinematics) scheme along with the techniques by Zijlema (1996),
 796 which prevents overshooting problems introduced by the QUICK method, were used to check that numerical
 diffusion poses no problem for $\Delta t = 0.02$ years, and a m_w mass grid with 200 logarithmically evenly
 798 distributed points. To ensure stability the Courant condition (i.e. Press et al. (1992)):

$$\frac{|g_w^i| \Delta t}{\Delta m_w} \leq 1, \quad (\text{G.4})$$

is prudent to fulfill. The essence of the criterion is that Δt should be small enough not to allow individuals
 800 to skip any mass cells m_w during their growth trajectory.

The grid m_w spans the offspring size m_0 to 85 kg to include maturation sizes up to the order of 20 kg.
 802 The grid for the background spectrum ends at m_{cut} , and the lower limit should be low enough to ensure
 food items for the smallest individuals in the functional species, i.e. 3 decades lower than m_0 . Identical
 804 Δm_w is used for the background and species spectra to ease computations in the overlap $[m_0; m_{cut}]$.

To save computational time the ODEs for the background spectrum (15) are solved analytically. The
 806 solution at time $t_0 + \Delta t$ for the semi-chemostatic equation is:

$$N_R(m, t_0 + \Delta t) = K(m) - \left(K(m) - N_R(m, t_0) \right) e^{-[r_0 m^{p-1} + \mu_p(m)] \Delta t}, \quad (\text{G.5})$$

where $K(m) = \frac{r_0 m^{p-1} \kappa m^{-\lambda}}{r_0 m^{p-1} + \mu_p(m)}$ is the effective carrying capacity at resource size m .
