Abstract: The first objective of this study was to determine the bioaccumulation kinetics of pyrene in the soft tissues of *Crassostrea gigas* (mantle, muscle, gills, digestive gland, and the remaining soft tissues). As bivalves can biotransform hydrocarbons in more polar compounds (metabolites) that are more easily excreted, the second objective was to investigate the oyster capacity to metabolize pyrene into its metabolite, the 1-hydroxypyrene. To these ends, oysters were exposed 24h to waterborne <sup>14</sup>C-pyrene then placed in depuration conditions for 15d. Oysters efficiently bioaccumulated pyrene in their soft tissues and equilibrium was reached within the exposure time. The metabolite1-hydroxypyrene was also detected in oyster tissues but represented only 4 to 14% of the parent pyrene. At the end of the exposure period, the gills and the mantle showed the highest pyrene proportion of total soft tissue content, i.e. 47% and 26%, respectively. After 15d of depuration, the mantle contained 32% and 30% of the remaining pyrene and 1-hydroxypyrene, respectively. As *C. gigas* did not display a high capacity for metabolizing pyrene, it can be considered as a good bioindicator species to survey and monitor pyrene contamination in the coastal marine environment.

#### 1. Introduction

38

39 Polycyclic aromatic hydrocarbons (PAHs) are found in many common products, such as 40 petrol, fumes and household heating (e.g. using oil, gas or wood). Petroleum spills and 41 discharges, seepages, industrial and municipal wastewater, urban and suburban surface run-42 off, and atmospheric deposition contribute to aquatic contamination caused by PAHs (Eisler, 43 1987). During the last decades, many studies have monitored the inputs, fluxes and fate of 44 PAHs in the marine environment (Obana et al. 1983; Baumard et al. 1999). However, in order 45 to assess the state of the marine ecosystem, it is necessary to know the fraction of these 46 compounds which can be taken up by aquatic biota and their potential toxic effects (Escartin 47 and Porte, 1999). The quality of aquatic environments can be assess through the analysis of organisms 48 considered as indicators of pollution, such as oysters, mussels and other bivalve molluscs 49 50 (Pereira et al. 1992; Jaffé et al. 1995; Lauenstein, 1995; Beliaeff et al. 1997; Gunther et al. 51 1999). Indeed, because of their biological (e.g. capacity of bioaccumulation, resistance to 52 physico-chemical stresses) and ecological characteristics (e.g. worldwide distribution, 53 abundance of their populations), bivalves are among the best candidates to be bioindicator 54 species (Phillips, 1976; Farrington and Tripp, 1993). These organisms can bioaccumulate a 55 large variety of pollutants at levels higher than those present in the surrounding waters or 56 sediments, and their behaviour can be recorded in short periods of time (Baumard et al. 1998; 57 Solé et al. 2000). In this way, mussels have been extensively used worldwide as sentinel 58 organisms to monitor the uptake and accumulation of PAHs in the coastal environments, in 59 the Mussel Watch Program in the USA (O'Connor 1996, O'Connor and Lauenstein 2006), the 60 Coordinated Environmental Monitoring Program (OSPAR 2010) and the Réseau National de 61 la Contamination CHimique (ROCCH 2008) in France. In this last country, oysters are also

used as a sentinel species in the ROCCH monitoring program, which is particularly relevant in areas where mussels are absent. The exposure of marine organisms to PAHs has often been evaluated by measuring tissue contaminant contents (Varanasi et al. 1989). However, when considering biotransformation capacities of these organisms, this approach becomes less relevant. Indeed, biotransformation refers to the entire modification of chemical molecules occurring in the organisms. Metabolism of PAHs in marine invertebrates is apparently related to cytochrome P450 (EC 1.14.14.1). This enzyme converts parent hydrophobic and lipid-soluble PAHs, into water soluble metabolites. However, the mechanisms by which the involved enzymes are regulated are still poorly understood (Hahn, 1998). In marine mammals and birds, some studies have shown that the low concentrations of PAHs in their tissues were due to a combination of inefficient bioaccumulation from food and rapid metabolisation and excretion of accumulated PAHs (Watanabe et al. 1989; Fossi et al. 1995). In the common sole Solea solea affected by a strong PAH pollution, the liver produced metabolites that were released through the bile (Budzinski et al. 2004). Previously, it was believed that molluscs possessed a weak to nonexistent ability to metabolize PAHs (Lee et al. 1972a; Palmork and Solbakken, 1981). Conversely, molluscs may have relatively strong metabolisation systems (McElroy et al. 2000) and it has been shown that molluscs collected in strongly polluted environments contained often low concentrations of PAHs (e.g. Varanasi et al. 1989; Baumard, 1997). The Pacific oyster Crassostrea gigas (Thunberg, 1793) has a high economic value in the world and especially in France. Indeed, most of French oyster-farming raise this species which production averages up to 128 000 tonnes per year (CNC, 2004). Many farmhouses exist all along the French coastline and they are very sensitive to marine contamination, especially during oil slicks. It is therefore fundamental to better understand the mechanisms of bioaccumulation of PAHs in this species.

Various studies have shown that pyrene and other PAHs with four benzene rings are among the most predominant PAHs in bivalves (Obana et al. 1983; Varanasi et al. 1985; Wade et al. 1988; Kaag et al. 1997). Moreover, pyrene is considered as one of the 16 most toxic contaminants for the environment and the dominant PAHs in the marine environment (Giessing et al. 2003). Therefore, the first aim of this study was to follow the kinetics of uptake and depuration of pyrene in the organs and tissues of *C. gigas* exposed via seawater. In order to study environmentally realistic contaminant levels, the pyrene used was <sup>14</sup>C-labelled and measured using highly sensitive radiodetection technique. The second objective of this work was to determine the presence and the kinetics of formation of 1-hydroxypyrene, i.e. the pyrene metabolite previously demonstrated to be predominant in fish bile (e.g. Krahn et al. 1987; Ariese et al. 1993),

#### 2. Materials and methods

# 2.1. Biological material

- 101 Oysters were purchased from a shellfish farm on the French Atlantic coast (La Rochelle).
- Organisms were then transferred to the Environment Laboratories premises (IAEA, Monaco).
- Prior to the experimentation, specimens were acclimated to laboratory conditions for two
- months (constantly aerated open-circuit aquarium; salinity:  $36 \pm 1$  p.s.u.; temperature:  $19 \pm 1$
- °C; pH: 8; light/dark cycle: 12h/12h). During acclimation, bivalves were fed phytoplankton
- using the Prymnesiophyceae *Isochrysis galbana* (10<sup>4</sup> cells ml<sup>-1</sup>). Recorded mortality was
- lower than 5% over the acclimation period.

108109

#### 2.2. Radiotracer and radioanalyses

- The <sup>14</sup>C-labelled 4, 5, 9, 10 pyrene was purchased from Sigma, USA. Specific activity was
- 2.17 10<sup>9</sup> Bq mmol<sup>-1</sup>. Stock solutions were prepared in methanol and a final concentration of
- 112  $27 \mu g L^{-1}$  was used.

Two mL of the mixtures containing pyrene and 1-hydroxypyrene or purified pyrene samples (see below) were transferred to 20 mL glass scintillation vials (Packard) and mixed with 10 mL of scintillation liquid (Ultima Gold, Packard). <sup>14</sup>C-radioactivity was measured using a 1600 TR Liquid Scintillation Analyser (Packard). Activity was determined by comparison with standards of known activities and measurements were corrected for counting efficiency and quenching effect. Counting time was adjusted to obtain a propagated counting error less than 5%.

### 2.3. Experimental procedure

#### 122 2.3.1. Uptake phase

Forty four oysters were placed in a 50L glass aquarium containing natural seawater (closed circuit) spiked with  $^{14}$ C-labelled pyrene. The initial pyrene concentration in the aquarium was 0.27 µg L $^{-1}$ . This concentration matches with PAHs values found in strongly polluted areas (Axelman et al. 1999). Every 30 minutes, seawater radioactivity was measured and pyrene was added as required in order to keep its concentration constant during the whole accumulation phase (24 h). Oysters were not fed during the exposure period. Four animals were collected at different times (0, 2, 5, 9, 19 and 24h) in order to follow the uptake kinetics of  $^{14}$ C-pyrene and the formation of its metabolite. At the end of the exposure period (24h), seawater was sampled to detect whether metabolites could have been released by exposed animals. At each sampling time, oyster soft tissues were dissected into five compartments: mantle, gills, muscle, digestive gland and remaining tissues (i.e., labial palps, gonad and heart). Each organ and tissue was weighed and crushed. Then, samples were treated with 200  $\mu$ L of  $\beta$ -glucuronidase-aryl-sulfatase mixture containing 100 000 units mL $^{-1}$  of glucuronidase (Sigma) and 7500 units mL $^{-1}$  of sulfatase (Sigma) for enzymatic deconjugation. To this purpose, the

138 samples were buffered to pH 5 with 3 mL of 5 M potassium acetate buffer. They were then 139 placed in an oven at 37°C during 20 hours. 140 Pyrene and 1-hydroxypyrene were extracted via two subsequent liquid/liquid extractions. The 141 first extraction was performed by adding 5mL of a hexane/dichloromethane solution (50:50) 142 and the second extraction was performed by adding 4mL of a methanol/dichloromethane 143 solution (10:90) to extract pyrene and 1-hydroxypyrene, respectively. For both extractions, 144 the samples were mechanically shaken for 30 minutes and then centrifuged at 6000 rpm for 5 145 minutes. In the first extraction, the organic phase (5 mL) was recovered in a flat bottom flask. 146 Following the second extraction, the organic phase was recovered and combined with the first 147 one. Two mL of the extracted solution was radioanalysed to determine the amount of pyrene 148 + 1-hydroxypyrene in each organ. 149 The rest of the mixture was concentrated under a gentle stream of nitrogen to 1 mL and then 150 separated by using upti-clean SPE glass columns Si/Cn-S (Interchim, Montluçon, France). 151 Pyrene was eluted with 5 mL of a hexane/dichloromethane (50:50) solution which was 152 radioanalysed.

two radioanalyses.

At the end of the exposure period, the remaining organisms were placed in an open circuit 50L seawater aquarium (salinity:  $36\pm1$  p.s.u.; temperature:  $19\pm1$  °C; pH: 8; light/dark cycle: 12h/12h). At different times of the depuration period (0, 6, 18, 36, 96,192 and 336 h) four oysters were collected and their soft tissues dissected in order to follow the variation in pyrene and its metabolite. The dissected tissues and organs were processed according to the same method as previously described.

The 1-hydroxypyrene content in each organ was calculated by comparing the results of the

# **2.4. Data analyses**

164 <u>2.4.1. Uptake kinetics</u>

A first order model was used to assess changes in pyrene concentration in oyster tissues along

time during the exposure to waterborne pyrene. In this model the change in tissue activity

with time was calculated by:

168

$$dA_{org}/dt = k_u A_{SW} - k_e A_{org}$$
 (Eq. 1)

170

- where  $A_{org} = activity$  of pyrene in tissue (Bq  $g^{-1}$  tissue)
- 172  $A_{SW} = \text{activity of pyrene in seawater (Bq g}^{-1} \text{ water)}$
- 173  $k_u = uptake rate constant (Bq g^{-1} h^{-1})$
- $k_e = \text{elimination rate constant (Bq g}^{-1} \text{ h}^{-1})$
- 175 t = time (h)

176

177 As A<sub>SW</sub> was maintained constant during the uptake experiment phase, Eq. (1) can be

integrated to estimate tissue activities at any exposure time by:

179

180 
$$A_{org} t = A_{SW} (k_u / k_e) (1-e^{-k_e t})$$
 (Eq. 2)

181

where  $A_{org} t = tissue$  activity at time t

183

When steady-state tissue activities are attained (i.e.  $dA_{org}/dt = 0$ ), the bioconcentration factor

185 (BCF) can be estimated as follows:

187 
$$A_{org} / A_{SW} = BCF = k_u / k_e$$
 (Eq. 3)

188

In this study, the BCF is the ratio between <sup>14</sup>C-labelled pyrene in the body and in the surrounding seawater.

191

192

# 2.4.2. Depuration kinetics

- 193 The depuration kinetics were best fitted using either a single-component exponential equation
- 194 (Eq.(4)) or a double-component exponential equation (Eq.(5)):

195

196 
$$A_t = A_0 (e^{-k_e t})$$
 (Eq. 4)

197 
$$A_{t} = A_{0s} (e^{-k_{es} t}) + A_{0l} (e^{-k_{el} t})$$
 (Eq. 5)

198

- where  $A_t$  = remaining activity at time t (Bq g<sup>-1</sup>)
- 200  $A_0 = \text{activity at time } \theta \text{ (Bq g}^{-1}), \text{ i.e. at the beginning of the depuration period}$
- 201  $k_e = \text{depuration rate constant } (Bq g^{-1} h^{-1})$

202

- For double-component exponential model (Eq. 5), a 'short-lived' component (s) and a long-
- 204 lived' component (l) describe the radiotracer proportion that is depurated rapidly (s) and
- slowly (l), respectively. For each exponential component (s and l), a biological half-life can
- be calculated ( $T_{b1/2s}$  and  $T_{b1/2l}$ ) from the corresponding depuration rate constants ( $k_{es}$  and  $k_{el}$ ,
- 207 respectively) according to the relation:

208

$$T_{b1/2} = \ln 2 / k_e$$
 (Eq. 6)

210

211

# 2.4.3. Statistical analysis

Model constants and their statistics were estimated by iterative adjustment of the model using the nonlinear curve-fitting routines in the Statistica 6 software. For depuration kinetics, best fitting models were selected between single- and double-component exponential equation, according to the highest determination coefficient and examination of residuals. The level of significance for statistical analyses was always set at  $\alpha$ =0.05.

#### 3. Results

# 3.1. Seawater exposure

Uptake of pyrene in five body compartments (mantle, gills, muscle, digestive gland and remaining tissues) of *C. gigas* exposed to spiked seawater for 24h is presented in Fig. 1. The parameters and statistics of the uptake kinetic of  $^{14}$ C-pyrene are summarized in Table 1. The steady-state BCF of pyrene in the whole soft parts of the oysters was observed within 24h and reached  $1560 \pm 630$  (Table 1). Among the tissues, the gills accumulated rapidly and strongly the contaminant with a BCF of  $2080 \pm 860$ . However, each organ accumulated the pyrene in a different way (Fig. 1). For example, during the uptake phase, the mantle and the remaining tissues efficiently accumulated waterborne pyrene but the state of equilibrium was not reached during the time frame of the experiment (Fig. 1).

The final distribution of the contaminant in each compartment after 24h of exposure is presented in Fig. 2. Among tissues, gills contained half of the whole body burden radioactivity and consistently showed the highest rate of accumulation with a  $k_u$  of 433 Bq  $g^{-1}$   $h^{-1}$  (Table 1). In contrast, the muscle was the organ with the lower rate of accumulation ( $k_u = 38$  Bq  $g^{-1}$   $h^{-1}$ ) and thus, only contained a very low proportion (5%) of the total quantity of  $^{14}$ C-pyrene present in oyster soft tissues (Fig. 2).

Quantification of the pyrene metabolites was carried out at each sampling time, and the proportion of 1-hydroxypyrene represented between 4 and 14% of the total radioactivity (Fig. 3).

At the end of the exposure period, the concentration of 1-hydroxypyrene in seawater was below the detection limit of the method.

#### 3.2. Depuration phase

At the end of the exposure time, non-contaminating conditions were restored and depuration kinetics of the pyrene were followed in the organs and tissues of the oysters for 15d. The loss of incorporated <sup>14</sup>C-labelled pyrene followed a single or a double exponential model in the different body compartments (Fig. 4 and Table 2). In the muscle, gills and mantle, depuration was best described by a double-component exponential equation (R<sup>2</sup> =0.42, 0.52 and 0.48, respectively). The resulting biological half-lives (T<sub>b1/2</sub>) ranged from 1.17 (mantle) to 9.35 hours (gills) for the short-lived compartment and from 2.75 (muscle) to 7.27 days (gills) for the long-lived compartment (Table 2). In contrast, a single-component exponential equation better fitted the depuration kinetics in the digestive gland and in the remaining tissues (R<sup>2</sup> =0.37 and 0.30, respectively). They were characterized by a relatively strong retention of pyrene: the resulting  $T_{b1/2}$  were 87.4 and 97.4 hours, respectively, (i.e., 3.64 and 4.05 days) (Table 2, Fig. 4). The distribution of <sup>14</sup>C-labelled pyrene among the oyster soft tissues was determined at the end of the depuration period (Fig. 5). It differed from the distribution observed at the end of the exposure period (Fig. 2), with a lower fraction associated to the gills (24  $\pm$  10 vs. 47  $\pm$ 13%) and a higher fraction associated to the digestive gland (19  $\pm$  10 vs. 6  $\pm$  4%) and the remaining tissues (21  $\pm$  18 vs. 16  $\pm$  3%). At the end of the depuration period, the digestive gland displayed the highest pyrene activity (data not shown). In contrast, the gills had lost 50% of their activity during the depuration phase. Figure 5 also shows the distribution of 1-hydroxypyrene between the body compartments at the end of the depuration period. 1-hydroxypyrene was distributed in similar proportion as pyrene in the oyster body compartments.

#### 4. Discussion

Oysters accumulated very efficiently the 14C-labelled waterborne pyrene following a saturation model and after a short exposure period (24h), organisms reached the state of equilibrium. Among soft tissues, the gills accumulated rapidly and strongly the contaminant with a BCF of 2080 (Table 1) likely because of the high filtration rate of oysters which could be as high as 3.9 L h<sup>-1</sup> g<sup>-1</sup> dry weight (Bougrier et al. 1995). Consequently, the gills displayed the highest activities at the end of the exposure phase. Absorption of pyrene onto gills might be facilitated in oysters, as it occurs in blue mussels Mytilus edulis which have a micellar layer which absorbs hydrocarbons (Lee et al. 1972a). Nevertheless, the accumulated pyrene was relatively rapidly lost from this tissue (Table 1). Indeed, pyrene proportion in the gills at the end of the depuration phase was half than at the end of the exposure period (Figs. 2 and 5). This decrease is due to a fast depuration rate of pyrene in the gills (Table 1). At the same time, the increase of pyrene proportions in the digestive gland and remaining tissues suggest that it was transferred towards from the gills to these tissues as previously reported in other organisms (Neff, 1979). Therefore, the decrease of pyrene observed in the gills was also due to a relative increase of the activity in other compartments, such as the digestive gland (data not shown). During the uptake phase, the mantle and the remaining tissues also accumulated pyrene but the steady-state was not reached for these compartments. This is probably due to the fact that, even if these tissues are in contact with seawater, their surface is much smaller than that of the

gills, and the cell types and the thickness of the epithelium differ completely (Auffret, 2003). The resulting uptake rates (k<sub>u</sub>) were lower for both tissues than for gills. During the depuration phase, the mantle released pyrene quickly. In contrast, the remaining tissues showed a slow increase of the pyrene proportion against the total pyrene content in oysters as well as of its metabolite proportion (against the total metabolite content in oysters) during the depuration period. It is well-known that tissues rich in lipids, e.g. gonads, accumulate preferentially PAHs because of the highly hydrophobic nature of the latter (Berthelin et al. 2000, Meador et al. 1995). Moreover, a strong increase of the activity in the remaining tissues was noticed during the third sampling in the depuration period (t = 36h). The four oysters studied at this moment showed the particularity of being in the reproduction stage and of having gonadic tissues more abundant than the average of other individuals. For this reason, having acknowledged the unlikely hypothesis that these observations could come partly from an error of manipulation, it seems that this increase of activity was rather due to a stronger retention in mature gonadic tissues. This conclusion is consistent with results of Ellis et al. (1993), where gonads from C. virginica displayed PAH concentrations five times higher than in somatic tissues. In contrast, the digestive gland and the muscle which are not truly in direct contact with seawater displayed lower BCF than the gills, the mantle and the remaining tissues (Table 1). Nevertheless, the uptake rate for the digestive gland was much higher than the one of the muscle. The steady-state of pyrene in the digestive gland was reached very quickly, i.e. after 9h while it took 19h in the muscle (Fig. 1). The results strongly suggest that during the exposure period pyrene was transferred from tissues in contact with seawater such as gills, towards the digestive gland. Moreover, the digestive gland showed a higher percentage of 1hydroxypyrene (19%) in relation to total radioactivity (pyrene + 1-hydroxypyrene) than the other organs (9-12%) and the proportion of pyrene and its metabolite in the digestive gland

309

310

increased from 6-10% at the end of the accumulation period to 19-24% at the end of depuration period (Figs. 2 and 5). This suggests that the digestive gland had a stronger metabolisation capacity of pyrene than the other tissues. Among all the tissues studied, the digestive gland and the remaining tissues displayed the strongest retention capacity with  $T_{b\frac{1}{2}}$  of 87.4 and 97.4h, respectively. Indeed, just like almost all organic contaminants, PAHs best store up in some tissues, namely in the hepatopancreas in invertebrates and in the liver in vertebrates (Meador et al. 1995). Because of their highly hydrophobic nature, PAHs are mostly accumulated in tissues with high lipid contents. The transformed PAH metabolites generally accumulate in the hepatopancreas (Lee et al. 1976; Neff et al. 1976; Meador et al. 1995). It has been proved that for some invertebrates and for several fish species exposed to PAHs either via water, food or sediments, the cytochrome P450 enzymatic system connected to an oxygenase function (MFO) is activated in their hepatic structure (Andersson and Forlin, 1992). In the case of fish, this enzymatic system allows excreting most of the PAHs bioaccumulated via the bile and the urine (Pritchard and Bend, 1991). This particular function was difficult to bring to light concerning bivalves. For a long time, it was admitted that bivalves did not possess a P450 system (Lee et al. 1972b; Vandermeulen and Penrose, 1978). However, more recent studies have shown that bivalves do possess a P450 system (Lake et al. 1985; McLeese and Burridge, 1987), allowing them to metabolize PAHs. As it is the case for the majority of marine invertebrates, such ability to metabolize PAHs is weaker than for vertebrates (Livingstone, 1994; Stegeman and Hahn, 1994). Data obtained on 1-hydroxypyrene in the tissues and organs of *C. gigas* seem to confirm that metabolisation of pyrene in oysters is relatively weak and therefore would not be the driving mechanism responsible for its elimination. It is however possible that because of the large volumes of water they filter continuously, water-soluble metabolites would be rapidly

excreted and, therefore, not accumulated in the tissues (James, 1989). If the event lasts only for few days, it is very likely that most of the accumulated PAHs are going to be eliminated. In contrast, Meador et al. (1995) suggested that, during a chronic exposure, a non negligible fraction of the PAHs could be stored in lipids and become less subject to the elimination by diffusion or by metabolisation.

In conclusion, *C. gigas* presents a good potential of bioaccumulation of the pyrene and seems to have a low metabolisation capacity for this compound. Such a bioaccumulation capacity suggests that *C. gigas* could be used as a valuable bioindicator for pyrene. Following a marine contamination, oysters are thus able to rapidly accumulate the contaminant in detectable concentrations. Besides, as this species is very common in several regions of the world, samples can be collected at any time and in many countries. This makes the situation easier for comparing data. However, its speed of depuration is also quick, thus it does not allow the recording of long-term pollution. On the contrary, it is very interesting for the monitoring of the pollution variations on short-term periods.

# 5. Acknowledgments

MW is an Honorary Senior Research Associate of the National Fund for Scientific Research (NFSR, Belgium) and held a 2008-2009 Invited Expert position at LIENSs (CNRS-Université de La Rochelle), supported by the Conseil Régional de Poitou-Charentes. This work was supported by the IAEA and LIENSs. The IAEA is grateful for the support provided to its Environment Laboratories by the Government of Monaco.
