Abstract

The paper presents a new method to measure heat release rate disturbances from flames when optical access is limited. The technique is based on the determination of the travel time of ultrasonic waves propagating through the flow. The link between heat release rate and sound travel time disturbances depends on the configuration considered. An expression is established here for the case of unconfined premixed flames driven by buoyancy forces associated with the Kelvin-Helmholtz instability formed by the interaction between accelerating hot burned gases and cold ambient air at rest. The system and the principle used for the determination of the sound travel time are then presented and validated under non-reacting conditions. Effects of the main parameters on the precision of this detection technique are examined experimentally. Measurements in reacting conditions are compared to heat release rate data obtained with another technique based on the chemiluminescence

emission. A good agreement is obtained between both signals for the different cases explored demonstrating the sensitivity of the proposed technique.
Keywords: Heat release rate; Chirp excitation method; Ultrasonic waves; Flame flickering; Diagnostic.

1. Introduction

Monitoring and controlling heat release rate disturbances is an important issue in practical combustion chambers because these perturbations are the sources of unsteady thermal stress, direct and indirect combustion noise when entropy waves are accelerated by the mean flow (see for example the recent review by Candel et al. (2009)). They may promote self-sustained thermoacoustic instabilities causing potential severe damages and early aging of components of the combustion chamber (Candel 2002; Lieuwen and Yang 2005). It is therefore necessary to have reliable tools to estimate these disturbances, but direct measurements are not available and techniques generally rely on optical diagnostics.

A widely used technique to estimate heat release rate is to collect the chemiluminescence emission from the flame. Chemiluminescence from hydrocarbon flames results from naturally excited intermediate radicals, such as OH^*, CH^* and C_2^*, formed within the flame front and emitting a photon during the transition to a lower energy state. These radicals are often considered as good markers of heat release rate (Gaydon 1957). Recording the natural emission from the flame is the simplest technique to obtain time-resolved data and is often used to estimate heat release rate perturba-

tions by collecting the total emission from the flame (see for example Hurle et al. (1968); Price et al. (1969); Ducruix et al. (2000)) or by local point measurements (Kojima et al. 2000; Hardalupas and Orain 2004). This has for example been validated in laminar premixed flames submitted to flow modulations in the absence of mixture composition inhomogeneities, where fluctuations in the chemiluminescence emission were shown to be proportional to flame surface area disturbances (Schuller et al. 2002). Spectral selection of OH^* or CH^* emissions is generally preferred for hydrocarbon flames but it is also possible to use other chemiluminescent species, such as C_2^* or CO_2^* (Samaniengo et al. 1995; Najm et al. 1998; Docquier et al. 2000). In more complex configurations, different additional phenomena modify this relation and effects of the turbulence intensity (Ayoola et al. 2006; Lauer and Sattelmayer 2010), flame strain rate (Hardalupas and Orain 2004; Ayoola et al. 2006; Nori and Seitzman 2009), flame front curvature (Najm et al. 1998), local mixture composition (Hardalupas and Orain 2004), temperature and pressure (Docquier et al. 2000; Higgins et al. 2001; Ikeda et al. 2002) must be included to obtain quantitative estimates of the heat release rate. Measurements are then often limited to flame images for qualitative analysis except in a few studies where the signal is calibrated using specific post-processing procedures (see for example Lauer et al. (2011); Palies et al. (2010)). One problem is that the chemiluminescence emission yields an information integrated in the line-of-sight and it is difficult to obtain spatially resolved data. The signal is also more difficult to interpret in non perfectly premixed systems (Balachandran et al. 2005b; Kim et al. 2010).

One possibility to improve spatial resolution is to use Laser Induced Fluorescence (LIF) by stimulating certain electronic transitions from the radicals present in the flow with a laser sheet intersecting the flame front. OH LIF is widely used since the OH peak mole fraction occurs in the burned gases just behind the reaction zone and the gradients of the fluorescence signal are found to correlate well with the position of the local flame front in turbulent flames (see for example Knikker et al. (2002); Sadanandan et al. (2008)). The CH fluorescence signal is a better tracer of the reaction zone due to its relatively short lifetime and its abundance over a narrow region in the flame zone (Nguyen and Paul 1996; Donbar et al. 2000), even though large deviations with heat release rate were highlighted for diluted flames during transient phenomena (Vagelopoulos and Frank 2005). Time resolved data are more difficult to obtain due to the limited repetition rates and energy delivered per pulse from the lasers, although OH and CH planar measurements at a few kHz were recently reported to characterize transient phenomena in complex turbulent reacting flows (see for example Tanahashi et al. (2008); Boxx et al. (2009); Stöhr et al. (2011)).

While these techniques enable to locate the flame front, quantitative estimates of spatially resolved data for the heat release rate are still challenging. It is generally admitted that the intermediate radical HCO present in the flame front correlates well with heat release rate but the stimulation of an electronic transition with a detectable fluorescence signal raises several difficulties (Jeffries et al. 1991). It was shown that the concentration of HCO can however be estimated by the product of the OH and CH_2O radical concen-

trations formed around the flame, whose fluorescences are easier to obtain. This has motivated a series of studies based on LIF measurements at different excitation wavelengths to estimate the local distribution of heat release rate in flow configurations of increasing complexity (Najm et al. 1998; Paul and Najm 1998; Fayoux et al. 2005; Balachandran et al. 2005a; Ayoola et al. 2006). This type of simultaneous measurements in unsteady flows remain however heavy to implement and require high power well-tuned laser beams at different wavelengths and specific optics.

The methods briefly presented above are all based on optical detection of radicals present in the flame and are difficult to implement when the optical access is limited. The objective of this study is to develop one original solution based on an acoustic method. This new technique relies on determination of the travel time of ultrasonic waves propagating through a flame.

Flames submitted to acoustic disturbances behave as low-pass filters and are only sensitive to the velocity component of sound waves (Ducruix et al. 2003). Low frequency pressure disturbances are transmitted through a flame without distortion. The cut-off frequency of the flame response is reached when the velocity perturbation wavelength is of the order of the flame length $\lambda \sim L$, which is typically limited to about 2 kHz for most typical applications. In the intermediate range of frequencies, sound waves are scattered by the strong jump in density across the flame (Cho 2009) and by turbulent wrinkles which develop along the flame for frequencies ranging from about 1 to 20 kHz (Lieuwen 2001). The incoherent scattered sound power first

increases exponentially with frequency and then saturates to a certain level when compared to the coherent sound power incident on the flame (Lieuwen et al. 2002). When the wavelength is of the order of the flame thickness, pressure perturbations may then strongly interact with the preheat zone $\lambda \sim \delta$ and consequently modify the local reaction rate (Peters and Ludford 1983; McIntosh 1991; Ledder and Kapila 1991). This occurs only at very high frequencies of the order of 100 kHz for typical hydrocarbon-air flames, except when flames are submitted to high accelerations at very high forcing levels (Durox et al. 1997a; Durox et al. 1998; Wangher et al. 2008).

Information carried by the scattered field from ultrasonic waves impinging the flow has already been used to analyze vorticity production in turbulent jets and swirling jets (Baerg and Schwarz 1966; Fabrikant 1983; Oljaca et al. 1998; Poulain et al. 2004) as well as to detect temperature fluctuations in inert turbulent flows (Contreras and Lund 1990; Elicer-Cortes et al. 2004). In the case of reacting flows, these investigations were limited yet to the examination of the scattered sound field by the flame as a function of the geometric properties of the reaction front and the characteristics of turbulence (Lieuwen et al. 2002; Richecoeur et al. 2009). It is shown in these references that flame front wrinkles induced by turbulence result in Doppler shifted scattered waves, the coherent scattered signal being significantly damped compared to the incident coherent ultrasonic pressure disturbances, but there has been no attempt yet to use ultrasonic waves to probe reacting flow properties.

This paper focuses on the use of ultrasonic waves and considers distur-

bances of the sound travel time $\Delta t'$ between an emitter and a receiver as an indicator of perturbations in the flame width. This information is then used to reconstruct low frequency heat release rate disturbances $\dot{Q}'$ for unconfined premixed flames driven by buoyancy induced oscillations. This phenomenon called "flickering" is associated with the Kelvin-Helmholtz instability formed by the buoyant interaction between the hot burned gases and cold ambient air (Durox et al. 1997b). It produces small heat release perturbations with typical frequencies around 10 Hz at ground level gravity (Durox et al. 1990; Kostiuk and Cheng 1995) and provides a generic configuration to validate our acoustic methodology for heat release rate reconstruction in the absence of turbulence and external forcing device. Analysis of turbulence effects is out of the scope of the present study and this important topic will be the object of future investigations. Reconstruction of heat release rate for flames submitted to harmonic flowrate modulation has already been undertaken (Li et al. 2011) and the present investigation constitutes the second validation of the technique when gravity effects must be considered.

The link between the rate of change of the sound travel time $\mathrm{d}\Delta\mathrm{t}/\mathrm{dt}$ for ultrasonic waves crossing the flame and heat release rate fluctuations $\dot{Q}'$ is established in section 2. The experimental configuration is detailed in section 3, while the methodology developed to determine the travel time of ultrasonic waves together with the post-processing of the incident and transmitted signals are presented in section 4. This relies on a pulse compression technology used for radar detection. The choice of the type of forcing signal to probe the flow is discussed in section 5. Validation of the acoustic methodology in

non-reacting flows is conducted in section 6. Experimental results in reacting flows are compared to theoretical estimates and data obtained with an optical technique in section 7. Conclusions are drawn in the final section.

2. Model for the sound travel time

The following analysis is restricted to laminar premixed flames characterized by a "flickering" of the flame tip induced by buoyancy forces acting on the hot burned gases plume surrounding the flame (Durox et al. 1990; Kostiuk and Cheng 1995). These low frequency oscillations are induced by flow perturbations featuring a large wavelength compared to the flame thickness. It is then possible to consider the flame front as a thin interface separating the reactive mixture from the combustion products. The flame front propagates with the laminar burning velocity S_L and second order effects such as stretch and curvature are neglected in this analysis. Successive approximations are made to obtain an analytical expression of the heat release rate as a function of the sound travel time. These developments offer a simple theoretical framework to analyze effects of the different flow parameters controlling changes in the sound travel time induced by flickering. This is used in the next section to validate the proposed technique by comparisons between predictions and measurements. This analysis is then completed by an independent experimental validation based on an optical technique.

Consider the case of a plane sound wave traveling through a homogeneous gas over a distance L at fixed temperature and composition characterized by

a speed of sound c_u. The propagation time Δt_0 is given by:

$$\Delta t_0 = \frac{L}{c_u} \tag{1}$$

167

168 [Figure 1 about here.]

The burned gases around a flame modify the speed of sound along the acoustic path and consequently change also the sound propagation time. This configuration is represented in Fig. 1 where acoustic waves emitted by a tweeter propagate through three different media corresponding to ambient air, the burned gases and the fresh reactive mixture. In the analysis developed below, ambient air and the unburned gases are characterized by the same speed of sound c_u. This approximation is reasonable for air-combustion systems due to the strong dilution by nitrogen when the reactants are injected at ambient temperature. This situation can be schematically represented by two different media represented in the right part in Fig. 1. The first medium is composed of burned gases characterized by a speed of sound c_b over a length of L_f and the second is filled with ambient air characterized by a speed of sound c_u and a length $L - L_f$. In this case, Eq. (1) is modified and the propagation time Δt of sound waves from the emitter to the receiver now writes:

$$\Delta t = \frac{L - L_f}{c_u} + \int_0^{L_f} \frac{\mathrm{dx}}{c_b} \tag{2}$$

By introducing in this expression the sound travel time in the absence of flame Δt_0 which remains constant for a fixed emitter to receiver distance

and taking first order perturbations one obtains:

$$\Delta t' = -\frac{L'_f}{c^*} \tag{3}$$

where $c^* = c_u c_b/(c_b - c_u)$ is an equivalent speed of sound. Only disturbances in the acoustic path length L_f are taken into account, fluctuations in temperature and composition of the fresh mixture and burned gases are neglected here. This approximation is valid as long as relative perturbations of the equivalent speed of sound remain small $c^{*\prime}/\overline{c^*} \ll L'_f/\overline{L_f}$, where the superscripts $\bar{(\cdot)}$ and $(\cdot)'$ are used to represent the mean and fluctuating components respectively. This may not be the case in some practical configurations, but it is admitted here.

For laminar flames stabilized on the rim of a burner, buoyancy effects induce a low frequency oscillation of the hot plume without significant change of temperature and composition of the burned gases before the flame tip (Kostiuk and Cheng 1994; Durox et al. 1997b). This results in turn in small perturbations in heat release rate and fluctuations of the burned gases volume. Consequently the length of the acoustic path L_f is also modified. This modification results in a disturbance of the travel time of ultrasonic waves based on Eq. (3).

The link between fluctuations in the sound travel time $\Delta t'$ and perturbations in the heat release rate $\dot{Q}'$ must now be established. The main steps of the derivation are presented below by assuming that the volume of the

burned gases V_b depends on the flame surface area A_f of the conical flame:

$$V_b = \alpha L_f A_f \tag{4}$$

where L_f is the apparent dimension of the burned gases in the line of sight of the emitter and receiver and α denotes a constant coefficient for fixed flow operating conditions and experimental arrangement. Since the flame is anchored at the burner rim, a mass balance between the burner outlet and the flame front yields $v_u A = S_L A_f$, where S_L denotes the laminar burning velocity, v_u represents the flow velocity at the burner outlet and A indicates the section area of the burner outlet. This yields an expression for the hot plume width L_f as a function of the burned gases volume:

$$L_f = \frac{S_L}{\alpha v_u A} V_b \tag{5}$$

In this expression, S_L only depends on the equivalence ratio, v_u is kept constant and α is time independent so that L_f can be substituted in Eq. (3) to yield:

$$\Delta t' = -\frac{S_L}{\alpha v_u A c^*} V_b' \tag{6}$$

Fluctuations in the travel time of ultrasonic waves are proportional to fluctuations in the volume of burned gases V_b'. The objective is now to determine fluctuations of the burned gases volume as a function of heat release rate disturbances.

[Figure 2 about here.]

For buoyancy driven oscillations, the flow can be considered isobaric. Using the simplified model presented in Fig. 2, a global energy balance over

the control volume yields:

$$\frac{\gamma p}{\gamma - 1}\left(\frac{\partial V_u}{\partial t} + \frac{\partial V_b}{\partial t}\right) = \dot{m}_u c_p T_u - \dot{m}_b c_p T_b + \dot{Q} \tag{7}$$

where the lateral surface of the control volume in contact with ambient air is supposed impermeable ($\dot{m}_i = 0$) and adiabatic ($\dot{Q}_i = 0$). The ratio of specific heat capacity $\gamma = c_p/c_v$ and ambient pressure p appear on the left side of Eq. (7), while the rate of heat released in the control volume $\dot{Q}$ and the sensible enthalpy fluxes $\dot{m}c_pT$ at the unburned (subscript u) and burned (subscript b) limits are responsible for changes in the unburned V_u and burned V_b volumes. In this expression, T denotes the temperature and $\dot{m}$ represents the mass flow rate. A first order perturbation analysis of Eq. (7) yields at low frequency:

$$\frac{\gamma p}{\gamma - 1}\frac{\partial V_b'}{\partial t} = \dot{Q}' \tag{8}$$

where fluctuations in the fresh reactants volume were neglected since $V_u/V_b \approx \rho_b/\rho_u = T_u/T_b \ll 1$. For methane-air flames $T_b/T_u \simeq 5-8$ depending on the mixture equivalence ratio ϕ.

Combining Eqs. (6) and (8), one finally finds that heat release rate disturbances induced by buoyancy effects are proportional to the rate of change in the sound travel time between the transmitter and receiver:

$$\dot{Q}' = -\frac{\gamma p}{\gamma - 1}\frac{\alpha v_u A c^*}{S_L}\frac{\partial \Delta t}{\partial t} \tag{9}$$

This last relation shows that it is possible to estimate heat release rate perturbations induced by flame flickering from fluctuations in the sound propagation time of ultrasonic waves crossing the hot plume of unconfined flames.

Heat release rate disturbances are then proportional to the rate of change of the sound travel time $\partial \Delta t / \partial t \propto \dot{Q}'$. The remaining part of this paper is devoted to validation of Eq. (9).

3. Experimental configuration

[Figure 3 about here.]

Experiments are conducted on an axisymmetric burner with a 20 mm outlet nozzle diameter. Laminar premixed methane-air flames are anchored at the burner rim. The flow rates of methane and air are premixed before entering the burner and the equivalence ratio can be modified by adjusting air and methane Bronkhorts massflow controllers. Ultrasonic pulses transmitted to air are generated by a small tweeter placed on one side of the setup, with a working bandwidth from 5 to 50 kHz. The acoustic waves are recorded by two microphones M1 and M2 (B&K, type 4938, working bandwidth 4 Hz - 70 kHz) before and after their passage through (a) a flame or (b) the corresponding jet flow in the absence of combustion. These microphones are alined so that ultrasonic waves cross on the burner symmetry axis in Fig. 3. A photomultiplier (PM) is also placed on the side of the burner to record the light emission from intermediate radicals present within the flame front. For the laminar premixed flames considered here, it is possible to estimate heat release rate perturbations $\dot{Q}'$ by examining fluctuations in the chemiluminescence intensity I of free radicals OH*, C_2* or CH* present in the reaction zone (Price et al. 1969; Schuller et al. 2002)

$$\dot{Q} = kI \tag{10}$$

The coefficient k is a function of the experimental apparatus and mixture composition. It can be determined by a calibration procedure detailed in section 7.

4. Determination of the sound propagation time

[Figure 4 about here.]

A pulse compression technique is used to determine the propagation time of ultrasonic waves between microphones M1 and M2 (Merrill 2008). Figure 4 presents the block diagram of the transmission and reception systems. A train of pulses, as illustrated in Fig. 5, is synthesized by a wave generator. This signal is amplified and transmitted to space using a tweeter. The ultrasonic waves generated are measured with fixed microphones before and after their passage through the perturbed flow. These sound pressure signals are then amplified, high pass filtered and post-processed to compute the cross-correlation between the incident and transmitted sound waves. Each train of pulses is a chirp signal with a constant amplitude β and a linear frequency modulation over a certain frequency bandwidth B and a time duration τ (Fig. 5). This technique enables to obtain a narrow compressed pulse response for the cross-correlation between the incident and transmitted signals with a main peak corresponding to the sought sound travel time Δt. Provided that the repetition time t_r between two successive chirps is large enough, the time resolution of the technique improves as the compression factor $B\tau$ increases (Klauder et al. 1960; Cook and Bernfield 1993; Merrill 2008).

[Figure 5 about here.]

Theoretically, the incident and transmitted signals can be expressed as:

$$S_i(t) = \begin{cases} \beta_i \sin\left(2\pi\left[f_i + \frac{B}{2\tau}t\right]t\right) & 0 \leqslant t \leqslant \tau \\ 0 & \text{elsewhere} \end{cases} \tag{11}$$

$$S_t(t) = \begin{cases} \beta_t \sin\left(2\pi\left[f_i + \frac{B}{2\tau}(t-\Delta t)\right](t-\Delta t)\right) & \Delta t \leqslant t \leqslant \tau + \Delta t \\ 0 & \text{elsewhere} \end{cases} \tag{12}$$

The correlation between these two signals is used to obtain a narrow compressed pulse response (Mahafza and Elsherbeni 2004):

$$R_{\text{corr}}(t) = \frac{1}{\tau}\int_{-\infty}^{+\infty} S_t^*(t')S_i(t'-t)\mathrm{d}t' \tag{13}$$

The sound propagation time Δt is determined by finding the maximum value of the envelope of the cross-correlation response. Examples of ideal generated (Eq. (11)) and transmitted (Eq. (12)) chirps together with the result of the cross-correlation are illustrated in Fig. 6.

[Figure 6 about here.]

Due to the different mechanical and electrical devices in the signal generation and reception, it is not desirable to operate with chirps with a square envelope because of the sudden changes in the signal amplitude at the leading and trailing edges of the sequence. A Hamming window is then applied to the rectangular chirp produced by the signal synthesizer to obtain a smooth transition in amplitude at the beginning and end of the chirp, but the response measured by the different sensors is still distorted as shown in Fig. 7 in the absence of flow between the emitter and receiver.

243 [Figure 7 about here.]

244 [Figure 8 about here.]

245 To improve results, a pre-processing applied to these raw signals is nec-
246 essary. The technique is the same for the incident and transmitted signals
247 and will only be detailed for the reference microphone M1 in Fig. 8. The
248 raw signal is first filtered with a high pass zero-phase shift filter to eliminate
249 the low frequency background noise induced by the flow and the generation
250 and measurement devices. The filtered result is shown in Fig. 8(a). A digital
251 Butterworth filter with a cut-off frequency f=100 Hz featuring an attenua-
252 tion of less than 3 dB in the pass-band and at least 30 dB in the stop-band
253 was used (Oppenheim and Schafer 1975). This filtered signal and the signal
254 generated by the synthesizer are processed by the cross-correlation algorithm
255 to locate the leading edge of the chirp. The resulting signal is multiplied by
256 a rectangular box function of duration τ to eliminate the signal outside the
257 chirp as shown in Fig. 8(b). A Hilbert transform is then used to obtain the
258 envelope of the signal, shown in Fig. 8(c). This envelope enables to renormal-
259 ize the signal presented in Fig. 8(b) and obtain a constant amplitude signal
260 as shown in Fig. 8(d). The pre-processed signals from microphones M1 and
261 M2 are then cross-correlated. The output is again processed by the Hilbert
262 transform to keep only the envelope. The location of the peak of the main
263 lobe yields the propagation time Δt.

264 [Figure 9 about here.]

265 Figure 9 shows an example of the normalized cross-correlation obtained
266 with and without pre-processing. It can be noted that the level reached by the

side lobes for the pre-processed response is significantly reduced compared to the result obtained without pre-processing. The resolution of the technique is indicated by the width of the main peak calculated at the level 0.5. The pre-processing clearly improves the result.

5. Parameters optimization for the chirp generation

[Table 1 about here.]

Different tests were conducted in the absence of flow and flame to optimize the technique for the generation and detection of the chirp ultrasonic signals. The influence of the frequency bandwidth B, initial frequency f_i, chirp duration τ and chirp repetition rate t_r on the precision of the measured sound travel time Δt was analyzed in this section. To avoid mixing different neighbor transmitted signals, the duration between two pulses $t_r - \tau$ must be larger than the fluctuations of propagation time Δt. It was checked in this case that results were independent on the repetition rate t_r. The range explored for the values of the three remaining parameters is synthesized in Tab. 1. In this table, the carrier frequency $f_0 = f_i + B/2$ is indicated instead of f_i to examine effects of the initial frequency. The influence of each parameter was studied separately by keeping the two others fixed. In these experiments, the signals from the microphones were sampled at a frequency $f_s = 2^{21}$ Hz over a duration 0.2 s and measurements were repeated 100 times for each case explored to obtain the confidence interval of the samples.

[Figure 10 about here.]

The measured sound travel times are plotted as a function of the frequency bandwidth B, pulse duration τ and carrier frequency f_0 respectively in Fig. 10. In these plots, error bars correspond to the maximal deviation over 100 repetitions and the black disks denote the mean value. It can be noted that an increase in the frequency bandwidth B or pulse-width duration τ greatly improves the precision in Fig. 10(a) and (b), but the choice of the pulse-width duration is limited when time resolved data are needed. For example, to obtain time resolved records with a sampling rate of 500 Hz, τ has to be less than 2 ms. Theoretically, the carrier frequency f_0 or initial frequency f_i has no effect on the precision (Merrill 2008). Figure 10(c) shows however that results feature some scatter depending on f_0. This phenomenon is again induced by the different mechanical and electronic responses of the transmitter and receiver devices. In the remaining experiments, the parameters chosen for the chirp generation were fixed to the optimal values indicated in Tab. 2.

[Table 2 about here.]

6. Validation in the absence of flame

The transmission of sound waves between microphones M1 and M2 under non-reacting conditions was investigated. Experiments were conducted for three different cases, (a) without burner, (b) with the burner between the two microphones but in the absence of flow, and (c) for a non-reacting jet flow (Fig. 3). The Reynolds number based on the flow velocity and nozzle diameter Re = 2900 corresponds to a laminar jet with a flow velocity typical of the reacting conditions explored in the next section. Parameters used to

generate the chirp are listed in Tab. 2. Microphones signals were sampled here at a frequency $f_s = 2^{21}$ Hz during a period of 0.2 s. This duration is long enough to collect 80 transmitted chirps for each record.

[Figure 11 about here.]

By modifying the horizontal position of M2 (Fig. 3), it is possible to determine the evolution of the travel time of ultrasonic waves Δt_0 as a function of the distance L between the two microphones. In these experiments, the horizontal distance between the two microphones was increased by steps of 5 mm to record the different sets of data. The evolution of the difference $\Delta(\Delta t_0) = \Delta t_0(L) - \Delta t_0(L_0)$ between measurements of the sound travel time recorded for two distances L and L_0 between microphones M1 and M2 is plotted in Fig. 11 as a function of the distance $\Delta L = L - L_0$, where the reference distance corresponds to $L_0 = 300\,\text{mm}$. The difference in sound travel time $\Delta(\Delta t_0)$ increases linearly with ΔL for all cases explored. All data collapse on the same line indicating that there is no scattering effects due to the presence of the burner or laminar jet. The slope $1/c_0$ indeed fits with predictions from Eq. (1), where $c_0 = 348$ m.s^{-1} is the speed of the sound in ambient air. This setup and the methodology developed can now be used to examine perturbations in the sound travel time induced by the presence of the flame between the two microphones.

7. Validation with flame

[Figure 12 about here.]

Laminar premixed conical flames are stabilized on the burner rim. As already discussed in the previous sections, while the flow is steady, the tip of the conical flame features a small regular oscillation called flickering caused by the unstable interface between the burned gases and ambient air (Fig. 12, left image). It is also known that a cylindrical tube on the top of the flame stabilizes the flow of the burned gases and the flickering phenomenon is attenuated (Kizirnis et al. 1984; Linteris and Rafferty 2008). This is illustrated in the right image in Fig. 12. Flickering features typical frequencies around $10 - 20$ Hz (Kostiuk and Cheng 1994; Durox et al. 1997b). This motion generates in turn small low frequency heat release rate perturbations that can be identified by measuring fluctuations in the light emission intensity I recorded by the PM or by determining fluctuations in the sound travel time Δt with the microphones M1 and M2.

[Figure 13 about here.]

Measurements are shown for a lean methane-air flame with a bulk velocity v_u=1.5 m.s^{-1} and equivalence ratio $\phi = 0.9$ with and without a quartz tube on the top of the flame. Signals are recorded here with the same sampling frequency $f_s = 2^{11}$ Hz but over a longer sampling time 1.5 s than in the experiments in the absence of combustion. The left graph in Fig. 13 shows that the light intensity $I(t)$ and sound travel time Δt both feature a periodic motion. Power spectral analysis based on the data collected with the PM and the microphones show that the main peak in both cases corresponds to the oscillation frequency $f = 16 \pm 1$ Hz. These measurements are in agreement with the flickering frequency deduced from the correlation of (Kostiuk and

Cheng 1994):

$$\frac{f^2 D}{g\xi(\xi-1)} = 0.00028 \left(\frac{v_u D}{\xi \nu}\right)^{2/3} \tag{14}$$

By taking $D = 20$ mm for the diameter of the burner outlet, $g = 9.8$ m.s^{-2} for the gravitational acceleration, $\xi = T_b/T_u = 7$ for the volumetric expansion ratio and $\nu = 1.5 \times 10^{-5}$ m^2.s^{-1} for the kinematic viscosity in the fresh reactants at room temperature, one also finds $f = 16$ Hz. This confirms that the two previous techniques highlight the same unsteady behavior induced by flame flickering. Results presented on the right in Fig. 13 clearly demonstrate that fluctuations in the light intensity I and travel time of ultrasonic waves Δt vanish when the quartz tube is used.

[Figure 14 about here.]

Fluctuations in the chemiluminescence emission intensity I and disturbances in the sound travel time Δt result both from heat release rate perturbations. The link between these quantities is obtained by plotting the evolution of the mean value of the light intensity $\bar{I}$ as a function of the flow velocity v_u at the burner outlet. Results are presented in Fig. 14 for four flames featuring different equivalence ratios $\phi = 0.85$, 0.90, 0.95 and 1.00. The evolution is linear $\bar{I} = \epsilon v_u$, where the coefficient ϵ depends on the equivalence ratio of the combustible mixture. It is then possible to obtain an expression for the coefficient k appearing in Eq. (10) linking the heat release rate $\overline{\dot{Q}}$ and the chemiluminescence intensity $\bar{I}$:

$$k = \frac{\overline{\dot{Q}}}{\bar{I}} = \frac{\overline{\dot{Q}}}{\epsilon v_u} = \frac{\rho_u \Delta q A}{\epsilon} \tag{15}$$

where ρ_u is the unburned mixture density, A the cross section area at the burner outlet and Δq the heating value per unit mass of reactive mixture. In this expression, it is assumed that all the mixture is burned. Combining Eqs. (9) and (15), the following relation between perturbations in chemiluminescence intensity I and sound travel time Δt can be derived:

$$\frac{d\Delta t}{dt} = \Xi\ I' \quad \text{where} \quad \Xi = -\frac{(\gamma-1)}{\alpha}\frac{S_L}{\epsilon v_u}\frac{\Delta q}{c_u^2}\frac{1}{c^*} \tag{16}$$

For a fixed mixture composition and flow velocity, fluctuations in the flame emission are proportional to the rate of change of the sound travel time of acoustic waves crossing the flame.

[Table 3 about here.]

In this study, conical flames featuring a regular flickering of the tip were found for operating conditions corresponding to equivalence ratios ϕ=[0.85 1.50]. It was not possible to stabilize flames leaner than ϕ=0.85 that blow-off. The rich limit ϕ=1.50 corresponds to a situation where the conical flame tip opens and the flickering phenomenon disappears. One difficulty with fuel rich operating conditions ($\phi \geq 1$) is that a diffusion flame surrounds the premixed conical flame stabilized in the center region, where the remaining fuel is burned. In these conditions, techniques based on analysis of the chemiluminescence emission do not reproduce heat release rate disturbances (Lauer and Sattelmayer 2010). This study was thus limited to fuel lean flames ($\phi \leq$=1). Measurements of $d\Delta t/dt$ and I' were conducted for lean premixed methane-air flames featuring different inlet flow velocities ranging from $v_u = 0.84$ to

1.68 m.s^{-1} and equivalence ratios ϕ varying from 0.85 to 1.00. Parameters fixed for the chirp generation are indicated in Tab. 2. Acoustic measurements were sampled at a frequency equal to 400 Hz corresponding to a repetition time $t_r = 2.5$ ms. The resulting signal for $\Delta t'$ was then filtered by a low-pass zero-phase shift filter with a cut-off frequency equal to 40 Hz. The PM signal was sampled at a frequency of 8192 Hz during a period of 1.5 s and is filtered with the same low pass filter. Comparisons between the two measurement techniques are presented in Fig. 15 for the six cases listed in Tab. 3. The opposite signal $-I'$ is plotted in this figure because the proportionality coefficient Ξ between I' and $d\Delta t'/dt$ given by Eq. (16) is negative. Signals were also rescaled in this figure to obtain comparable oscillations levels. The two signals $d\Delta t/dt$ and $-I'$ match well in phase and relative amplitude for all cases, clearly demonstrating that the rate of change of the sound travel time of ultrasonic waves is proportional to fluctuations in light intensity emission: $d\Delta t/\mathrm{dt} \propto \mathrm{I}'$.

[Figure 15 about here.]

[Figure 16 about here.]

Instead of plotting the signals $d\Delta t/dt$ and I' as a function of time like in Fig. 15, it is also interesting to plot $d\Delta t/dt$ as a function of I' for the different operating conditions explored. One example is presented in Fig. 16 for the case C2 (see Tab. 3). The value of the coefficient Ξ appearing in Eq. (16) can then be determined by a linear regression. These values and the corresponding regression coefficients r^2 are indicated in Tab. 3 and confirm the linear link between $d\Delta t/dt$ and I' for all cases explored. Data determined

experimentally can also be compared to predictions using values indicated in Tab. 4 to estimate the coefficient Ξ appearing in Eq. (16). Predictions are plotted in Fig. 17 and are compared to measurements for two different equivalence ratios $\phi = 0.85$ and $\phi = 1.00$ as a function of the nozzle outlet flow velocity v_u. The distributions of experimental results match well again predictions confirming the validity of Eq. (16) and the possibility to detect heat release rate fluctuations by measuring perturbations in the transmission time of ultrasonic waves crossing flames.

[Table 4 about here.]

[Figure 17 about here.]

8. Conclusion

A new technique was presented to detect small heat release rate disturbances in premixed flames submitted to low frequency instabilities driven by buoyancy forces when the optical access is limited. This technique is based on the determination of the travel time of ultrasonic waves transmitted through the flames. An experimental validation of the proposed technique was conducted on a generic configuration with a tweeter to produce the ultrasonic waves and two microphones to record the incident and transmitted signals through different laminar flames. An analytical relation was derived linking sound travel time and heat release rate disturbances. Time resolved measurements obtained with the acoustic methodology were compared with optical data based on records of the chemiluminescence emission from the flames. A good agreement was obtained for the different cases explored demonstrating

that the transmission of ultrasonic waves can effectively be used to estimate heat release rate disturbances. It was also shown that the proposed technique is very sensitive to small disturbances in heat release rate. These results are encouraging and motivate further development of this technique to investigate heat release rate disturbances in more complex configurations.

Aknowledgement

Jingxuan Li is supported by a doctoral fellowship from China Scholarship Council, Project 111, Grant No. B08009. The authors wish to thank Dr. Daniel Durox for helpful discussion about buoyancy effects and assistances with color Schlieren technique.
