Abstract— Optoelectronic oscillators based on high Q optical resonators are presented in this paper. These oscillators use a Pound-Drever-Hall laser stabilization technique and two different types of resonators: fiber ring and monocrystalline disk resonators. Noise processes in the oscillators are discussed, particularly the influence of the laser noise conversion and nonlinear optical scattering noise. A modeling approach using CAD software is also proposed.

Keywords- optoelectronic oscillators; microwave photonics; fiber ring resonators; whispering gallery mode resonators; phase noise

I. INTRODUCTION

Microwave oscillators based on optical frequency references have become quite common, at least the ones based on fiber optics spools which have been studied since 1994 [1]. These optoelectronic oscillators (OEOs) take benefit of the ultra-low losses in silica fibers, and thus of the large delay provided by long fibers in the kilometer range. This large delay is equivalent to a high microwave quality factor (Q_{RF}), and Q factors higher than 10^6 can be reached at an application frequency of 10 GHz. However, these delay line OEOs suffer from different drawbacks which are the fiber spool size, making the system hard to stabilize in temperature, and the spurious modes generation. Many approaches have been proposed to solve these problems, but they still quite complex and the system remains bulky.

An alternative solution instead of using delay lines in OEOs, is the use of optical resonators [2], [3]. Optical quality factors (Q_{opt}) as high as 10^8 to 10^{11} may be obtained with different types of optical resonators: fiber ring resonators (FRRs), monocrystalline disks, silica spheres or toroids, Fabry-Perot ultra stable cavities... Using these optical resonators, the equivalent microwave quality factor is linked to the optical quality factor by the relation below:

$$Q_{RF} = Q_{opt} \times \frac{f_{RF}}{f_{opt}} \quad (1)$$

where f_{RF} and f_{opt} are respectively the microwave (RF) and the optical frequencies.

From (1) we can see that interestingly, and unlike microwave resonators, the equivalent Q_{RF} s of these optical

resonators increase while increasing the RF application frequency f_{RF} . As an example, a Q_{opt} factor of 10^9 , at $1.55\text{ }\mu\text{m}$ wavelength ($\sim 200\text{ THz}$), results in an equivalent Q_{RF} factor of 10^5 at 20 GHz. This is lower than the equivalent Q_{RF} factor of a long delay line but still particularly interesting if compared to the Q_{RF} factor of conventional microwave resonators, taking also into account the reduction in system size if we replace the delay line by a resonant device.

A special case of resonant or regenerative OEOs is the coupled OEO (COEO) [4], in which a microwave oscillator is coupled to an optical oscillator. Like the resonator approach, the COEO allows a reduction in the fiber length, while keeping high performances. The advantage of the COEO relies in the fact that the laser and the resonator are the same device. However, system size and Q_{opt} factor could be better in passive resonator based OEOs, if problems of noise conversion and laser stabilization can be efficiently resolved.

In this paper, noise processes in OEOs based on either FRRs or tridimensional monocrystalline resonators are discussed. All these OEOs use the same system to stabilize the laser onto the resonator: a Pound Drever Hall (PDH) technique [5]. Some noise processes are studied theoretically, especially those related to the laser amplitude (AM) and frequency (FM) noise conversion, thanks to a system design approach developed on Agilent ADS microwave software. Experimental results are also provided.

II. RESONATOR BASED OPTELECTRONIC OSCILLATOR

The OEOs described in this paper are based on ultra-high Q_{opt} optical resonators featuring a comb of resonances with microwave spacing called free spectral range (FSR). The resonator FSR must be a sub-multiple of the application frequency. In this case, the beat note between two or three optical modes of the resonator will be used in the microwave domain. Before setting up the filtering of the microwave signal, it is necessary to stabilize the laser carrier on one of the modes of the resonator. The extreme Q_{opt} factors of these resonators make them very sensitive to the incident light power. When the light wave is resonant inside the resonator, the circulating intra-cavity power can be as high as 54 times the incident light power, depending on the resonator Q_{opt} factor. This induces a strong thermal effect [6], which shifts the optical resonance and the resonator is no more coupled to the laser unless a feedback

system is used to maintain the laser at the resonance frequency. Also, the high circulating intra-cavity power can lead to the generation of many nonlinear optical effects inside the resonator, as we will see later in section IV.

Many feedback approaches can be used to stabilize the laser to the resonance frequency. First, using whispering gallery modes (WGM) disks or sphere resonators, one can take benefit of a natural counter-rotating wave inside the resonator to optically lock the laser to the resonator [7]. Of course, this requires an accurate control of the resonator-laser distance. A self-thermal lock can be also realized in some cases, depending on the thermal expansion parameters of the resonator, but such a lock process is not reliable enough for all applications. The approach we have chosen, the PDH technique, is based on an electrical feedback to the laser: the phase transition at the resonance is converted into an error signal and fed-back to control the laser frequency. This approach is very reliable in time and it can be applied to any laser having a linewidth smaller than the resonance linewidth and on which a frequency control parameter is available.

The OEO system is depicted in Fig. 1. The laser is first locked to the resonator thanks to a PDH low frequency (LF) loop and then the microwave oscillation is started thanks to a high frequency (HF) loop. The HF loop includes a RF amplifier, a phase shifter and, in the case of FRR, a mode selection filter, because we use a 20 meter long FRR that features a 10 MHz FSR. This is not the case of the WGM disk resonator, which is of millimeter size and thus its resonant comb features a FSR higher than 12 GHz. For OEOs based on WGM resonators, the microwave filter is thus useless.

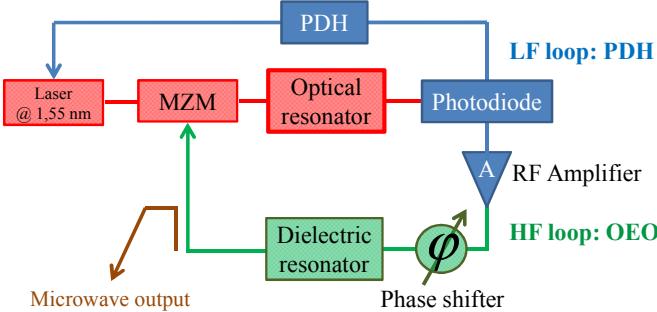

Figure 1. OEO setup based on a PDH loop to stabilize the laser and a HF loop to maintain the microwave oscillation; PDH: Pound Drever Hall, MZM: Mach-Zehnder modulator.

III. FIBER RING AND WGM OPTICAL RESONATORS

The above OEO system has been firstly set up with a FRR [8]. The resonator is realized with two low loss fibered directional couplers with low coupling factors (about 1%) linked with an optical fiber of a few meters, Fig. 2. As an example, we have been able to obtain a Q_{opt} factor of 5.1×10^9 with a 20 meter long FRR. It is a relatively small device (planar device) featuring an equivalent Q_{RF} factor of 5.1×10^5 at 20 GHz, which is above conventional microwave resonators Q_{RF} factors. This FRR's Q_{opt} factor is very similar to Q_s of WGM disk resonators, and the first goal in using this fibered resonator was to set up an OEO system which would be compatible with WGM resonators in order to study them

accurately. However, the performances of the FRR are already very interesting. Also, it is much easier than WGM resonators to set up, thanks to the well-established technology of fibered directional couplers.

The other types of resonators we have studied are WGM silica spheres and calcium fluoride CaF_2 polished disk resonators, Fig. 2. These resonators are coupled to the laser thanks to tapered fibers and a Nano-scale positioning system. This coupling system is very efficient, but it remains a laboratory experiment system. We have obtained Q_{opt} factors in the range of 10^8 both on silica spheres and CaF_2 disks. Q_{opt} as high as 10^{11} have already been demonstrated with CaF_2 disks [3].

IV. NOISE IN A RESONATOR BASED OEO

Unlike microwave oscillators, in which phase noise is dominated by RF amplifiers noise, the phase noise in OEOs is generally dominated by noise processes occurring in the optical part of the system. This is even more true for resonator based OEOs, in which the required correlation between the laser and the resonance frequency may induce specific noise processes. Also, the resonator ultra-high Q_{opt} factor may lead to an induced nonlinear optical scattering noise inside the resonator, converted into microwave phase noise in the OEO setup.

Two types of laser noise conversion processes are particularly important: the laser AM and FM noise conversion. Because the photodiode performs amplitude detection, it is obvious that the laser AM noise may have an influence on the microwave phase noise. Also, this is generally the parameter which determines the signal to noise ratio (unless there are too much losses through the resonator) and thus the OEO phase noise far from the carrier. However, for most applications, the close to the carrier phase noise performance (1 Hz to 10 kHz) is the most critical parameter. At these offset frequencies, a 1/f like frequency noise is observed.

To determine the ratio of laser AM and FM noise conversion into RF phase noise, a modeling approach has been set up using Agilent ADS microwave software. This approach takes benefit of the harmonic balance technique provided by ADS to describe the nonlinear signal and noise conversion processes occurring between the laser frequency (~ 200 THz), the microwave frequency and the DC. Because ADS does not include models for optical devices, we have developed our own models, which are either based on equivalent circuit descriptions or on mathematical black box descriptions. As an example, the laser is described with a classical frequency source with its FM noise, and an amplitude modulator is added to model the laser AM noise.

Fig. 3 depicts the model used for the resonator. In this case, a FRR was modeled and described using modified models of ideal lines and coupled lines of ADS. The resonant comb, the FSR and the Q_{opt} factor are accurately described with this approach on any of the four ports of this resonator and simulation results fit very well with our experimental measurements data. One of the advantages of such ADS resonator model is the capability of easily simulating very complex scheme based on multiple optical resonators.

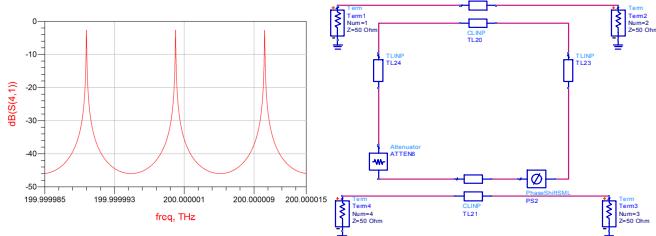

Figure 3. FRR model using ADS, and S_{21} amplitude simulation results.

For our OEO application and noise investigations, an interesting study which can be performed on ADS is on the way the optical modes are translated into electrical resonances in a system including: laser + modulator + optical resonator + photodiode. If a classical Mach-Zehnder linear modulation is used ($V_{\text{bias}} = V_{\pi/2}$), the modulated laser carrier features two optical sidebands which simultaneously go through two lateral modes of the resonator. This process gives birth to a unique microwave mode at the photodiode output, which results from the two optical modulation sidebands and the laser carrier folded one onto the other.

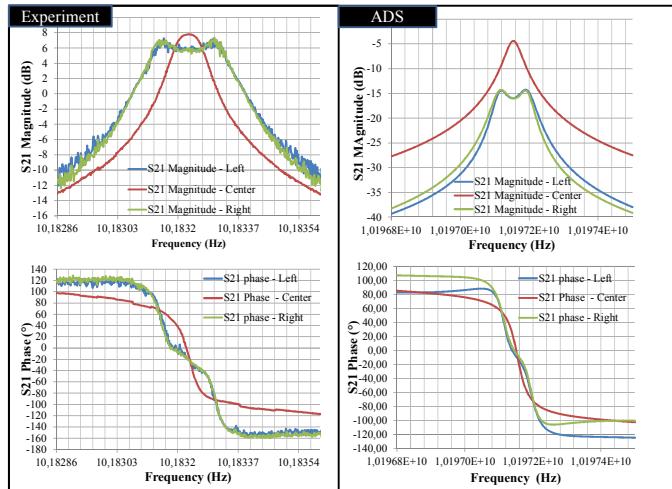

Figure 4. S_{21} RF amplitude and phase responses through modulator + optical resonator + photodiode; Experimental and ADS simulation results. Case of a laser perfectly centered on the mode (red curve) and of a shift between the laser frequency and the resonator frequency (blue and green curves).

If the laser is perfectly centered on one of the modes, and the two lateral sidebands are identical, then a microwave mode identical to the optical modes of the comb (same 3 dB bandwidth and phase slope) is observed in the microwave domain. However, if the laser is not perfectly centered, the

phase slope of the microwave signal (and thus the Q_{RF} factor) is reduced, as it can be seen from the simulation results in Fig. 4. Moreover, if the laser is not at the center of the resonance, the system becomes sensitive to laser frequency fluctuations, and thus it is able to convert the laser phase noise into electrical phase and amplitude noise. This simulation demonstrates how important is the laser lock and the ability to control this locking process. Such a possibility is well provided by the Pound-Drever-Hall approach.

Another problem in these systems relies on the starting up of optical nonlinear processes inside the resonator due to the high circulating intra-cavity power. This will also degrade the microwave phase noise. The two main processes to be considered are Rayleigh and Brillouin scatterings. We have experimentally found that the stimulated Brillouin scattering (SBS) process occurs at relatively low input power in these resonators, at least in the case of FRR [9], depending on its Q_{opt} factor. Once this process starts, a Brillouin (back-reflected) Stokes wave downshifted in frequency from the laser carrier by about 10.8 GHz (for silica fibers) can be observed. Using a 20m long FRR, and because of the high circulating intra-cavity power, we have been able to detect the generation of the seventh order Brillouin line at 10 dBm of optical input laser power, Fig. 5. This parasitic signals mix either inside the resonator (they modulate the amplitude of the main signal) or at the photodiode level with the main signal, thus increasing the RF phase noise, especially close to the carrier.

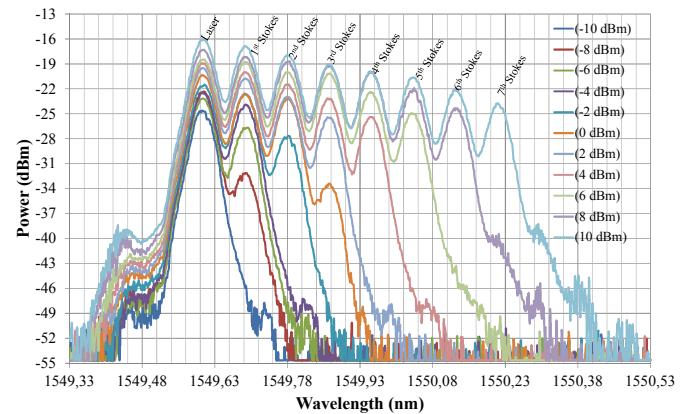

Figure 5. Stimulated Brillouin scattering lines generation inside a 20m long fiber ring resonator with a Q_{opt} factor of 3.5×10^9 .

The Brillouin scattering generation also leads to nonlinear losses inside the resonator which will be added to the resonator intrinsic loss. After being generated, above the SBS threshold, the Brillouin scattering converts any additional laser power injected above this threshold to its own power and generates other Brillouin lines (Fig. 5). This will cause laser carrier depletion, and thus it leads to the degradation of the noise to carrier ratio of the optical link. Fig. 6 shows the DC detection of the photodiode at the resonator third output using an oscilloscope, where we can clearly notice the saturation in the detected signal while the laser frequency is scanning a resonance line of the resonator and when its injected power inside the resonator starts to be above the SBS threshold.

Therefore, a good performance close to the carrier can only be obtained at low optical input power, unless a specific set up can reduce the onset of these processes, while maintaining a high Q_{opt} . This could be possible if optical fibers of different materials are used together (different Brillouin gain frequencies, thus a reduced global Brillouin gain), or if the fiber material is locally changed (thermally or mechanically), and also when changing the fiber structure (e.g. increasing its core diameter...).

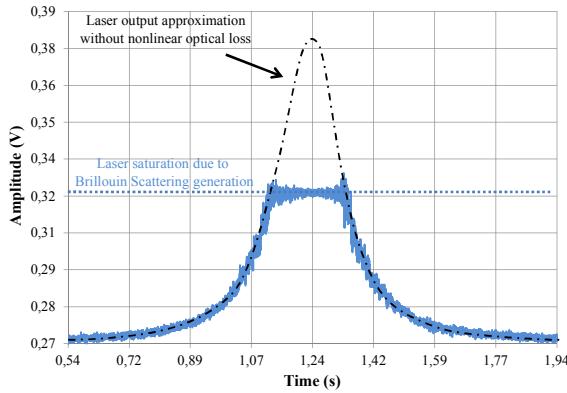

Figure 6. Visible laser carrier saturation, due to the Brillouin scattering generation, by measuring the photodiode DC voltage at the resonator third output, while the laser frequency is scanning a resonance line.

V. OEO PHASE NOISE MEASUREMENTS

Fig. 7 depicts the measured phase noise of a 10.2 GHz OEO realized with a FRR featuring a Q_{opt} factor of 3.5×10^9 (equivalent $Q_{\text{RF}} = 1.8 \times 10^5$) [9], and of a 12.5 GHz OEO realized with a CaF_2 disk resonator featuring a Q_{opt} factor of 1.4×10^8 (equivalent $Q_{\text{RF}} = 9 \times 10^3$). Compared to microwave oscillators having same Q_{RF} factors, these two oscillators feature a higher phase noise. This is due to the optical noise contribution which is still not completely optimized in spite of taking into account the remarks of paragraph IV. The peaks in the phase noise of the CaF_2 disk OEO may come from mechanical perturbations in the coupling using tapered fibers.

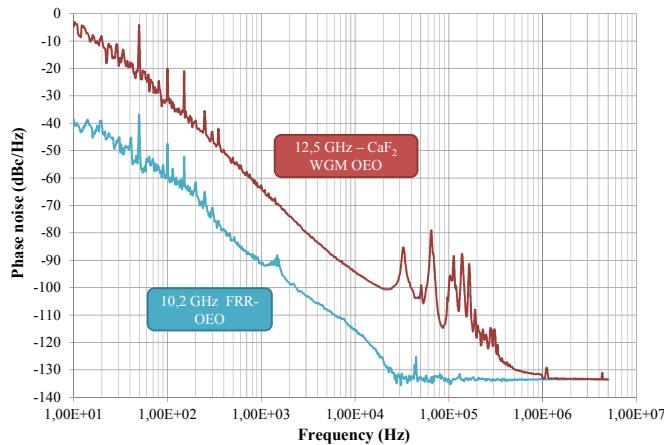

Figure 7. Phase noise of OEOs realized with a CaF_2 resonator (12.5 GHz) and a 20 meter long fiber ring resonator (10.2 GHz). Measurements are performed with an Agilent E5052 B signal source analyzer.

Work is in progress to reduce these contributions, particularly in the case of the FRR in which solutions exists to remove some of the nonlinear optical effects. In the case of the disk resonator, attempts to improve the phase noise will be first based on an improvement of the resonator Q_{opt} factor.

VI. CONCLUSION

Noise in optoelectronic oscillators based on fiber ring and whispering gallery modes resonators has been studied in this paper. It has been confirmed through theoretical and experimental studies that the phase noise in these OEOs is generally dominated by noise processes occurring in the optical part of the system. In resonator based OEOs, a correlation between the laser and the resonator frequency is required and a specific laser AM and FM noise conversion processes may be induced if this condition is not respected. Also, the high optical Q factors of these resonators can lead to the generation of some nonlinear optical scattering effects at low laser input optical power. Working at low enough optical power is mandatory in order to avoid this noise type and to get a good OEO phase noise. Further investigations include the design of new high Q optical resonators, immunized against nonlinear optical effects.
