Abstract

The flow past a sphere rotating about an axis aligned with the streamwise direction is numerically investigated. The dynamics is governed by the incompressible Navier–Stokes equations and depends on two control parameters: the Reynolds number Re and rotation rate Ω . The present investigation systematically covers the range $Re \leq 350$ and $\Omega \leq 2$. First, the axisymmetric steady base flow (whether stable or not) is computed for all values of the control parameters. Then, after linearization of the equations about the base flow, the growth rates and frequencies of the leading eigenmodes are obtained. Fully nonlinear direct numerical simulations yield the detailed flow fields and hydrodynamic forces acting on the sphere. Different wake modes (low-frequency periodic helical, quasiperiodic shedding and high-frequency periodic helical) are identified and their characteristic frequencies precisely determined.

Keywords: wake, vortex shedding, drag, lift, quasiperiodic, bifurcation, instability

1. Introduction

At moderate Reynolds numbers, our understanding of the wake dynamics for a fixed sphere in uniform upstream flow is by now fairly complete. More complex scenarios prevail when additional effects are taken into account, such as shear in the oncoming flow, the presence of a wall, rotation of the obstacle or non-spherical shapes. Most of these configurations break the axisymmetry of the formulation. The purpose of the present investigation is to shed new light on the dynamics prevailing in a situation governed by two control parameters but preserving the axisymmetry of the problem: the wake of a sphere rotating about an axis aligned with the incident flow.

The bifurcation scenario followed by the wake of a fixed sphere in uniform upstream flow is now fairly well established, both experimentally and numerically (Nakamura, 1976; Sakamoto and Haniu, 1995; Johnson and Patel, 1999; Ghidersa and Dušek, 2000; Schouveiler and Provansal, 2002; Thompson et al., 2001): at low Reynolds numbers a steady, axisymmetric flow prevails; beyond a first critical Reynolds number, $Re_1 \simeq 212$, the flow bifurcates and a steady non-axisymmetric wake with planar symmetry is selected; beyond a second critical Reynolds number, $Re_2 \simeq 272$, periodic shedding sets in, but conserves the symmetry plane. At still larger Reynolds numbers, the planar symmetry is broken (Mittal, 1999), and the wake becomes progressively disordered and turbulent (Ormières and Provansal, 1999; Tomboulides and Orszag, 2000; Constantinescu and Squires, 2004). Careful measurements of the hydrodynamic forces (drag, lift, torque) acting on the sphere allow characterization of these different flow régimes (Maxworthy, 1965; Benjamin, 1993; Bouchet et al., 2006).

In many situations of practical interest, the incoming flow is not perfectly uniform. In the presence of shear (Dandy and Dwyer, 1990; Kurose and Komori, 1999; Kim et al., 2005; Kim, 2006; Bagchi and Balachandar, 2002a), strain (Bagchi and Balachandar, 2002b) or stratification (Hanazaki, 1988), the lack of

*E-mail: benoit.pier@ec-lyon.fr

axisymmetry modifies the bifurcation scenario and the hydrodynamic forces. If the obstacle is not fixed but allowed to interact with the flow, it may rotate and rise or fall under the action of torque and gravity (Bagchi and Balachandar, 2002a; Jenny et al., 2003; Jenny and Dušek, 2004; Jenny et al., 2004; Veldhuis et al., 2005; Fernandes et al., 2007; Ern et al., 2012). Numerous studies have also addressed the wake of deformable bodies such as bubbles or droplets (Legendre and Magnaudet, 1997; Kurose et al., 2001; Magnaudet et al., 2003; Legendre et al., 2006; Sugioka and Komori, 2007; Rastello et al., 2009, 2011).

Of particular interest in the present context are the flows around axisymmetric but non-spherical bodies. When the symmetry axis of disks or ellipsoids is aligned with the incident flow, the problem remains axisymmetric and the wake dynamics depend not only on the Reynolds number but also on the aspect ratio. For the extreme case of an infinitely thin disk, Fabre et al. (2008) have identified new vortex shedding modes and introduced a symmetry-based model to explain this scenario and predict the evolution of the lift force. For a thicker disk, yet more régimes have been found (Auguste et al., 2010). Meliga et al. (2009) use the leading eigenmodes derived from global stability theory and develop a weakly nonlinear model that accurately predicts the sequence of bifurcations for a thin disk. The efficiency of this model relies, among other things, on the fact that the leading eigenmodes have very similar growth rates, favouring (weak) nonlinear interactions which control the complex bifurcation scenario. Inspired by these findings, the present investigation revisits the configuration used by Kim and Choi (2002): the wake of a sphere rotating about a streamwise oriented axis. The rotation of the sphere introduces a chirality in the problem but does not break the axisymmetry. The growth rates of the leading eigenmodes depend on two parameters, Reynolds number and rotation rate, and competition between these is expected to lead to rich dynamics, possibly amenable to weakly nonlinear interaction models.

The paper is organized as follows. After formulating the problem and presenting the numerical methods in §2, axisymmetric base flows and their linear stability properties are discussed in §3. The different finite-amplitude vortex shedding régimes and associated hydrodynamic forces are presented in §4. Finally, §5 summarizes the results.

2. Problem formulation and numerical method

The study is carried out using the incompressible Navier–Stokes equations. The Reynolds number is defined as $\text{Re} = U_\infty D / \nu$, where U_∞ is the free-stream velocity, D the sphere diameter and ν the kinematic viscosity.

Throughout this investigation, cylindrical coordinates are used with r , θ and z (u , v and w) denoting radial, azimuthal and axial coordinates (velocities) respectively. The z -axis is aligned with the free-stream velocity and the origin is at the center of the sphere. For later use, a Cartesian (x, y, z) -frame is also defined. Using non-dimensional variables based on U_∞ and D , the total velocity and pressure fields are denoted by $\mathbf{u}(r, \theta, z, t)$ and $p(r, \theta, z, t)$ respectively and are governed by the momentum and continuity equations,

$$\partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} + \nabla p = \frac{1}{\text{Re}} \Delta \mathbf{u} + \mathbf{f}, \quad (1)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2)$$

with boundary conditions

$$u = v - \Omega r = w = 0 \quad \text{for} \quad r^2 + z^2 = 1/4, \quad (3)$$

$$u = v = w - 1 = 0 \quad \text{for} \quad r \rightarrow \infty \quad \text{or} \quad z \rightarrow \pm\infty. \quad (4)$$

Here Ω is the non-dimensional rotation rate (based on U_∞ and D) of the sphere about the z -axis. The dynamics of the rotating-sphere wake are then completely determined by two control parameters, Re and Ω .

The numerical method closely follows the technique successfully implemented for studying the non-rotating sphere wake (Pier, 2008). An immersed boundary method (Fadlun et al., 2000; Mittal and Iaccarino, 2005; Zhang and Zheng, 2007) is used, whereby the presence of the sphere is enforced through the externally applied volume force \mathbf{f} in the momentum equation (1). Thus, the entire space is assumed to be filled

Figure 1: Flow structure of the basic axisymmetric wake for (a) $Re = 150$ and $\Omega = 1$, (b) $Re = 250$ and $\Omega = 1$, (c) $Re = 250$ and $\Omega = 2$. Solid (dashed) isolines correspond to positive (negative) values of azimuthal vorticity, spaced by 0.5.

Figure 2: (a) Growth rate ω_i and (b) frequency ω_r of the leading eigenmode for axisymmetric basic wakes, computed for $\Omega = 0.0, 0.2, \dots, 2.0$ and $Re = 100, 125, \dots, 400$.

with fluid and the body force ensures that the boundary conditions (3) of a rotating sphere are met. All flow fields are Fourier-expanded in the azimuthal coordinate θ , while the (r, z) -plane is discretized on a Cartesian grid using finite-differences in z and Chebyshev collocation points in r . The time-marching algorithm uses a second-order accurate predictor-corrector fractional-step method, similar to (Hugues and Randriamampianina, 1998).

3. Axisymmetric base flows and linear stability

Axisymmetric wakes have been computed by retaining only the axisymmetric component in the azimuthal Fourier expansions. For all Reynolds numbers and rotation rates considered in the present study, the sphere wakes were found to approach a steady state when time-marching the governing equations (1,2).

The structure of the basic axisymmetric wake for different values of the control parameters is illustrated in figure 1 by isolines of the azimuthal vorticity $\omega_\theta = \partial_z u - \partial_r w$.

The linear stability of these axisymmetric wakes is probed by computing the response to a non-axisymmetric perturbation. Here only a single non-axisymmetric azimuthal Fourier component is retained in the

Figure 3: Temporal evolution of energy E_1 (arbitrary units) contained in first azimuthal harmonic for $\Omega = 0.0, 0.4, \dots, 2.0$ and $Re = 250$ (a), $Re = 325$ (b).

expansions of the flow fields, and the Navier–Stokes equations are linearized around the previously computed basic flow. Growth rates and frequencies of the most unstable modes are then derived from the time-series of selected flow components, recorded at a fixed spatial location. Such a flow component f is expected to evolve as $f \propto \exp(-i\omega t)$, where ω is the complex eigenvalue associated with the mode. The growth rate ω_i is then obtained by a linear fit of $\log|f|$, while the frequency ω_r is obtained by spectral analysis of the compensated $f \exp(-\omega_i t)$. Thus, the growth rates ω_i and frequencies ω_r are obtained for the most unstable mode at each setting of the control parameters Re and Ω . These values are shown in figure 2. It is observed that two distinct mode types lead to instability, depending on the control parameters: at moderate rotation rates and low Reynolds numbers, the instability is dominated by a “slow” mode, the frequency of which scales nearly linearly with the sphere rotation rate Ω . In contrast, at higher parameter values, a “fast” mode dominates, whose frequency is approximately independent of Ω . Similar behaviour is observed for the nonlinear dynamics, as discussed below.

4. Nonlinear dynamics

To investigate the nonlinear dynamics, a finite number of azimuthal Fourier harmonics are retained and the direct numerical simulations take into account the nonlinear coupling between all these modes. When starting integration, the initial condition is chosen as the previously computed axisymmetric base flow with a small non-axisymmetric perturbation. In situations where this axisymmetric flow is unstable, the non-axisymmetric perturbation starts to grow exponentially in time. After a transient growth phase, nonlinear effects come into play that limit the amplitude growth. At large times, the system is found to approach a periodic or quasiperiodic régime, or to display irregular behaviour.

Monitoring the temporal evolution of the energy E_1 contained in the first azimuthal harmonic illustrates the development of non-axisymmetric components in the sphere wake. In Figure 3, the energy content E_1 is plotted for $0 \leq \Omega \leq 2$ and $Re = 250$ and 325 . For the wakes corresponding to these plots, after entering a finite-amplitude régime, the energy E_1 is seen to reach either a constant value or to converge towards a state of periodic oscillations. At larger values of the Reynolds number, irregular oscillations may also be found to persist indefinitely.

To further characterize the flow dynamics, the hydrodynamic forces acting on the sphere have been computed. These forces are obtained by spatial integration of the volume force used in the immersed boundary method; there is no need to evaluate components of the stress tensor at the sphere surface. The drag coefficient C_z measures, in non-dimensional units, the component of the force acting in the z -direction aligned with the outer flow. The lift coefficients C_x and C_y are obtained by projection onto the x - and y -axes respectively, while the lateral force coefficient C_l is defined as $C_l = \sqrt{C_x^2 + C_y^2}$.

Figure 4: Temporal evolution of hydrodynamic forces for $Re = 225$ and $\Omega = 1$. C_z : drag; C_x and C_y : lift forces; C_l : transverse force. Initial condition consists up of the axisymmetric base flow with a small-amplitude non-axisymmetric perturbation.

Figure 5: Snapshot of vorticity fields in the helical régime at $Re = 225$ and $\Omega = 1$. Isolines of azimuthal vorticity in two orthogonal planes.

For axisymmetric wakes, all coefficients vanish except the drag C_z . In configurations where the axisymmetric base flow is unstable, the development of finite non-axisymmetric flow components is accompanied by a similar development of transverse forces, characterized by C_x and C_y (and C_l). The constant, periodic, quasiperiodic or irregular values taken by these hydrodynamic force coefficients characterize the associated wake dynamics.

4.1. Helical régime

The wake behaviour observed for $Re = 225$ and $\Omega = 1$ is typical of the dynamics prevailing after the first destabilization of the axisymmetric flow. Figure 4 illustrates the temporal evolution of the force coefficients, starting from the slightly perturbed (and unstable) axisymmetric base flow. After a transient régime characterized by growth of transverse force components, the wake is seen to approach a state of constant drag, slightly higher than for the base flow (figure 4a). Lift coefficients C_x and C_y display harmonic oscillations, out of phase by a quarter-period, while the magnitude of the lateral force C_l is observed to tend to a constant value (figure 4b). This is further illustrated by the time-trace in the (C_x, C_y) -plane (figure 4c): beyond the transient phase, a perfect circle is described at a constant angular speed.

The spatial structure of the wake flow is illustrated in figure 5, where isolines of the azimuthal vorticity are plotted for two orthogonal (x, z) - and (y, z) -planes.

Temporal spectral analysis of the force coefficients (as well as of any other flow components) demonstrates that this régime is characterized by a single frequency. For $Re = 225$ and $\Omega = 1$, the periodicity of the lift coefficients is obtained as $\omega_x = \omega_y = 0.31$. In fact, it can be shown that the entire wake is in a *helical* state, characterized by “solid-body” rotation of the flow field about the z -axis at constant angular speed. This means that the flow is steady in a frame of reference rotating about the z -axis at ω_x ($= \omega_y$). Note that the angular speed $\omega_x = \omega_y$ is well below the sphere rotation rate $\Omega = 1$.

4.2. Quasi-periodic vortex shedding

For $Re = 275$ and $\Omega = 0.8$, a different behaviour is obtained. Again, the development of non-axisymmetric components is accompanied by an increase in drag. But here, no steady state is reached: the drag coefficient

Figure 6: Temporal evolution of hydrodynamic forces for $\text{Re} = 275$ and $\Omega = 0.8$.

Figure 7: Snapshot of vorticity fields in the quasiperiodic régime at $\text{Re} = 275$ and $\Omega = 0.8$.

continues to oscillate (figure 6a). Lift coefficients C_x and C_y display quasiperiodic oscillations while the lateral force C_l fluctuates with the same periodicity as the drag (figure 6b). This behaviour leads to a more complex pattern in the (C_x, C_y) -plane, see figure 6(c). Temporal spectral analyses show that these signals are characterized by two distinct (and incommensurate) frequencies: $\omega_x = \omega_y = 0.21$ and $\omega_z = \omega_l = 0.62$. Indeed, C_z and C_l are periodic (with same frequency $\omega_z = \omega_l$) while C_x and C_y are quasiperiodic (displaying a combination of ω_z and ω_x).

A snapshot of the spatial structure of the associated vorticity fields is given in figure 7. This dynamics can be interpreted as a quasiperiodic vortex shedding régime, corresponding to the combination of a helical mode (“solid-body rotation” about the z -axis at ω_x) and vortex shedding waves travelling axially downstream (frequency ω_z).

4.3. High-frequency helical régime

For $\text{Re} = 300$ and $\Omega = 1$ a further wake behaviour is observed, representative of a third class of flow dynamics. After a relatively long transient, the system approaches a (single-frequency) periodic state. The drag C_z and the lateral force C_l reach constant values, while the lift coefficients C_x and C_y display harmonic oscillations in quadrature, leading to a circular time-trace in the (C_x, C_y) -plane (figure 8). This régime is again of periodic helical vortex shedding type, characterized by a single frequency $\omega_x = \omega_y = 0.90$. Note that the frequency of this “solid-body” rotation is quite closer to the sphere rotation rate Ω . Hence, this régime could be termed “high-frequency helical vortex shedding”.

The corresponding vorticity fields are illustrated for two orthogonal planes in figure 9. Although this régime is periodic and the flow fields would be steady in a frame rotating at ω_x around the z -axis, these vorticity fields closely resemble those prevailing in the quasiperiodic régime (see figure 7) and are rather different from those of the low-frequency helical régime (see figure 5). It is as if the axial vortex shedding and the helical “solid-body” rotation were locked together, or “frozen” (Kim and Choi, 2002).

4.4. Characteristic frequencies

For each Reynolds number and sphere rotation rate, the characteristic frequencies have been determined via temporal Fourier analyses of long time series of the force coefficients. The helical frequencies ω_x ($= \omega_y$)

Figure 8: Temporal evolution of hydrodynamic forces for $\text{Re} = 300$ and $\Omega = 1$.

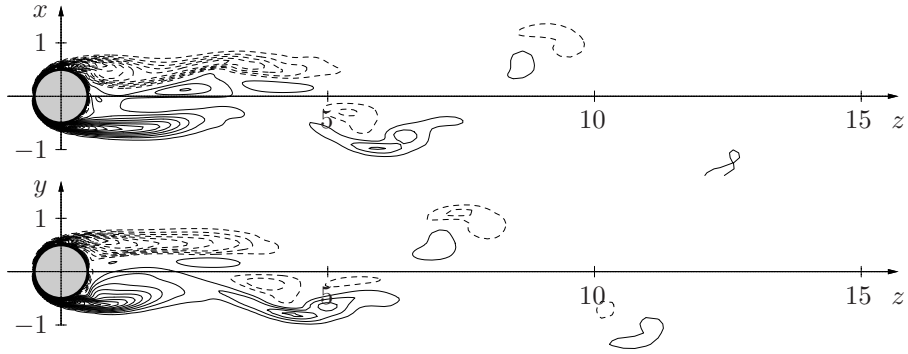

Figure 9: Snapshot of vorticity fields in the high-frequency helical régime at $\text{Re} = 300$ and $\Omega = 1$.

Figure 10: Characteristic frequencies prevailing in the rotating-sphere wake. (a) Frequencies $\omega_x = \omega_y$ dominating the fluctuations of the lift coefficients C_x and C_y . (b) Frequencies $\omega_z = \omega_l$ governing the oscillations of the drag and lateral force coefficients C_z and C_l . Solid curves correspond to low- or high-frequency helical régimes. Dashed curves indicate quasiperiodic vortex-shedding (or disordered) régimes.

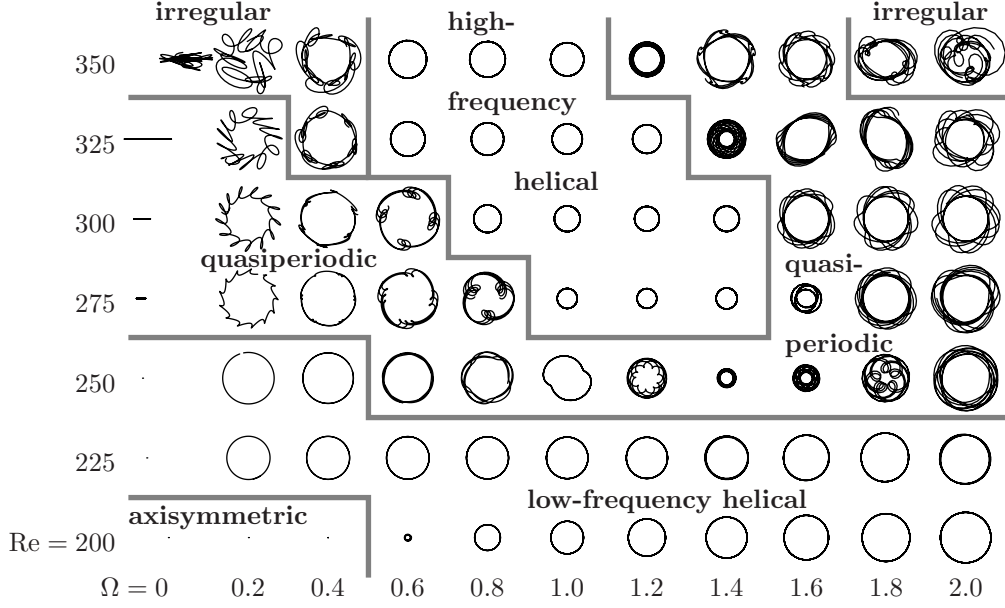

Figure 11: Map of the different régimes as a function of the control parameters.

are plotted in figure 10(a), while the axial frequencies $\omega_z (= \omega_l)$ are shown in figure 10(b). In these plots, solid curves correspond to low- and high-frequency modes while dashed curves indicate quasiperiodic (or disordered) vortex shedding. Note that helical frequencies dominating the fluctuations of the lift coefficients C_x and C_y are obtained for any non-axisymmetric flow, while the axial vortex-shedding frequencies governing the oscillations of the drag and lateral force coefficients C_z and C_l are only relevant in the quasiperiodic shedding régimes.

In figure 10(a), it is seen that ω_x displays an almost linear dependence on Ω in the low-frequency helical and quasiperiodic régimes. Transition from low-frequency helical to quasiperiodic vortex shedding hardly affects these values. In the high-frequency helical régimes, however, order of magnitude larger values for ω_x are obtained. The axial frequencies ω_z shown in 10(b), correspond more specifically to axially travelling vortex shedding waves and display only weak dependence on the rotation rate Ω .

5. Conclusion and discussion

Direct numerical simulations have been carried out in order to systematically cover the governing parameter space for sphere rotation rates $\Omega \leq 2$ and Reynolds numbers up to $Re = 350$. Figure 11 presents a map of the observed régimes characterized by the associated time-traces of the lift coefficients in the (C_x, C_y) -plane.

At low Reynolds numbers, the axisymmetric wake is stable. When the Reynolds number is increased, a low-frequency helical régime takes over, characterized by constant values of drag (C_z) and transverse force (C_l). The flow field is found to rotate around the z -axis at constant frequency $\omega_x = \omega_y$ without deformation. Indeed, in such a rotating frame, the flow field would be time-independent. The rate ω_x at which the wake rotates around the axis is found to increase almost linearly with the sphere rotation rate Ω , and this régime can be viewed as a continuous deformation, through axial rotation, of the well-documented steady planar symmetric state for non-rotating spheres in the range $Re_1 < Re < Re_2$, with $Re_1 \simeq 212$ and $Re_2 \simeq 272$ (Johnson and Patel, 1999; Mittal, 1999; Ghidersa and Dušek, 2000; Schouveiler and Provansal, 2002).

A second bifurcation occurs when the Reynolds number is increased, leading to a quasiperiodic state which can be interpreted as a modulation (at a second incommensurate frequency ω_z) of the previous helical régime. A rotating frame in which the flow field would be steady no longer exists. Again, this régime can be viewed as the continuation through axial rotation of the periodic vortex shedding régime that prevails

for $Re > Re_2 \simeq 272$ for a non-rotating sphere. In the non-rotating case, onset of vortex shedding occurs through a Hopf bifurcation (Schouveiler and Provansal, 2002). Here, our results indicate that this remains true along the entire boundary separating the low-frequency helical wakes from the quasiperiodic wakes. However, many more computations would be necessary to prove that the amplitude of the second-frequency component scales as the square-root of the distance to this critical boundary.

The third type of behaviour, termed the high-frequency helical régime, occurs at still larger Reynolds numbers. This periodic régime does not have an analogue in the non-rotating $\Omega = 0$ case. While the transition from the low-frequency helical to the quasiperiodic régime is a continuous process, the switching from quasiperiodic to high-frequency helical régimes is discontinuous in the control parameters. Indeed, the dominant ω_x -frequency prevailing in the wake abruptly increases while the amplitude of the transverse forces (C_l) suddenly drops. The nature of the associated bifurcation remains unclear. Despite several attempts at slowly modifying one of the control parameters, no hysteresis was found.

At yet larger Reynolds numbers, irregular states have been observed. No systematic survey of the parameter space beyond $Re = 350$ has been attempted since this would require much finer spatial meshes to obtain reliable results.

In future work, it would be interesting to address the nature of the bifurcations between the different régimes in more detail and to test whether the theory of Meliga et al. (2009) can be adapted to the present configuration.
