Abstract

Using median-unbiased estimation based on Augmented-Dickey-Fuller (ADF) regressions, recent research has questioned the validity of Rogoff's "remarkable consensus" of 3-5 year half-lives of deviations from PPP. The confidence intervals of these half-life estimates, however, are extremely wide, with lower bounds of about one year and upper bounds of infinity. We extend median-unbiased estimation to the DF-GLS regression of Elliott, Rothenberg, and Stock (1996). We find that combining median-unbiased estimation with this regression has the potential to tighten confidence intervals for the half-lives. Using long horizon real exchange rate data, we find that the typical lower bound of the confidence intervals for median-unbiased half-lives is just under 3 years. Thus, while previous confidence intervals for median-unbiased half-lives are consistent with virtually anything, our tighter confidence intervals are inconsistent with economic models with nominal rigidities as candidates for explaining the observed behavior of real exchange rates and move us away from solving the PPP puzzle.

1. Introduction

During the past decade, a number of studies using long-horizon data have changed the focus of research on Purchasing Power Parity (PPP) from the narrow question of whether or not the real exchange rate contains a unit root to the broader question of the persistence of deviations from PPP. Abuaf and Jorion (1990), Diebold, Husted and Rush (1991), Glen (1992), Cheung and Lai (1994), and Lothian and Taylor (1996) all reach the same conclusion: the hypothesis of a unit root in real exchange rates can be rejected and the half-life of the PPP deviations varies between 3 and 5 years.¹ In his well-known survey, Rogoff (1996) discusses the “remarkable consensus” of these half-lives and coins the phrase “purchasing power parity puzzle” to describe the difficulty in reconciling these slow speeds of adjustment with the high short-run volatility of real exchange rates. The slow speed of adjustment is problematic for models with nominal rigidities which predict faster convergence to PPP of 1 to 2 year half-lives.

Although the 3 to 5 year consensus has become the common starting point in attempts to “solve” the PPP puzzle, the consensus itself is problematic. The studies cited above generally calculate least squares point estimates of the half-lives from first order autoregressive processes. Point estimates alone do not provide a complete measure of persistence. Cheung and Lai (2000) supplement point estimates with conventional bootstrap confidence intervals in order to measure the precision of the half-life estimates. Their confidence intervals, however, are not valid under the unit root null and, even if long run PPP holds, are biased downwards in small samples.² In addition, the least squares estimates of half-lives are biased downward, providing an inaccurate picture of the speed of adjustment to PPP.

Two recent papers address these issues using classical estimation techniques.³ Murray and Papell (2002) use the median-unbiased estimation methods of Andrews (1993) and the approximately median-unbiased methods of Andrews and Chen (1994) for Dickey-Fuller (DF) and Augmented Dickey-Fuller (ADF) regressions respectively. They calculate point estimates and confidence intervals for half-lives of PPP deviations for post-1973 quarterly

¹ Engel (2000) raises the question of whether these rejections are caused by size distortions.

² See Kilian (1998), Hansen (1999), Kilian (1999), and Inoue and Kilian (2002) for further discussion of bootstrapping autoregressive processes with unit roots or near unit roots.

³ See Kilian and Zha (2002) for a Bayesian perspective.

1
2
3 US dollar real exchange rate data for 20 countries. Rossi (2005) uses the confidence interval
4 estimation methods of Elliott and Stock (2001) and Hansen (1999) to calculate bias-
5 corrected confidence intervals for half-lives of PPP deviations for 17 floating real exchange
6 rates. Despite the differences in methodology, the results of the two papers are nearly
7 identical. The lower bounds of the 95% confidence intervals are mostly just above one year,
8 while the upper bounds are generally infinite. These results, however, do not help “solve”
9 the PPP puzzle. While the lower bounds are consistent with relatively fast convergence to
10 PPP as predicted by models with nominal rigidities, the upper bounds are consistent with a
11 unit root in real exchange rates and no convergence to PPP even in the very long run.⁴
12
13
14
15
16
17
18

19 These results indicate that univariate methods are unlikely to be informative about the
20 persistence of post-1973 real exchange rates.⁵ Focusing on post-1973 rates, moreover,
21 ignores most of the available data. While long-horizon data mixes fixed and flexible
22 nominal exchange rate regimes and, therefore, cannot answer the question of whether PPP
23 would hold with a century long flexible nominal exchange rate regime, it can potentially
24 answer the question of whether PPP has held over the last century.
25
26
27
28
29

30 This potential has been greatly facilitated by the work of Taylor (2002), who develops
31 real exchange rate data for over 100 years for 20 countries. An important contribution of
32 Taylor’s work is that, for the first time, it is possible to investigate real exchange rate
33 persistence using long-horizon data with approximately the same set of advanced countries
34 as is commonly used in studies with post-1973 data.
35
36
37
38

39 The purpose of this paper is to improve inference on the persistence of PPP deviations in
40 long-horizon real exchange rates. We extend the methodology developed by Andrews
41 (1993) and Andrews and Chen (1994) for Dickey-Fuller and Augmented Dickey-Fuller
42 regressions, respectively, to the DF-GLS regression proposed by Elliott, Rothenberg, and
43 Stock (1996). We compute median-unbiased and approximately median-unbiased point
44 estimates and confidence intervals for half-lives of PPP deviations for DF-GLS regressions.
45
46
47
48
49

50
51 ⁴ Taylor (2001) and Imbs et al. (2005) investigate time aggregation and sectoral heterogeneity bias,
52 respectively, although their results remain controversial. We treat the CPI based real exchange rate as the
53 object of interest, and thus dealing with these potential sources of bias is beyond the scope of this paper.

54 ⁵ Panel methods have been used extensively to test for unit roots in post-1973 real exchange rates. Murray and
55 Papell (2005), Choi, Mark and Sul (2006) and Lopez (2008) examine real exchange rate persistence with panel
56 methods. Elliott and Pesavento (2006) use univariate unit root tests with stationary covariates to investigate
57 PPP in post 1973 data. These covariate augmented unit root tests have not yet been extended to calculate
58 unbiased half-life estimates.
59
60

1
2
3 We use Taylor's (2002) data for 9 annual US dollar real exchange rates for developed
4 countries with over a century of data for each country. To our knowledge, this is the first
5 paper which corrects for median-bias in DF-GLS regressions.
6
7

8
9 Andrews (1993) shows how to calculate median-unbiased point estimates and
10 confidence intervals for half-lives in DF regressions, and tabulates the bias for a range of
11 parameter values and sample sizes. We conduct a similar tabulation for DF-GLS
12 regressions. We find that, while the estimates from DF-GLS regressions are still biased
13 downwards, the extent of the bias is much less than in Dickey-Fuller regressions due to the
14 absence of deterministic terms. In addition, the confidence intervals for median-unbiased
15 estimators are tighter for DF-GLS regressions than for ADF regressions. This demonstrates
16 the potential for sharper inference on the persistence of shocks to the real exchange rate than
17 has been previously available.
18
19

20
21 We proceed to calculate median-unbiased point estimates and confidence intervals for
22 half-lives of PPP deviations for the 9 long-horizon real exchange rates. The point estimates
23 of the half-lives are considerably larger than what would be expected based on Rogoff's 3-5
24 year "consensus". The median value (among the 9 rates) based on the DF-GLS regression is
25 7.46 years, with a median 95% confidence interval of [2.86, 21.24] years.
26
27

28
29 The major result in both Murray and Papell (2002) and Rossi (2005) is that, for quarterly
30 post 1973 real exchange rates, the confidence intervals of the half lives were so wide as to
31 be consistent with virtually anything.⁶ We find a very different result here. The median
32 lower bound of our 95% confidence intervals is just under 3 years. Since the half-lives that
33 would be predicted from models with nominal rigidities are generally 1 to 2 years, our
34 results are inconsistent with the predictions from such models. While we obtain greater
35 information about the persistence of shocks to the real exchange rate, the PPP puzzle
36 becomes more problematic.

52 **2. Median-Unbiased Estimation in DF-GLS Regressions.**

53
54

55
56 ⁶ Murray and Papell (2002) also analyze 6 long horizon (1900-1996) real exchange rates, but the set of
57 counties is non overlapping with the series used here, and they are constructed with WPIs rather than CPIs as
58 in Taylor (2002).
59
60

Murray and Papell (2002) use the median-unbiased techniques of Andrews (1993) and Andrews and Chen (1994) to compute point estimates and confidence intervals for PPP half-lives. Since these estimates are based on ADF regressions, they do not optimally exploit the sample information. We propose an extension of the Andrews (1993) and Andrews and Chen (1994) methodology to the DF-GLS regression. The objective here is to obtain tighter confidence intervals than those of Murray and Papell (2002) to potentially shed more light on the PPP puzzle.

The extension of median-unbiased estimation to DF-GLS regressions is straightforward. Andrews' (1993) exactly median-unbiased estimator is based on DF regression

$$q_t = c + \alpha q_{t-1} + u_t, \quad (1)$$

whereas the Andrews and Chen's (1994) approximately median-unbiased estimator is based on the ADF regression

$$q_t = c + \alpha q_{t-1} + \sum_{i=1}^k \phi_i \Delta q_{t-i} + u_t, \quad (2)$$

where k lagged differences are included to account for serial correlation.⁷

Instead of working with the data in levels as in the ADF regressions, we simply work with the GLS demeaned (or detrended) data in the auxiliary DF-GLS regression

$$q_t^\mu = \alpha q_{t-1}^\mu + \sum_{i=1}^k \phi_i \Delta q_{t-i}^\mu + u_t, \quad (3)$$

where q_t^μ is the GLS demeaned real exchange rate. That is, $q_t^\mu = q_t - \tilde{\beta} z_t$, where $z_t = 1$,

$\tilde{\beta} = \left(\sum \tilde{z}_t^2 \right)^{-1} \sum \tilde{z}_t \tilde{q}_t$, $\tilde{q}_t = (q_1, (q_2 - \alpha q_1), \dots, (q_T - \alpha q_{T-1}))'$, $\tilde{z}_t = (1, (1 - \alpha), \dots, (1 - \alpha))'$,

$\alpha = 1 + c/T$, and $c = -7$.⁸ Since deterministic terms have been removed by GLS demeaning, none are present in the above regression.⁹ When $k = 0$, as in Andrews (1993),

⁷ The regression with only a constant and a lagged dependent variable is Case 2 in Andrews (1993). Cases 1 and 3 have no deterministic regressors, and a constant and time trend respectively. Since we are interested in the strict interpretation of PPP, for our purposes Case 2 is appropriate.

⁸ We note that the α s in equations (2) and (3) are in general not the same, but we use the same notation for convenience.

⁹ Again, since we are interested in the strict interpretation of PPP, we do not allow for deterministic time trends, although doing so is straightforward.

1
2
3 the median-unbiased estimator is exact, and when $k > 0$, as in Andrews and Chen (1994), the
4 median-unbiased estimator is approximate.¹⁰
5
6
7

8 9 *2.1 Exactly Median-Unbiased Estimation*

10 We compute our exactly median-unbiased estimator for equation (3) with $k = 0$ for the
11 sample sizes considered by Andrews (1993). We also report 90% confidence intervals.
12 Specifically, for each value of α , we generate 10^5 AR(1) processes with *iid* Gaussian
13 innovations. To find the median-unbiased estimator, we find the value of α such that the
14 median of the least squares estimator is equal to the least squares estimate. For example, if
15 α_{LS} , the least squares estimate of α , is 0.915 and $T + 1 = 125$, then α_{MU} , the median-
16 unbiased estimate of α based on the DF-GLS regression, is 0.930. A similar exercise leads
17 to the construction of confidence intervals. Our estimator is reported in the top panel of
18 Table 1, and Andrews' estimator, based on equation (1), is reported in the bottom panel of
19 Table 1.¹¹
20
21
22
23
24
25
26
27

28 The median-unbiased estimator of α in the AR(1) case is only exact if the distribution
29 of the innovations is correctly specified. If the errors are non Gaussian, which they are
30 likely to be in most economic time series, then the above procedure will not produce exactly
31 median-unbiased estimates. However, Andrews (1993) demonstrates that the median-
32 unbiased estimator is quite robust to departures from Normality. Specifically, if the error
33 terms are skewed and kurtotic, but have finite variance, then the approximation error
34 resulting from incorrectly assuming Gaussian errors is quite small.
35
36
37
38
39
40

41 Two features of Table 1 are important to highlight here. First, while median-bias is
42 present in the least squares estimator of α in DF-GLS regressions, it is not as severe as the
43 bias in ADF regressions. This accords with intuition since bias worsens as the number of
44 deterministic regressors increases. The auxiliary DF-GLS regression contains no
45 deterministic terms, while the ADF regression contains a constant. Second, the confidence
46 intervals from the DF-GLS regressions are tighter than from the ADF regressions.
47
48
49
50
51

52
53
54 ¹⁰ See Andrews and Chen (1994) and Murray and Papell (2002) for further details concerning the computation
55 of approximately median-unbiased estimators.

56 ¹¹ While our subsequent empirical application reports 95% confidence intervals, we report 90% confidence
57 intervals in Table 1 in order to directly compare our estimator to Andrews' estimator, for which he does not
58 report 95% confidence intervals.

60

Uniformly, the lower bounds of the confidence intervals for the median-unbiased estimator of α are higher in the DF-GLS regressions than in the ADF regressions. Similarly, with only a few exceptions when $T + 1 = 40$, the upper bounds from the DF-GLS regressions are higher than from the ADF regressions. Even though both the upper and lower bounds are higher, the confidence intervals are uniformly tighter in the DF-GLS case. This demonstrates that our proposed methodology has the potential to extract more information on the persistence of shocks to real exchange rates than it has been previously available.

2.2 *Approximately Median-Unbiased Estimation*

When $k > 0$, even if the distribution of the innovations is correctly specified, the median-unbiased estimator is no longer exact, but approximate. In addition, the half-life, which is based on the impulse response function, is a nonlinear transformation of an approximately median-unbiased estimate, and is therefore biased. In this subsection, we conduct a simulation study of the half-life estimate to determine how our proposed half-life estimator performs relative to that of Andrews and Chen (1994), in terms of bias and precision.

We consider four values of α : 0.85, 0.90, 0.95, and 1. For each value of α , we generate multiple parameterizations, either 2nd or 3rd order autoregressions. The true half-lives of all the parameterizations we consider range from 3.3 years to infinity. For each parameterization, we generate 10^5 artificial AR processes with *iid* Gaussian innovations and compute the approximately median-unbiased estimate of the half-life, as well as the 95% confidence interval, using our proposed methodology, as well as that of Andrews and Chen (1994). The half-life is computed directly from the impulse response function, and is defined as the number of periods required for the impulse response function to fall permanently below one half. In the simulations, the value of k is set to its true value at each iteration, although in practice it would have to be estimated. The results are reported in Table 2. Our estimator is reported in columns 3 and 4, with those of Andrews and Chen in the last two columns.

There are three main features of Table 2 worth noting. First, although not severe, our point estimate of the half-life is downward biased for every data generating process we consider. Second, the bias in our point estimator is greater than the bias of the Andrews and Chen (1994) estimator. Third, our 95% confidence intervals are tighter than those of

1
2
3 Andrews and Chen (1994) in every case and are closer to the true value of the half life. Our
4 lower bounds are always higher and, except for the case where the true half-life is infinity,
5 our upper bounds are always lower. The confidence interval of the half-life provides
6 essential information as it accounts for the variability of the estimate, allowing for a more
7 complete comparison of the persistence of shocks to the exchange rate with the predictions
8 from economic models than would be obtained from the point estimates alone.¹² Our 95%
9 confidence intervals as well as those of Andrews and Chen (1994) have the correct rate of
10 coverage by construction, Hence, the narrowing of the confidence interval confirms a gain
11 in precision due to the absence of deterministic term in our method.¹³ By combining the gain
12 in efficiency from the DF-GLS regressions with the median unbiased technique, our
13 proposed methodology leads to notably tighter confidence intervals than those computed
14 from the Andrews and Chen (1994) methodology, and demonstrates the ability to gain more
15 information regarding the PPP puzzle when the median-unbiased estimator is only
16 approximate.

30 **3. Empirical Results: The Persistence of Shocks to the Real Exchange Rate**

31 Taylor (2002) collects nominal exchange rate and price level data through 1996 for 20
32 countries, each for over 100 years, yielding 19 US dollar denominated real exchange rates.
33 The price levels are consumer price indices or, if not available, GDP deflators. We extend
34 Taylor's data through 1998, and omit Argentina, Brazil, and Mexico, in order to focus solely
35 on developed countries. This leaves us with 16 dollar denominated real exchange rates:
36 Australia, Belgium, Canada, Denmark, Finland, France, Germany, Italy, Japan, the
37 Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, and the United Kingdom. The
38 data begin as early as 1870, and exact starting dates for each real exchange rate are provided
39 in Table 3.
40
41
42
43
44
45
46
47

48 Before we compute half-lives, we must first address the issue of structural change. It is
49 quite possible, even likely, that a more than century long real exchange rate spanning many
50 different nominal exchange rate regimes will exhibit structural change. Furthermore, the
51 relationship between structural change and the median-bias of least squares estimates of α
52
53
54
55

56 ¹² Using a different methodology, Rossi (2005) only reports confidence intervals for half-lives.

57 ¹³ The gain in precision leads to a smaller variance, hence narrower confidence intervals.
58
59
60

1
2
3 is not yet fully understood. So that we can focus only on persistence, rather than persistence
4 in the presence of structural change, we only estimate half-lives for those real exchange
5 rates where there is evidence that structural breaks do not occur.
6
7

8
9 How can we test for the absence of structural change? We use the analytical results in
10 Perron (1989), who established that the presence of structural change lowers the power of
11 tests for a unit root when structural change is ignored, and the simulation evidence of Papell
12 and Prodan (2007), who show that, in the context of models with two breaks, structural
13 change causes a sharp decrease in power even if there are two equal breaks of opposite sign.
14 We use these results to determine which of our 16 real exchange rates can be analyzed
15 without having to account for structural breaks. Specifically, if the null hypothesis of a unit
16 root is rejected with a DF-GLS test, we conclude that the series is $I(0)$ and free of substantial
17 structural change, given the low probability of obtaining such a rejection when structural
18 change is present.¹⁴ Lopez, Murray, and Papell (2005) perform the DF-GLS unit root test
19 on our 16 real exchange rates, using the modified Akaike information criterion (MAIC) lag
20 selection of Ng and Perron (2001). They reject the unit root null at the 5% level for 9 dollar
21 denominated real exchange rates: Australia, Belgium, Finland, Germany, Italy, The
22 Netherlands, Spain, Sweden, and the UK. We will focus only on these 9 real exchange
23 rates.
24
25

26 We compute median-unbiased estimates of half-lives, and 95% confidence intervals, for
27 our remaining 9 stationary dollar denominated real exchange rates. As in our previous
28 simulation experiment, the half-life is defined as the number of years required for a unit
29 shock to dissipate by one-half, and is based directly on the impulse response function for
30 each real exchange rate. In Table 3, we report half-life estimates from DF-GLS
31 regressions where the lag length has been chosen using MAIC.
32
33

34 The point estimates of the half-lives in Table 3 are larger than what has been previously
35 reported in the literature. The median point estimate is 7.46 years, with 5 of the 9 half-lives
36 lying outside Rogoff's (1996) 3-5 year interval. This strengthens Murray and Papell's
37 (2002) conclusion that the literature surveyed by Rogoff (1996) does not accurately
38 represent the behavior of real exchange rates. Furthermore, the 95% confidence intervals
39
40

59
60

¹⁴ We note that if the series exhibits mild structural change, where the size of the break is small relative to the innovation standard deviation, then it is possible to reject the unit root null.

1
2
3 paint a much different picture of the persistence of deviations from PPP, vis-à-vis models
4 with nominal rigidities. The median values of the lower and upper bounds for half-lives of
5 PPP deviations are [2.86, 21.24] years and, with the exception of the US/Finland real
6 exchange rate, every lower bound is greater than 2 years.
7
8
9

10 An interesting feature of Table 3 is that the differences between α_{LS} and α_{MU} are quite
11 small. This is due to the lack of deterministic terms in the auxiliary DF-GLS regression.
12 Since the least squares half-life and the median-unbiased half-life are almost equal, one
13 might be tempted to simply estimate the OLS half-life from the DF-GLS regression and
14 forgo the median-bias correction. This is only a viable strategy if one is not concerned with
15 the variability of the estimate. The practice in this literature is to look at confidence
16 intervals for half-lives, not just point estimates. It is well known that constructing
17 confidence intervals based on α_{LS} is problematic. The resulting confidence intervals do not
18 have the correct coverage probabilities.¹⁵ However, the 95% median-unbiased confidence
19 intervals have known coverage by construction. Thus, if one is interested in well behaved
20 half-life confidence intervals, the fact that α_{LS} and α_{MU} are similar in the DF-GLS context
21 seems largely unimportant.
22
23
24
25
26
27
28
29
30
31
32

33 We would like to know whether the larger point estimates and lower bounds of the
34 confidence intervals that we report in Table 3 (compared with previous work) are solely
35 caused by differences in techniques, or if differences in the data also play a role. To assess
36 this, we also compute median-unbiased half-lives and 95% confidence intervals based on
37 ADF regressions with general-to-specific (GS) lag selection and using the methodology
38 proposed by Rossi (2005).¹⁶ These are reported in Table 4 and 5, respectively.
39
40
41
42
43

44 The point estimates of the half-lives from ADF regressions in Table 4 are also larger
45 than what has been previously reported in the literature. The median point estimate is 4.95
46 years, with 4 of the 9 half-lives lying outside Rogoff's (1996) 3-5 year interval. As with the
47
48
49

50
51 ¹⁵ Although we do not report them, we have constructed confidence intervals for α , and thus the half-life, based
52 on the OLS estimates. We used the delta-method, as well as both a parametric and a nonparametric bootstrap.
53 In every case, these confidence intervals are shifted to the left of those reported in Table 3, and the coverage
54 probabilities are much less than 95%.

55 ¹⁶ General-to-specific lag selection starts with a maximum lag, typically 8 in annual data, and does a sequence
56 of hypothesis tests to determine the significance of the coefficient on the longest lagged first difference term.
57 The procedure stops once a significant coefficient is found. See Hall (1994) and Ng and Perron (1995) for
58 further discussion.
59
60

1
2
3 DF-GLS regressions in Table 3, the 95% confidence intervals paint a much different picture
4 of the persistence of deviations from PPP than models with nominal rigidities. The median
5 values of lower and upper bounds for half-lives of PPP deviations are [2.92, 18.22] years
6 and, again with the exception of the US/Finland real exchange rate, every lower bound is
7 greater than 2 years.
8
9

10
11
12 The confidence intervals reported in Table 5 show that, while they all have very similar
13 coverage (close to 95%), our methodology leads to significantly lower upper bound. Indeed,
14 Rossi's median confidence intervals are [3.87, ∞), [3.46, ∞) using Elliott and Stock (2001)
15 and [5.72, ∞) and [6.38, ∞) using Hansen (1999), for the approximate and exact half life
16 respectively.
17
18
19

20
21 What emerges from juxtaposing Tables 3, 4 and 5 is the conclusion that our tighter
22 confidence intervals are both technique and data driven. Applying Andrews and Chen's
23 (1994) methodology to Taylor's (2002) longer data set results in much tighter intervals than
24 Murray and Papell (2002) report using the same technique for the post-1973 floating period.
25 A similar conclusion holds for several of Rossi's results, especially when using Elliott and
26 Stock (2001). It is also the case that our technique is partially responsible for the tightening
27 of the intervals as shown in Table 5. Yet, this point may not be immediately apparent from
28 Table 4 given that the median confidence interval is tighter than the median confidence
29 interval in Table 3. This is purely an artifact of lag selection. If $k_{MAIC} = k_{GS}$, the half-lives
30 are based on the DF-GLS regression are uniformly tighter than those based on the ADF
31 regression.¹⁷ In practice, the selected lags will differ, and if $k_{MAIC} \neq k_{GS}$, DF-GLS intervals
32 will not be uniformly tighter than ADF intervals, and vice-versa.
33
34
35
36
37
38
39
40
41
42

43 The sets of confidence intervals are narrower than what currently exists in the literature.
44 This is especially true for Tables 3 and 4. Using the largest available dataset, we are unable
45 to reconcile the predictions of exchange rate models with nominal rigidities with the
46 behavior of real exchange rates. Therefore, while tighter confidence intervals translate to
47 more information about the persistence of deviations from PPP, this increase in information
48 moves us away from solving the PPP puzzle.

4. Conclusion

Rogoff's (1996) "remarkable consensus" of 3-5 year half-lives of PPP deviations was based on studies using biased estimates that underestimate the magnitude of the PPP puzzle. Subsequent work using data for industrialized countries from the post-1973 flexible exchange rate period has obtained ambiguous conclusions. In Murray and Papell (2002) and Rossi (2005), the confidence intervals for half-lives are so wide that they are consistent with virtually anything. They range from a speed of reversion to PPP that is predicted by models with nominal rigidities (half-lives between 1 and 2 years) to the failure of PPP to hold in the long run (infinite half-lives).

In this paper, we investigate the purchasing power parity puzzle for Taylor's long-horizon data using more precise techniques. We extend the median-unbiased estimation methodology developed by Andrews (1993) and Andrews and Chen (1994) to the DF-GLS regression of Elliott, Rothenberg, and Stock (1996), and report both point estimates and confidence intervals. Our simulations show that combining the DF-GLS regression with the median unbiased correction leads to tighter confidence intervals than when median unbiased technique is applied to the widely used ADF regression

Rogoff (1996) argues that the combination of high short-run real exchange rate volatility and "glacial" speeds of mean reversion produce the PPP puzzle. Using the largest available data and an improved estimator, we find half-lives of PPP deviations to be much larger than his 3 – 5 year consensus. Another contribution of our work is to augment the information conveyed by point estimates with confidence intervals. In our earlier work, median-unbiased confidence intervals for PPP deviations were too wide to be informative. In this paper we see something much different. Similar to previous work, the upper bounds of the confidence intervals are quite high. In contrast to previous work, however, the lower bounds are also so high that we can rule out consistency with models based on nominal rigidities. While our quantitative results are very different from those reported by Rogoff, our conclusions are in some respects very similar. Using more precise techniques with a longer span of data moves us further away from solving the PPP puzzle.

¹⁷ We do not report these results here, except for the US/UK real exchange rate, where the selected lags are equal.

*Using the methodology of Andrews and Chen (1994).

Table 5. Comparison of the 95% Confidence Intervals for the Half Lives

Country	Elliott and Stock (2001)*		Hansen (1999)*		DF-GLS-MU**
	HL_a	HL^*	HL_a	HL^*	HL_{MU}
Australia	[3.87, ∞)	[3.77, ∞)	[5.72, ∞)	[6.24, ∞)	[4.36, ∞)
Belgium	[3.11, 50.32]	[2.94, 47.55]	[9.53, ∞)	[10.46, ∞)	[2.37, 12.67]
Finland	[4.11, 44.42]	[2.85, 30.82]	[6.43, ∞)	[7.15, ∞)	[1.27, 4.02]
Germany	[5.45, ∞)	[5.26, ∞)	[5.47, ∞)	[6.05, ∞)	[5.14, 72.86]
Italy	[0.77, 4.32]	[0.77, 4.32]	[6.13, ∞)	[6.48, ∞)	[2.24, 12.49]
Netherlands	[4.00, ∞)	[3.77, ∞)	[5.66, ∞)	[6.38, ∞)	[4.14, 34.29]
Spain	[4.73, ∞)	[4.45, ∞)	[8.07, ∞)	[8.94, ∞)	[3.03, 35.07]
Sweden	[3.53, 135.83]	[3.32, 127.99]	[5.47, ∞)	[6.18, ∞)	[2.76, 21.24]
UK	[3.67, ∞)	[3.46, ∞)	[3.82, ∞)	[4.43, ∞)	[2.86, 12.55]

We follow Rossi (2005)'s choice of tests and notation: $HL_a = \max\{\ln(0.5)/\ln(a), 0\}$ and $HL^ = \max\{\ln(0.5b(1))/\ln(a), 0\}$, where $b(1)$ is the "correction term". These half life were generated using Rossi(2005) programs
