Objective: To investigate the relationship between a fragmented QRS complex (fQRS) and parameters of infarct size (IS) and no reflow assessed by cardiac magnetic resonance (CMR) in patients with acute myocardial infarction.

Patients and methods: Patients with a fQRS were compared with patients without fQRS. CMR was performed in 246 consecutive patients within the week following the AMI. Early and late gadolinium-enhanced images were examined to assess IS and microvascular obstruction. Left ventricular ejection fraction (LVEF) and left ventricular volumes were also determined.

Results: 128 (52%) presented a fQRS on the first 12-lead ECG 36 hours post-AMI. Despite similar demographic, electrocardiographic and clinical features, patients with a fQRS were more likely to be male (85 vs. 72%, $p=0.018$) and had a higher systolic blood pressure on admission (141 vs. 132 mmHg, $p=0.005$). Furthermore, patients with a fQRS had a significantly lower LVEF, and larger IS than did patients without fQRS as assessed by CMR. Interestingly, myocardial perfusion abnormalities after infarction determined by first-pass perfusion images (microvascular obstruction=MO) and late perfusion images (persistent MO=PMO) were significantly more frequent in the fQRS group (Table 1). By multivariate logistic regression analysis, only infarct size (OR=0.456; 95% CI: 1.03-1.07, $p=0.001$) was an independent predictor of a fragmented QRS. Table 1: CMR data according to the presence of fQRS. N(%) or median (25th-75th).

Conclusions: This population-based study revealed that fragmentation of the QRS is associated with increased IS and myocardial perfusion abnormalities, and decreased LVEF. These findings give further support to the argument that fQRS is a reliable marker of infarct size and could explain its strong prognostic value after AMI.
