ABSTRACT: Evidence of global warming is now unequivocal, and studies suggest that it has started to influence natural systems of the planet, including the oceans. However, in the marine environment, it is well-known that species and ecosystems can also be influenced by natural sources of large-scale hydro-climatological variability. The North Atlantic Oscillation (NAO) was negatively correlated with the mean abundance of one of the subarctic key species *Calanus finmarchicus* in the North Sea. This correlation was thought to have broken down in 1996, however, the timing has never been tested statistically. The present study revisits this unanticipated change and reveals that the correlation did not break down in 1996 as originally proposed but earlier, at the time of an abrupt ecosystem shift in the North Sea in the 1980s. Furthermore, the analyses demonstrate that the correlation between the NAO and *C. finmarchicus* abundance is modulated by the thermal regime of the North Sea, which in turn covaries positively with global temperature anomalies. This study thereby provides evidence that global climate change is likely to alter some empirical relationships found in the past between species abundance or the ecosystem state and large-scale natural sources of hydro-climatological variability. A theory is proposed to explain how this might happen. These unanticipated changes, also called 'surprises' in climatic research, are a direct consequence of the complexity of both climatic and biological systems. In this period of rapid climate change, it is therefore hazardous to integrate meteo-oceanic indices such as the NAO in models used in the management of living resources, as it has been sometimes attempted in the past.

INTRODUCTION

There is unequivocal evidence that the world is warming at an unprecedented rate (Intergovernmental Panel on Climate Change 2007). Many studies suggest that global warming is having a discernible impact on biological and ecological systems of the biosphere, although it remains difficult to decipher the influence of natural climatic variability from global warming in many oceanic regions. For example, climatic variability related to the North Atlantic

Oscillation (NAO) strongly influences marine ecosystems, and a large range of physical and biological responses to the NAO have been documented (Ottersen et al. 2001).

In the North Sea, Fromentin & Planque (1996) provided evidence that year-to-year fluctuations in the state of the NAO and the abundance of the subarctic key-structural species *Calanus finmarchicus* around the British Isles were correlated negatively (Fromentin & Planque 1996). They also showed that the warm temperate species *C. helgolandicus* was posi-

*Email: gregory.beaugrand@univ-lille1.fr

tively related to the NAO although the relationship was weaker and with a 1 yr lag. Many hypotheses were proposed to explain the link between the NAO and these species: wind-induced turbulence and prey-predator interactions, the influence of temperature on competition between both species, bottom-up control, changes in biogeographical boundaries between both species, the volume of Norwegian Sea Deep Water in which *C. finmarchicus* is known to overwinter and the flow of the European shelf edge current (Heath et al. 1999, Beaugrand 2009).

Subsequently, Planque & Reid (1998) attempted to forecast the abundance of *Calanus finmarchicus* in the North Sea as a function of the NAO. Such forecasting would have been very helpful as the species is of great importance for higher trophic levels. However, the relationship between the NAO and the abundance of *C. finmarchicus* surprisingly broke down. This was unexpected as the relationship held for >30 yr. It ceased apparently from 1996, a year marked by one of the most extreme negative phases of the NAO (Planque & Reid 1998). The relationship has been recently revisited (Kimmel & Hameed 2008) but the timing from when it ceased was assumed to be 1996. The authors proposed an alternative model function of the abundance of *C. finmarchicus* the previous year and the state of the NAO. They tested the model for 3 periods: 1958 to 1980, 1958 to 1992, and 1981 to 2002 and showed that the model performed better during the period 1958 to 1980 than after. However, no analysis was performed to identify the timing of the shift in the correlation between the 2 variables. Kimmel & Hameed (2008) also hypothesised that the reduction in the abundance of the sub-arctic copepod was mainly related to increasing sea water temperatures.

The main objectives of the presented paper are:

(1) To investigate statistically when the negative correlation between *Calanus finmarchicus* and the NAO broke down,

(2) To demonstrate that sea temperature modulates the relationship between the state of the NAO and the abundance of *Calanus finmarchicus* in the North Sea, and

(3) To examine which large-scale hydro-climatological phenomenon might be at the origin of the alteration of the thermal regime of the North Sea and the decline in the abundance of *Calanus finmarchicus* in the North Sea.

I finally propound a theory that explains how global climate change might have influenced the relationship between the NAO and *Calanus finmarchicus*. This theory might be used to better com-

prehend (1) the influence of natural climatic variability on species and (2) how this influence might be altered by global warming.

MATERIALS AND METHODS

Biological data

Biological data on *Calanus finmarchicus* and *C. helgolandicus* (1958 to 2007) come from the Continuous Plankton Recorder (CPR) survey (Reid et al. 2003a). The CPR survey is seen as one of the longest, richest (in terms of species information), and geographically extensive ecological surveys in the world.

Hydro-climatological data

The North Atlantic Oscillation (NAO; 1958 to 2007) is a basin-scale alternation of atmospheric mass over the North Atlantic, between the high pressures centred over the subtropical Atlantic and low pressures around Iceland. The winter NAO index, corresponding to months from December to March, was used in this study (Hurrell et al. 2001).

The Atlantic Multidecadal Oscillation (AMO; 1958 to 2007) is a large-scale oceanic phenomenon and the source of natural variability in the range of 0.4°C in the region covered by this study (Keenlyside et al. 2008).

Northern Hemisphere Temperature (NHT; 1958 to 2007) anomalies were used as an index of large-scale change in sea surface temperature. The data were provided by the Hadley Centre for Climate Prediction and Research, Meteorological Office, Exeter, UK (www.metoffice.gov.uk).

Mean annual Sea Surface Temperature (SST; 1960 to 2007) in the North Sea originated from the International Comprehensive Ocean-Atmosphere Data Set (ICOADS, 1-degree enhanced data) (Woodruff et al. 1987).

Key questions in this study

(1) Did the relationship between NAO and abundance of *Calanus finmarchicus* break down in 1996?

I examined the relationship between the winter NAO index and *Calanus finmarchicus* by sliding correlation analysis (Kirby & Beaugrand 2009) to detect

when the relationship between the 2 variables breaks down. Sliding correlation analysis can be sensitive to the size of the time window. That is why the linear coefficient of Pearson was calculated from the beginning of the time series (1958) to the end (2007) by using 2 different time windows (10 and 15 yr; Fig. 1a,b). Probabilities were adjusted for temporal autocorrelation (Beaugrand 2009). As a result of the correlation analyses, scatterplots of the abundance of *C. finmarchicus* as a function of the winter NAO index were presented for 3 periods: 1958 to 1962; 1963 to 1987; and 1988 to 2007 (Fig. 1c).

(2) *Is the relationship between NAO and abundance of *Calanus finmarchicus* modulated by the thermal regime of the North Sea?*

To relate the correlation calculated between the NAO and *Calanus finmarchicus*, SST values were averaged for each time period corresponding to the windows (10 and 15 yr) used in the sliding correlation analysis (Fig. 1d).

(3) *What large-scale climatic phenomenon is at the origin of the alteration in the thermal regime of the North Sea?*

I then examined graphically the relationships between the relative proportion of *Calanus finmarchicus* (subarctic) and *C. helgolandicus* (warm-temperate) in the North Sea as a function of mean annual SST, NHT anomalies, the NAO and the AMO (Fig. 2). This analysis was conducted to attempt to explain why the correlation between the NAO and *C. finmarchicus* ceased and what processes modulate the correlation. All analyses were programmed in MATLAB (MathWorks).

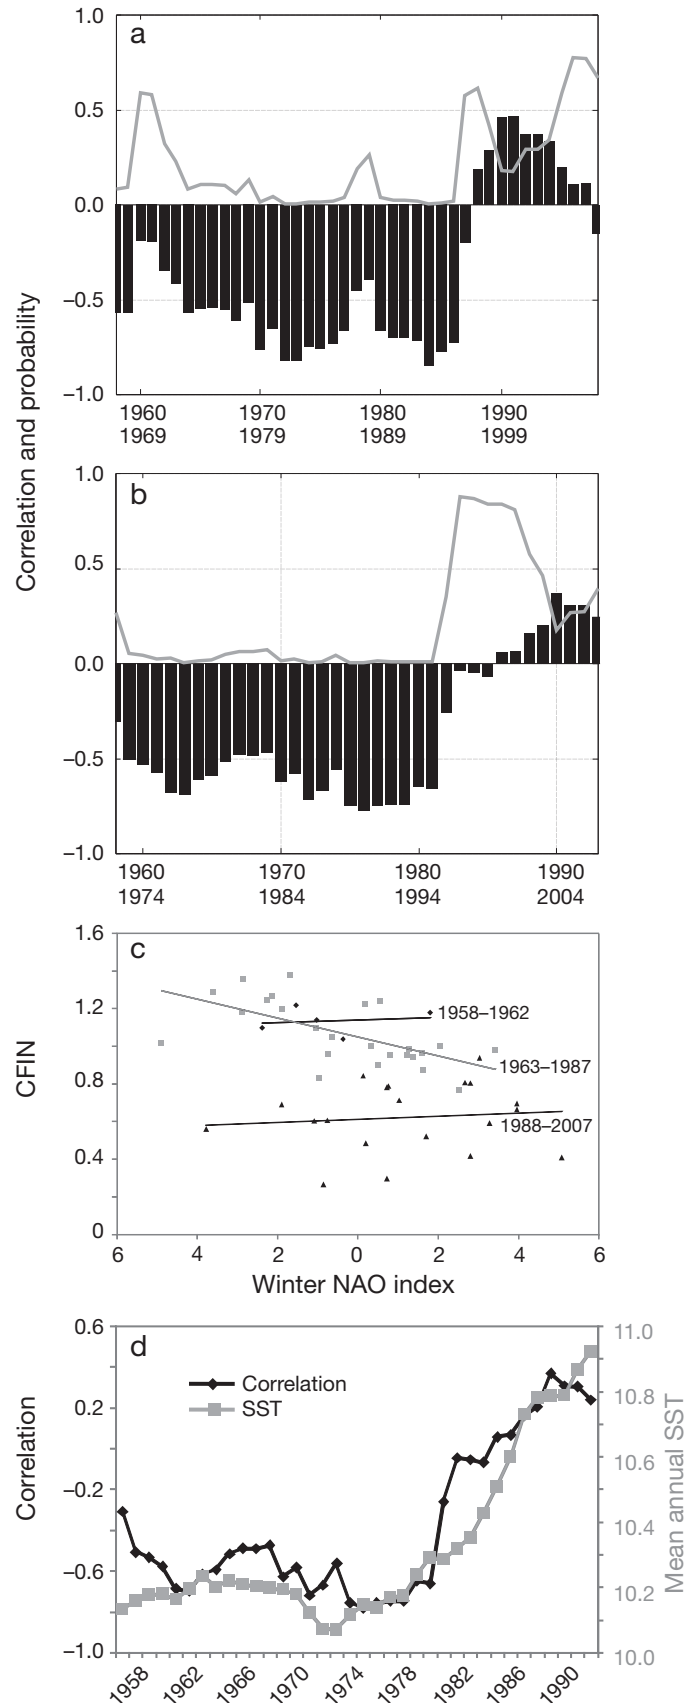

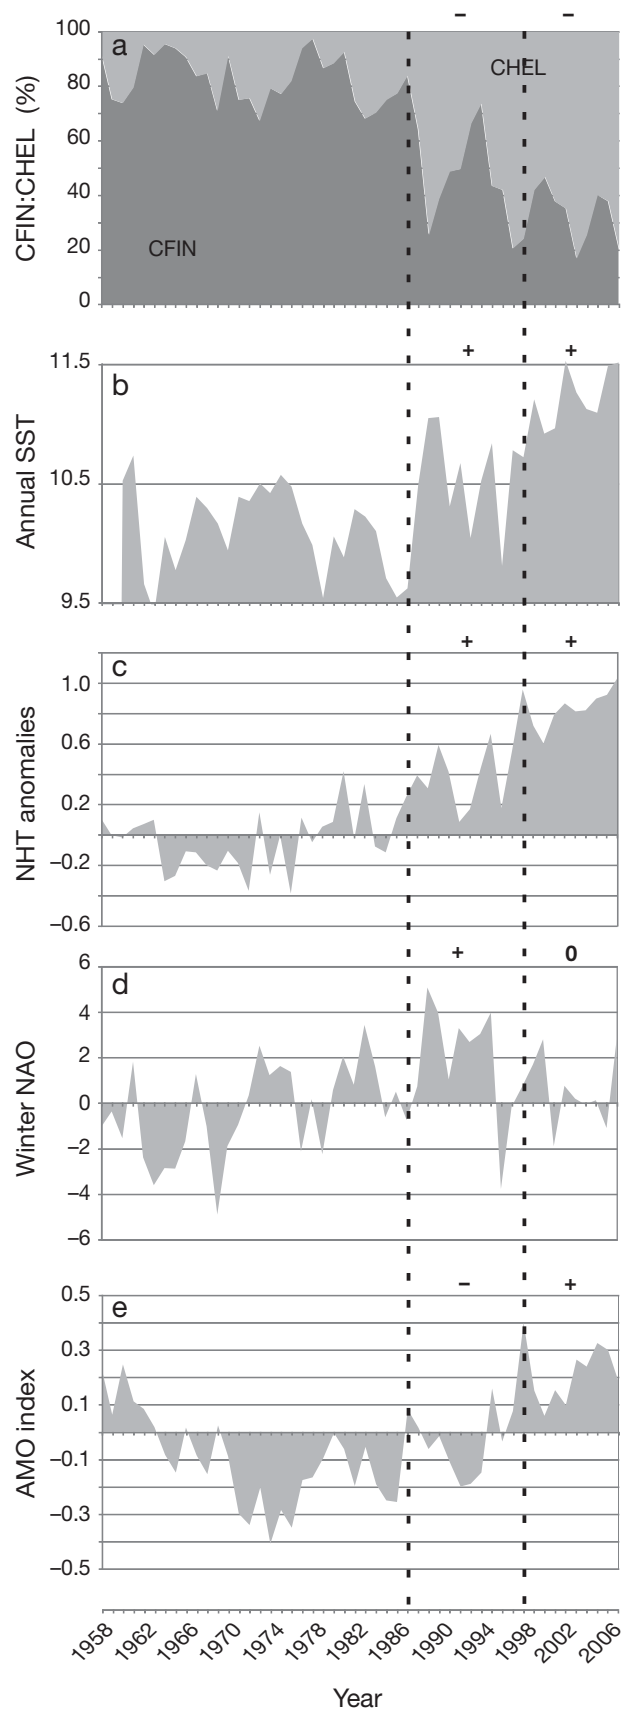

Fig. 1. *Calanus finmarchicus*. Sliding correlation analysis between the winter NAO index and the mean annual abundance (as $\log_{10}(x+1)$) for the period 1958 to 2007, using a time window of (a) 10 yr and (b) 15 yr. Black bars: correlation values; grey line: values of probability after correction to account for temporal autocorrelation. For the x-axis labels, upper and lower years indicate the beginning and the end of the time period for the correlation analysis, respectively. (c) Scatterplots of *C. finmarchicus* as a function of the winter NAO index for the period 1958 to 1962 (◆), 1963 to 1987 (■), and 1988 to 2007 (▲). (d) Long-term changes in the correlations (in black) based on a time window of 15 yr and mean annual sea surface temperature (SST) (in grey) for the corresponding period. CFIN: mean annual abundance of *C. finmarchicus* in the North Sea

RESULTS

(1) Did the relationship between NAO and abundance of *Calanus finmarchicus* break down in 1996?

Results from sliding correlation analyses (time window of 10 yr) indicate that correlations between the winter NAO index and the mean annual abundance of *Calanus finmarchicus* in the North Sea were negative from 1958 to 1987 and became positive from 1988 onwards (Fig. 1a). After correcting for autocorrelation, the probability was significant at the threshold of 0.1 until 1986, although the probability was not significant in the periods 1960 to 1963 and 1978 to 1979 (starting year of the sliding correlation analysis). This analysis based on a short time window (10 yr) indicates more accurately the timing of the shift than longer time windows but can be more influenced by short-scale events. Based on a time window of 15 yr, the relationships were significantly negative from 1960 to 1981 but appear less significant at the beginning of the time series (Fig. 1b). From 1982, the correlation became non-significant and slightly positive. The scatterplots showed a strong negative correlation between the NAO and *C. finmarchicus* during the period 1963 to 1987 ($r = -0.62$; $p < 0.1$; $n = 25$) and an absence of correlation for the periods 1958 to 1962 ($r = 0.09$; $p > 0.1$; $n = 5$) and 1988 to 2007 ($r = 0.15$; $p > 0.1$; $n = 20$; Fig. 1c). These analyses show that the correlations did not break down in 1996 as originally suggested (Planque & Reid 1998) but rather after the North Sea ecosystem shift.

(2) Is the relationship between NAO and abundance of *Calanus finmarchicus* modulated by the thermal regime of the North Sea?

I found a significant relationship between NAO–*Calanus finmarchicus* correlations and mean annual SST in the North Sea based on both time windows (10 yr: $r = 0.68$; $p = 0.09$; $n = 41$; 15 yr: $r = 0.92$; $p = 0.02$; $n = 36$; Fig. 1d).

Fig. 2. *Calanus finmarchicus* and *C. helgolandicus*. Long-term changes in the proportion of the species as percentage (a), in relation to mean annual sea surface temperature (SST) (b), NHT anomalies (c), the winter NAO index (d), and the AMO index (e). The 2 vertical dashed lines indicate the years 1988 and 1998. CFIN: percentage of *C. finmarchicus*; CHEL: percentage of *C. helgolandicus*. Positive and negative anomalies are indicated by '+' and '-', respectively. Average values: '0'

(3) *What large-scale climatic phenomenon is at the origin of the alteration in the thermal regime of the North Sea?*

I further examined long-term changes in the percentage of *Calanus finmarchicus* (subarctic species) and *C. helgolandicus* (warm-temperate, pseudo-oceanic species) in relation to changes in mean annual SST and large-scale, hydro-climatological indices (Fig. 2). At the beginning of the time period, *C. finmarchicus* represented about 80% of *Calanus* in the North Sea but only represented about 20% of the *Calanus* in 2007 (Fig. 2a). Interestingly, the correlations between the NAO and *C. finmarchicus* started to decrease when mean annual SST increased in the North Sea (see Figs. 1 & 2a,b). The regional warming was correlated positively to NHT anomalies ($r = 0.69$; $p = 0.01$; $n = 48$; Fig. 2c). The decrease in the NAO-*C. finmarchicus* correlation was not apparent because the warming coincided with the sustained positive phase of the NAO during the 1980s (Fig. 2d). The decrease in the NAO-*C. finmarchicus* correlation became apparent from 1996 when the NAO entered a sustained phase of average NAO values (i.e. NAO values ~ 0), whereas temperature anomalies became highly positive in the North Sea, coinciding with the positive phase of the AMO after the end of the 1990s (Fig. 2e). For the time period 1960 to 2007, the correlation between the NAO and *C. finmarchicus* was lower (although remaining globally significant; $r = -0.41$; $p = 0.1$; $n = 48$) than the correlation between mean annual SST and the copepod ($r = -0.65$; $p = 0.02$; $n = 48$). It is clear from these results that neither the NAO or the AMO can explain the collapse of *C. finmarchicus* in the North Sea (Fig. 2d,e).

DISCUSSION

This paper had 3 scientific objectives. The first objective was to revisit the timing of the end of the correlation between *Calanus finmarchicus* and the NAO in the North Sea proposed by Planque & Reid (1998). The analyses provide evidence that the relationship between the state of the NAO and the abundance of *C. finmarchicus* in the North Sea did not break down in 1996 as originally stated but in the 1980s (Fig. 1a,c). It is not reasonable to be more accurate on the timing because in sliding correlation analysis the identification of the years when a correlation breaks down often varies as a function of the time window (Fig. 1a,b). However, the results suggest that the relationship decreases between the

beginning and the end of the 1980s. Planque & Reid (1998) proposed that the relationship broke down in 1996, a year characterised by a pronounced negative NAO index. Subsequently, some studies have assumed that the timing was 1996 (e.g. Reid & Beaugrand 2002, Kimmel & Hameed 2008), and the temporal evenness of the relationship has never been tested. Note however that the timing of change in the correlation strength justifies why Kimmel & Hameed (2008) distinguished a period 1980 to 2002 in their analysis. Using both observed and modelled data from these authors (data from their Fig. 3), I found a change in the strength of the correlations between observed and modelled abundance of *C. finmarchicus* that corresponded to the shift in the correlations detected in Fig. 1, i.e. between 1982 (time window of 15 yr) and 1987 (time window of 10 yr; figures not shown). The more accurate identification of the period from when the relationship breaks down (1982 to 1987, Fig. 1) is important because it provides an essential indication on the underlying mechanisms. This new period corresponds to the time of the abrupt ecosystem shift in the North Sea (Reid et al. 2001, Beaugrand 2004, Beaugrand et al. 2008).

The second scientific objective was to examine whether or not the relationship was modulated by the thermal regime in the North Sea. Although this was hypothesised by Kimmel & Hameed (2008), this was not demonstrated. In the present study, I found a strong positive covariation between the NAO-*Calanus finmarchicus* correlation and the mean annual SST in the North Sea (Fig. 1d).

The third scientific objective of this paper was to investigate which large-scale hydro-climatological phenomenon might have forced the long-term relationship between the NAO and *Calanus finmarchicus*. The analyses revealed that large-scale temperature anomalies were highly and positively associated with the North Sea thermal regime (Fig. 2), the change in the strength of the correlation between *C. finmarchicus* and the NAO (Figs. 1 and 2), as well as the proportion of *C. finmarchicus* on total *Calanus* in the North Sea (Fig. 2a). Both the AMO and the NAO did not play a constant role during the period 1958 to 2007.

In the light of these results, I propound here a theory that explains the collapse of the NAO-*Calanus finmarchicus* relationship (Fig. 3). This theory is mainly based on the concept of the ecological niche (Hutchinson 1957). Using only temperature as a dimension of the niche, this can be called a bioclimatic envelope or climatic or more accurately, a thermal niche (left part of Fig. 3). I postulate that (1) the

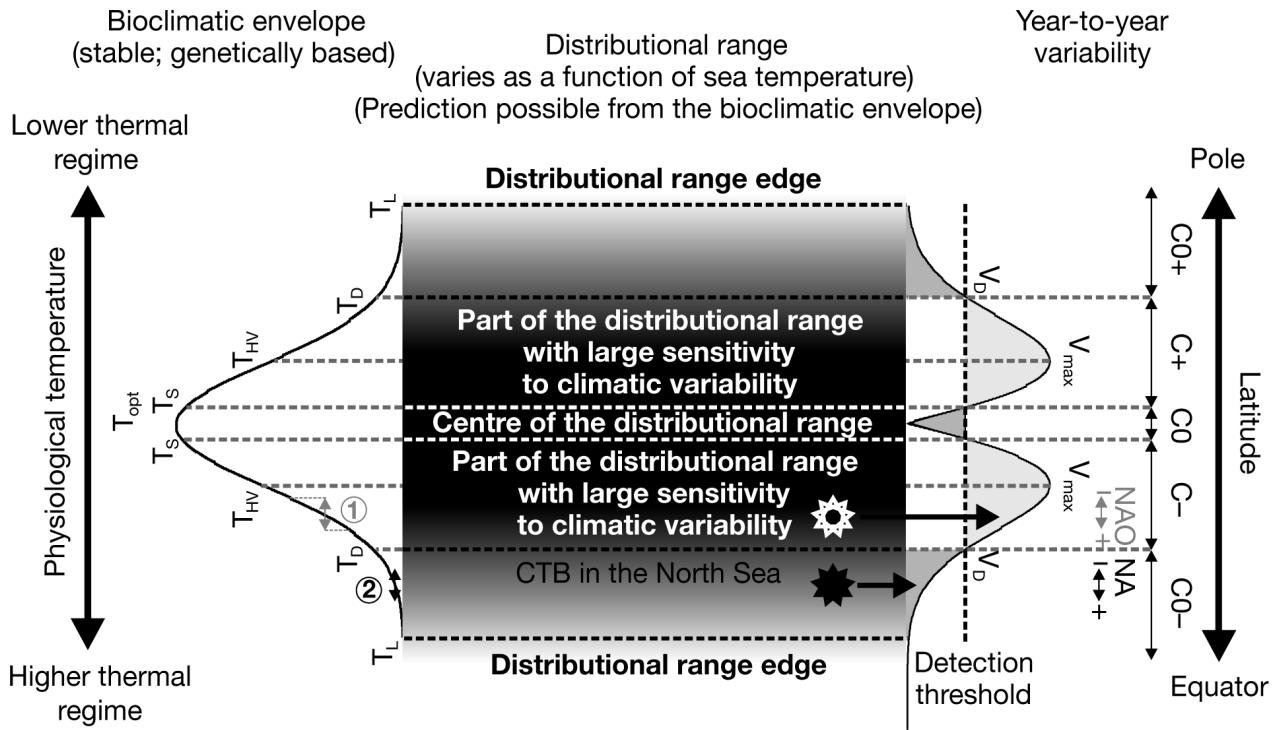

thermal niche, genetically based, is stable at a decadal scale, invoking the niche conservatism hypothesis (Crisp et al. 2009); (2) the bioclimatic envelope determines the distributional range of a species (central part of Fig. 3); (3) the NAO influences *C. finmarchicus* by its exclusive (positive in the North Sea) influence on SST, see however the discussion in Dickson & Turrell (2000), Reid et al. (2003b). By calculating the primary differences between each probability of occurrence (or theoretical abundance) as a function of temperature, I can provide an assessment of the sensitivity of the species to the year-to-year variability in temperature (right part of Fig. 3). Higher sensitivity is expected at the section of the bioclimatic envelope T_{HV} corresponding to V_{max} in zones C+ and C-. These zones define the region of the distributional range where the species is the most influenced by climate. Note that maximal sensitivity (and therefore maximal year-to-year variability) is not located at the edge of the species' distributional range but in regions of the bioclimatic envelope where the greatest local slopes occur. When the probability of occurrence becomes lower, the noise associated to the biological time series (e.g. noise related to sampling) is likely to prevent the detection of the climatic signal (zones C0+ and C0-). Detection is function of the value of the detection threshold and therefore to the noise associated to the time series (Fig. 3), which determines T_D and T_S . The species is abundant or has a high probability of occurrence in a given area when temperatures are optimal. The abundance of a species is likely to be stable and less sensitive to sea temperature changes towards the optimal section of the niche (zone C0), the width of this region depending on T_S .

Prior to the shift, the thermal regime of the North Sea was 1°C (annual average) lower, being in the part of the bioclimatic envelope characterised by a higher sensitivity (and year-to-year variability in SST; zone C-; Fig. 3). Therefore, the positive influence of the NAO on SST was susceptible to trigger large changes in the probability of occurrence (or abundance) of *Calanus finmarchicus* (see the grey double arrow and associated dashed grey lines in the left part of Fig. 3). However, the thermal regime of the North Sea changed, which triggered an abrupt ecosystem shift in the 1980s. Beaugrand et al. (2008) showed that the North Sea abrupt ecosystem shift was related to the northward migration of a Critical Thermal Boundary (CTB) in the North Sea, as indicated by the annual isotherm 9 to 10°C (see their Fig. S4; see also the theoretical position of CTB in Fig. 3, herein). This boundary, which reflects the

limit between the Atlantic polar and the temperate biomes, was located in the North Sea prior to the shift and then moved and became positioned north of the North Sea after the shift. When the boundary was present in the North Sea, the NAO used to influence its position and therefore the abundance of *C. finmarchicus*. When the boundary was southwards, the abundance of *C. finmarchicus* was probably higher and inversely.

Since CTB disappeared from the North Sea, the NAO had no longer an effect on its position and therefore on *Calanus finmarchicus*. The post-shift thermal regime in the North Sea corresponds to the section of the niche (zone C0-) when NAO-mediated changes in SST are no longer sufficient to generate large changes in the probability of occurrence (or abundance) of *C. finmarchicus* (see Point 2 in the left part of Fig. 3). Helaouët et al. (2011) have recently shown, at a monthly scale, that the thermal regime in the North Sea was increasingly outside the bioclimatic envelope of *C. finmarchicus*. Once the thermal regime is below zone C-, the NAO, which remained moderate especially since the beginning of the 1990s (see Fig. 2d), has not been sufficient to exert a strong influence on annual SST and in turn on the abundance of *C. finmarchicus*. It should be noted that only an extreme negative NAO such as December 2009 to February 2010 might influence the abundance of *C. finmarchicus* (influence towards zone C-) because, at present, the thermal regime is too warm. An extreme positive influence, which could precipitate the disappearance of *C. finmarchicus* from the North Sea, would not strongly influence the abundance of the species (see the left part of Fig. 3 corresponding to zone C0-).

Myers (1998) showed that the amount of published correlations that have been confirmed when revisited was low. However, correlations between the environment and fish recruitment was often significant at the margin of the distributional range of species. According to the theory I propose, the highest temperature-induced changes in the abundance of a species should be located in places where the thermal regime corresponds to the zone of greatest local slopes of the species' bioclimatic envelope (V_{max} and T_{HV}). Myers (1998) also noticed the absence of significant correlation at the centre of the distributional range, which he attributed to the strong effect of density-dependence. According to the theory, this might also be related to the fact that the centre of the distributional range of a species corresponds to the optimal section of the niche, which is less sensitive to changes in temperatures (zone C0). At the time of the

- ① Higher changes in the probability of occurrence prior to the shift in the thermal regime in the North Sea
 ② Smaller changes in the probability of occurrence after the shift in the thermal regime in the North Sea

Fig. 3. Idealised conceptual scheme showing the relationships between the distributional range of a species, its bioclimatic envelope and its expected year-to-year variability. The grey surface at the centre of the figure denotes the species distributional range, the greyshade being proportional to the probability of occurrence of the species. The diagrams on the left and right sides of the figure represent the species bioclimatic envelope and the expected year-to-year variability, respectively. The year-to-year variability was assessed from the bioclimatic envelope by calculating the primary difference of each theoretical probability of occurrence as a function of temperature. The bimodal distribution exhibits a maximal variability V_{\max} corresponding to greatest slopes (T_{HV} , HV for High Variability) of the bioclimatic envelope. The centre of the species distributional range corresponds to the optimal part (T_{opt}) of the bioclimatic envelope. This stable part, delimited by T_s (s for stable), is thereby characterised by low year-to-year variability. The detection threshold corresponds to the theoretical value from which the signal becomes detectable, i.e. stronger than the noise (e.g. associated to sampling) associated to the biological time series. Areas in dark grey on the right of the figure indicate geographical regions and the section of the bioclimatic envelope (T_D ; D for Detection) where the year-to-year variance of the signal is inferior to V_D (D for detection) and where it is therefore likely to remain undetected. Areas in light grey indicate regions where the variance of the signal is superior to the variance of the noise associated to the biological time series. T_L are the temperatures below and above which temperatures become lethal. The white star indicates the mean thermal regime of the North Sea prior to the shift in the relationship NAO–*Calanus finmarchicus* and the black star indicates the mean thermal regime of the North Sea after the relationship NAO–*C. finmarchicus* ceased. Prior to the shift, the effect of the NAO on *C. finmarchicus* was highly detectable because the North Sea thermal regime was in the section of the bioclimatic envelope where the year-to-year variability was high (regions highlighted in light grey). After the shift, the North Sea thermal regime was about 1°C higher (annual average) and the amount of year-to-year variability was too low to be detected. Note however that at the edge of the spatial distribution no relationship between temperature and *C. finmarchicus* can be expected, even if the variance associated to the noise of the biological time series become negligible. C0–: zone of weak (undetectable) negative influence of a climatic index (e.g. NAO) on *C. finmarchicus*; C–: zone of detectable negative influence; C0: zone of no influence; C+: zone of detectable positive influence; C0+: zone of weak (undetectable) positive influence. This scheme is highly dependent on the shape of the bioclimatic envelope and its breadth or degree of eurythermy of species. In this model, the NAO is assumed to affect the species through its positive influence on sea surface temperature (SST) as this is the case in the North Sea. Note however that the NAO can have a negative influence on SST (e.g. the Subarctic Gyre). This model can be applied more directly using annual SST. The double vertical grey arrow (left and right part of the figure) indicates the theoretical (high) influence of the NAO on *C. finmarchicus* prior to the increase of the thermal regime in the North Sea (white star). The double vertical black arrow (left and right part of the Fig.) indicates the theoretical (small and undetectable) influence of the NAO on *C. finmarchicus* after the increase of the thermal regime in the North Sea (black star).

CTB: Critical Thermal Boundary in the North Sea, which is the isotherms 9 to 10°C (Beaugrand et al. 2008)

study by Meyers (1998), it was not known that global climate change might become a force capable of shifting the distributional range of species (Cheung et al. 2008, Lenoir et al. 2011). The theory suggests that our capability to predict species' responses to climate change in a given area is high in the part of the geographical range that has a thermal regime corresponding to zones C+ or C– (Fig. 3). In regions corresponding to zones C0+ and C0–, it might be impractical to develop models for ecosystem management that integrate indicators of climate change (especially temperature), because the signal is likely to be too small in comparison to the noise of the biological time series to provide any reliable information on the state of the biological system. At the centre of the species' distributional range corresponding to zone C0, no response of the species to climate change is likely to be observed. Only a joint concerted approach combining sites that encompass the full distributional range of a species is likely to provide the best predictive capability.

The use of past empirical relationships between biological or ecosystem responses and large-scale sources of hydro-climatological variability are problematic because they do not consider potential trade-offs or thresholds associated to the non-linearity of biological systems. As the present theory suggests, part of this non-linearity can be explained by the non-linear thermal preferendum of species.

Incorporating an unanticipated outcome, also called a 'surprise' in climatic research (Intergovernmental Panel on Climate Change 2007), and uncertainty undoubtedly represents the most difficult challenge that scientists and ecosystem managers will have to face in a warmer world. This paper shows that global warming can cancel well-documented empirical relationships between large-scale climatic variability (here the NAO) and key biological components of the ecosystem (here, the mean annual abundance of *Calanus finmarchicus*). As with climate, biological systems are complex. Species react differently to temperature change as a function of the position of their thermal niche (Beaugrand & Kirby 2010) and temperature might also change both the strength and sign of species relationships (Kirby & Beaugrand 2009).

These findings have implications for some empirical relationships such as the NAO and the Atlantic cod (Brander 2005), the Pacific Decadal Oscillation (PDO) and the ecosystem state of the North Pacific (Hare & Mantua 2000), the Atlantic Subarctic index and the ecosystem state in the North-east Atlantic (Hatun et al. 2009), and the North Pacific Gyre Oscillation (NPGO) and the ecosystem state in San Fran-

cisco Bay (Cloern et al. 2010). Will all these interesting and currently robust empirical relationships hold in a warmer world? It is possible that other well-known empirical relationships between large-scale sources of natural variability and species, bio-coenoses or ecosystems might cease in the future if climate continues to warm. In this period of rapid climate change, it is therefore hazardous to integrate meteo-oceanic indices such as the NAO in models used in the management of living resources as it has been attempted in the past.
