## A B S T R A C T

A process route to the fabrication of quaternary chalcogenides ( $\text{Cu}_2\text{CoSnS}_4$ ,  $\text{Cu}_2\text{ZnSnS}_4$ ) particles is proposed in molten KSCN at 400 °C. This high temperature route allows the formation of highly pure and highly crystallized quaternary chalcogenides particles. Control of primary crystallites size is demonstrated by altering the chemical homogeneity of the precursors. This method could be exploited to prepare building blocks for the fabrication of low-cost solar cell absorbers.

## 1. Introduction

Quaternary chalcogenides ( $\text{Cu}_2\text{CoSnS}_4$ ,  $\text{Cu}_2\text{ZnSnS}_4$ ) materials have been of interest for many years because they possess suitable direct band gap and high absorption coefficient for application in solar energy conversion [1,2]. These materials have recently attracted increased attention for photovoltaic conversion since they are composed of only abundant non-toxic elements.  $\text{Cu}_2\text{ZnSnS}_4$  (CZTS) is thus considered as a promising material for low cost absorber layer for solar cells [3]. Extensive pioneering work on this material employing evaporation based approach under vacuum was performed by the group of Prof. Katagiri [4,5]. Using RF co-sputtering of Cu and binary ZnS and SnS materials, a 6.77% efficient solar cell was demonstrated in 2008 [5]. More recently, efficiency of quaternary chalcogenides based solar cells via an ink printing process route involving the use of nanosized  $\text{Cu}_2\text{ZnSnS}_4$  building blocks has been recently reported up to 9.66% [6]. Indeed, direct liquid deposition approaches are particularly attractive for large scale manufacturing due to their compatibility with high throughput deposition techniques such as tape casting. Various processing routes have already been proposed for the preparation of  $\text{Cu}_2\text{ZnSnS}_4$  particles [7,8,9,10]. These routes involve the use of coordinating solvent such as oleyl-amine or surfactants and are performed at synthetic temperatures ranging from 225 °C to 300 °C. Because defects usually act as hole/electron recombination centers during the photovoltaic conversion, the development of new process routes allowing the preparation of highly crystallized quaternary

chalcogenides particles is of great interest [11] since these materials should exhibit lower defect concentration.

Here we report on a high temperature route ( $T = 400$  °C) to the formation of highly crystallized quaternary chalcogenides building blocks involving direct reactions between metal oxides or metallic salts precursors in molten KSCN.

## 2. Experimental section

Preparation of quaternary chalcogenides in molten KSCN was investigated using two different procedures. A first procedure involves metal oxides as metal sources:  $\text{SnO}_2$  (Acros), ZnO or CoO (Acros),  $\text{Cu}_2\text{O}$  (Aldrich). The metal oxides were used as-received without any post milling stage in order to avoid any impurity contamination. These metal oxide raw materials consist of aggregates possessing various aggregate sizes in the micronic range as determined from SEM: 20  $\mu\text{m}$  ( $\text{SnO}_2$ ), 5  $\mu\text{m}$  ( $\text{Cu}_2\text{O}$ ), 2  $\mu\text{m}$  (CoO), 1  $\mu\text{m}$  (ZnO). A solid precursor, denoted oxide precursor was prepared by intimate mixing performed in a solid vortex mixer (Top Mix, Fisher Scientific) of these metal oxide aggregates with solid KSCN, (Sigma-Aldrich > 99%). With the objective to improve the chemical homogeneity of the solid precursors, a modified procedure involves in a first stage a  $\text{SnO}_2$  (or  $\text{SnO}_2\text{-M}(\text{OH})_2$ ,  $\text{M} = \text{Co, Zn}$ )– $\text{Cu}_2\text{O}$  intimate mixture prepared from roto-evaporation at 80 °C under vacuum of an ethanolic dispersion formed from a precipitated  $\text{SnO}_2$  or co-precipitated  $\text{SnO}_2\text{-M}(\text{OH})_2$  with  $\text{Cu}_2\text{O}$  particles. In a second stage, a homogeneous oxide precursor was achieved by mixing in a solid vortex mixer of this freshly prepared  $\text{SnO}_2$  (or co-precipitated  $\text{SnO}_2\text{-M}(\text{OH})_2$ )– $\text{Cu}_2\text{O}$  mixture with solid KSCN.

Similarly, in a second procedure, a salt precursor was prepared by intimate mixing using the same solid vortex mixer of metallic salts as metal sources:  $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$  (Fisher Scientific),  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  (Sigma Aldrich),  $\text{ZnCl}_2$  (Sigma Aldrich) and solid KSCN. For these two procedures, the precursors were transferred into an alumina crucible and post heat treated under  $\text{N}_2$  controlled atmosphere. Reaction mixtures were maintained at various temperatures ranging from  $T = 300^\circ\text{C}$  to  $550^\circ\text{C}$  with various duration times  $t$  ( $3\text{ h} < t < 48\text{ h}$ ). After cooling at room temperature, the black CZTS powder was separated and collected from excess KSCN by subsequent washings in deionized water, EtOH and finally dried at room temperature in air.

The resulting CZTS samples were characterized by SEM (JEOL JSM-6510), XRD (Bruker AXS D4) and Raman Spectroscopy. Raman spectroscopy was performed on washed, dried solid samples using a Horiba Jobin Yvon XPlora spectrometer with  $\lambda = 633\text{ nm}$  at a laser power  $P = 1.7\text{ mW}$ .

### 3. Results and discussion

Preliminary experiments were performed using oxide precursors with  $(\text{Cu}:\text{M}:\text{Sn}:\text{S})_{\text{moles}} = (2:1:1:\text{S})$  compositions, where S denotes

the number of KSCN moles and  $\text{M} = \text{Zn}$  or  $\text{Co}$ . Formation of the desired quaternary chalcogenide structures was observed in the temperature range  $350^\circ\text{C} < T < 500^\circ\text{C}$ . At a too low temperature,  $T = 300^\circ\text{C}$ , XRD patterns (not shown) revealed incomplete transformation of the oxide raw materials. In a typical experiment, oxide precursors with an optimal KSCN composition  $(\text{Cu}:\text{M}:\text{Sn}:\text{S})_{\text{molar ratio}} = (2:1:1:15)$  were heat treated at  $400^\circ\text{C}$  during 24 h. Corresponding X-Ray diffraction patterns of  $\text{Cu}_2\text{CoSnS}_4$  (CCTS) and  $\text{Cu}_2\text{ZnSnS}_4$  (CZTS) samples (Fig. 1) exhibit peaks corresponding to the quaternary chalcogenide quadratic phase. Indeed, fine inspection of the diffractograms recorded on CCTS samples reveals the presence of  $\text{SnO}_2$  and  $\text{Co}_3\text{S}_4$  as minor structures. Because the corresponding oxide metal sources were incorporated in the reaction mixture as large micronic particles, improvement of precursors chemical homogeneity was investigated with the objective to prepare samples exhibiting a single quaternary chalcogenide quadratic phase. Thus, more homogeneous precursors involving precipitated  $\text{SnO}_2$  or co-precipitated  $\text{SnO}_2\text{--Co}(\text{OH})_2$  were investigated. Corresponding XRD patterns of the resulting oxide precursors after heat treatment in similar conditions of temperature and duration as previously described

show a single CCTS phase confirming effect of chemical homogeneity of the precursors on the preparation of highly pure CCTS in molten KSCN.

Similar to the formation of CCTS, the CZTS XRD patterns reveal presence of  $\text{SnO}_2$  structure as a minor constituent. Using the same modified procedure, preparation of samples exhibiting a single CZTS phase was achieved via a mixture involving use of a freshly precipitated  $\text{SnO}_2$  intimately mixed to  $\text{Cu}_2\text{O}$  and  $\text{ZnO}$  particles.

In addition to the XRD, Raman investigation was performed to fully characterize the samples. Indeed, Raman characterization is crucial to complete CZTS structure identification since XRD does not allow the distinction between the CZTS and  $\text{ZnS}$ ,  $\text{Cu}_2\text{SnS}_3$  structures. As an example, a peak was observed at 345  $\text{cm}^{-1}$  indicating presence of cubic  $\text{ZnS}$  [12] for the CZTS sample prepared from an oxide precursor involving  $\text{Cu}_2\text{O}$ ,  $\text{SnO}_2$ ,  $\text{ZnO}$  and KSCN as raw materials (Fig. 2). In contrast, by improving the chemical homogeneity of the oxide precursor using the

modified procedure, Raman spectrum of the resulting sample shows a main peak at 335  $\text{cm}^{-1}$  and secondary peaks at 286 and 361  $\text{cm}^{-1}$  [13] attributed to the CZTS structure.

The Raman spectra recorded on CCTS samples show a slight variation of the main peak frequency determined at 326  $\text{cm}^{-1}$  with secondary peaks at 288  $\text{cm}^{-1}$  and 359  $\text{cm}^{-1}$ . Indeed, although no reference to the best of our knowledge has been published concerning CCTS, these peaks are consistent with the totally symmetric vibration involving the motion of sulfur atoms of quaternary chalcogenides [13] and could be attributed to CCTS. More important, the high value of the primary crystallite determined by XRD is consistent with the low value of the FWHM determined from the Raman spectra of the CCTS and CZTS samples (Table 1) and indicates the formation of highly crystallized quaternary chalcogenides particles in molten KSCN at 400 °C.

Indeed, XRD and Raman data reveal large differences concerning the CCTS and the CZTS formation from oxide raw materials in molten

**Fig. 3.** Morphology of quaternary chalcogenides particles prepared in molten KSCN at 400 °C (a) CCTS particles,  $\text{Cu}_2\text{O}$ - $\text{CoO}$ - $\text{SnO}_2$ -KSCN precursor. (b) CZTS particles  $\text{Cu}_2\text{O}$ - $\text{ZnO}$ - $\text{SnO}_2$ -KSCN precursor, (c) CZTS particles,  $\text{CuCl}$ - $\text{ZnCl}_2$ - $\text{SnCl}_4 \cdot 5 \text{H}_2\text{O}$ -KSCN precursor. Scale Bar = 10  $\mu\text{m}$ . Insert: High magnification images. Scale Bar = 1  $\mu\text{m}$ .

KSCN. In contrast to the formation of CCTS particles which occurs without cobalt sulfide phase, formation of non-desired ZnS was observed during the CZTS synthesis although using ZnO raw material of slighter small particle size compared to CoO. In addition, larger primary crystallite sizes as calculated from the Scherrer equation (Table 1), consistent with the lower FWHM values of the main Raman peak were determined for CCTS particles (Table 1). In addition, compared to bulk CZTS, unexplained large FWHM values of the secondary Raman peak centered around  $305\text{ cm}^{-1}$  were determined on CZTS samples. All these observations suggest an easier formation of the CCTS quaternary chalcogenide structure in comparison to CZTS.

SEM observation of the as-synthesized samples (Fig. 3) indicates that the quaternary chalcogenides particles are indeed of micronic size and largely aggregated with a polydisperse size distribution. High magnification images show that these particles are composed of primary crystallites possessing sizes larger than  $1\text{ }\mu\text{m}$ .

Interestingly, our data clearly show large variation in primary crystallite size of the CZTS crystals. Because the chemical homogeneity of the various components into the precursors was shown to greatly affect the primary crystallite size and probably the nucleation rate of the quaternary chalcogenide particles, we have investigated preparation of CZTS particles from precursors made from metallic salts. In a typical experiment, an intimate mixture of the various metallic salts and KSCN with (Cu: Zn: Sn: S = (2: 1: 1: 15) composition was heat treated at  $T = 400\text{ }^{\circ}\text{C}$  for 16 h. XRD and Raman spectra performed on samples synthesized at temperature of  $400\text{ }^{\circ}\text{C}$  and duration time of 16 h demonstrated that the resulting product can be fully identified as a pure CZTS compound. As expected, particles prepared from salts precursors exhibit smaller primary crystallite sizes of around 12 nm, as calculated from the Scherrer equation using the full-width at the half-maximum of the chalcogenide (112) XRD peak. Consistently, the FWHM of the main peak of the Raman spectra ( $\text{FWHM} = 16\text{ cm}^{-1}$ ) display a higher value indicating a lower short range order compared with the samples synthesized from the oxide precursors. High magnification SEM images confirm the presence of smaller size of primary crystallites compared with samples synthesized using an oxide precursor. Nevertheless, these primary crystallites are fully aggregated with size in the micronic range exhibiting non-well defined morphology.

Depending on the precursors, various mechanisms have been already proposed for the formation of the metallic sulfide particles in molten KSCN. Thermal decomposition of KSCN starts at  $275\text{ }^{\circ}\text{C}$  [14] with S formation:  $\text{SCN}^- = \text{S} + \text{CN}^-$ . Using oxide precursors, formation of the quaternary chalcogenides is achieved with the following reaction:  $\text{Cu}_2\text{O} + \text{ZnO} + \text{SnO}_2 + 4\text{ KSCN} = \text{Cu}_2\text{ZnSnS}_4 + 4\text{ KCNO}$  [15]. In contrast, formation of the quaternary chalcogenides from metallic salts probably involves the following steps [15]: i/  $\text{S} + 2\text{ CN}^- = \text{S}^{2-} + \text{C} + \text{N}_2$  or  $\text{S} + 2\text{ CN}^- = \text{S}^{2-} + \text{C} + \text{N}_2$  ii/  $2\text{ Cu}^+ + \text{Zn}^{2+} + \text{Sn}^{2+} + 4\text{ S}^{2-} = \text{Cu}_2\text{ZnSnS}_4$ . The lower crystallite sizes determined on samples prepared

from salt precursors suggest a higher nucleation rate for the formation of the quaternary chalcogenides. This higher nucleation rate probably arises from the high concentration of directly available metallic cations in the molten KSCN.

#### 4. Conclusions

A high temperature route to the formation of pure, highly crystallized quaternary chalcogenide ( $\text{Cu}_2\text{CoZnS}_4$ ,  $\text{Cu}_2\text{ZnSnS}_4$ ) particles is proposed in molten KSCN at  $400\text{ }^{\circ}\text{C}$ . We demonstrated the crucial role of the chemical homogeneity of the various  $\text{Cu}_2\text{O}$ – $\text{MO}$ –( $\text{M} = \text{Zn}$  or  $\text{Co}$ )– $\text{SnO}_2$ –KSCN precursors in order to achieve a pure quaternary chalcogenide structure. The chemical homogeneity of the precursors was also shown to greatly affect the nucleation rate of the quaternary chalcogenide particles. Smallest primary crystallite sizes were thus achieved using a salt precursor ( $\text{CuCl}$ – $\text{ZnCl}_2$ – $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ –KSCN) promoting a high nucleation rate regime probably resulting from directly available metallic cations. These results thus highlight the ability to synthesize highly pure and highly crystallized CZTS particles with controlled primary crystallite sizes.
