#### Abstract

We present the results of a combined analysis of 248 morphological characters and sequences from 3 genes for 29 species of Xeromelissinae and 7 outgroup taxa including representatives of the colletid subfamilies Colletinae, Euryglossinae, Hylaeinae, Paracolletinae, and Scrapterinae. The paracolletine genus Trichocolletes was used to root the tree. The results agree with most of those obtained in an earlier, entirely morphological analysis. Noteworthy are (1) the paraphyly of Chilimelissa in relation to Xeromelissa, and (2) the lack of sister group relationship between Hylaeinae and Xeromelissinae. Other than minor rearrangements resulting from swapping adjacent nodes, the only major difference is the placement of one species of Chilicola, C. aenigma, which no longer groups within C. (Chilioediscelis), but instead appears to be closer to Xenochilicola. The influence upon phylogenetic results caused by highly morphologically autapomorphic taxa is discussed.

bee / Colletidae / phylogeny / Neotropical / Xeromelissinae

## 1. INTRODUCTION

Xeromelissinae is a subfamily of Colletidae of moderate size (approximately 200 species) all of which are restricted to the New World. As the name implies, these bees are generally found in xeric habitats, mostly in temperate areas of southern South America. Xeromelissine bees are typically small to minute, and generally slender.

The taxonomy of Xeromelissinae has had a complex history, summarized by Packer (2008). No tribal divisions are currently accepted within the subfamily: the previous tribal level classification having been dispensed with by Michener and Rozen (1999).

[^0]There are four currently recognized genera, the phylogenetic relationships among which, according to Packer's (2008) analysis of a large number of morphological characters, are summarized in Figure 1.

Only Chilicola has been considered large and/or diverse enough to warrant division into subgenera, of which there are now fifteen. Chilimelissa, as commonly recognized (e.g. Michener, 2000) is comparatively speciose and diverse, although no formal subdivision into subgenera has yet been made as phylogenetic analysis of it remains incomplete. Xenochilicola comprises three species, and Xeromelissa is monotypic and only includes $X$. wilmattae Cockerell. Packer (2008) found Xeromelissa to render Chilimelissa paraphyletic, and as a consequence proposed a revised generic classification for Xeromelissinae.

The purpose of the present paper is to test Packer's classification of the Xeromelissinae

Figure 1. Summary of phylogenetic relationships among xeromelissinae genera according to the analysis of the morphological data set by Packer (2008: Figs. 1 and 2).
by comparing results among morphological, molecular and total evidence analyses.

## 2. METHODS

### 2.1. Taxon sampling

Different taxa were available in a form suitable for DNA sequencing than were used in the previous morphological analysis. Consequently, there are fewer representative subgenera of Chilicola, but more species of Chilimelissa, than in the earlier study and the remaining two genera are represented by only a single species each. Chilicola is abbreviated as "Cc.", Chilimelissa as "Cm.", and Colletes as "Co.". There are also differences in the outgroups used for molecular and morphological analyses. In some cases (such as Hylaeus affinis (Smith)), the same outgroups available for DNA were scored for the morphological characters. In others, only congeners could be used, with the result that Colletes cunicularius L., Scrapter nitida Friese, Euhesma halictoides (Rayment), and Callohesma calliopsiformis (Cockerell) were used for morphology whereas Co. bicolor Smith, S. niger Lepeletier and Serville, E. crabronica (Cockerell), E. platyrhina (Cockerell), and Ca. calliopsella (Cockerell) were sequenced. Packer (2008) used Colletes to root the entire tree (which included representatives of three other subfamilies related to the Xeromelissinae Hylaeinae, Euryglossinae, and Scrapterinae ${ }^{1}$ ). Here

[^1]we use the paracolletine genus Trichocolletes to root the entire tree, including Colletes. This decision is based upon results of a higher level phylogeny of the entire Colletidae (Almeida, 2007).

In instances where only one sex is known for a species that was used in the molecular data set, that sex was coded for the morphological characters and a closely related species was used for the other sex. This was necessary twice: females of Chilicola tricarinatoides Packer and males of Cc. liliana Packer are unknown. Females of $C c$. tricarinata Packer and males of Cc. olmue Toro and Moldenke, respectively, were used in their place. Similarly, there are a few cases where the species that was sequenced was very closely related to one that was studied morphologically, these taxa were combined in the total evidence analysis. Thus Cc. unicarinata Packer and Cc. chubutense Packer; Cc. andina Toro and Moldenke and Cc. araucana Toro and Moldenke; Cc. mantagua Toro and Moldenke and Cc. vicugna Toro and Moldenke; Cc. brzoskai Michener and Cc. (Oroediscelis) sp. were used for morphological and molecular data, respectively.

In total, 36 taxa were included in the analyses, 7 representing outgroups. The complete list of taxa and their provenances are provided in Table S1 (online material).

### 2.2. Morphological characters

We simply scored all exemplars for the same characters as were used by Packer (2008) and do not reiterate the characters or their states here. In cases where additional character states were required for
the different suite of species used, these are described in Appendix 2 (online material). Similarly, we only present the data matrix for those taxa not included in the previous analysis (Appendix 3: online material).

### 2.3. Choice of molecular data

Molecular data were collected from three gene loci that have been providing robust results for insect phylogenetic studies (Danforth, 1999; Danforth et al., 2004). Elongation factor-1 alpha, F2 copy (EF-1 $\alpha$ ) and the large subunit 28 S rRNA locus (28S rRNA), regions D1-D5 were chosen to resolve deeper relationships among outgroup and ingroup taxa, and within Xeromelissinae as well. These genes have been used to successfully recover Tertiary to Cretaceous age divergences in bee phylogenies (e.g., Danforth et al., 1999, 2004, 2006a, b). $\mathrm{EF}-1 \alpha$ has been the most widely used nuclear protein-coding gene for insect phylogenetics (see Danforth et al., 2004, pp. 310-311 for comments on this gene) The third gene sampled was cytochrome oxidase 1 (COI), a mitochondrial protein-coding gene known for its utility in species-level phylogenetic studies of insects (e.g. Danforth, 1999).

Primer information for each gene is presented in Table S2 (online material).

### 2.4. DNA extraction, PCR, and sequencing

Genomic DNA was extracted using phenolchloroform protocols (Doyle and Doyle, 1990, adapted by Danforth, 1999) but without use of liquid nitrogen and RNase. Tissue was taken from the thoracic musculature and/or legs depending on the rarity and size of available specimens. The phenol-chloroform-isoamyl alcohol stage was performed in Phase-Lock Gel® 2.0 mL Eppendorf tubes to facilitate the separation of phenol from the remainder and thus increase the final DNA yield. PCR amplifications of the genes listed above were done for 35 cycles under the following conditions: an initial denaturation at $94{ }^{\circ} \mathrm{C}$ for 60 s , followed by 35 cy cles under the following conditions: an initial denaturation at $94{ }^{\circ} \mathrm{C}$ for 90 s , followed by 35 cycles of denaturation at $94{ }^{\circ} \mathrm{C}$, annealing at $48-58{ }^{\circ} \mathrm{C}$, and extension at $72{ }^{\circ} \mathrm{C}$ - specific conditions for each locus amplified are listed in Table S2. Prior to sequencing, most PCR products were gel-purified in
low melting point agarose gels (FMC, Rockland, Maine) overnight at $4^{\circ} \mathrm{C}$. DNA was recovered from gel slices using the Promega Wizard PCR Preps DNA Purification kit. Gel purification was unnecessary for PCR products that produced a single product: both fragments of 28 S rRNA and the upstream 1100 bp fragment of EF- $1 \alpha$. Automatic DNA sequencing was performed using the Applied Biosystems Automated 3730 DNA Analyzer employing Big Dye Terminator chemistry and AmpliTaq-FS DNA Polymerase at Cornell University Life Sciences Core Laboratories Center.

### 2.5. Data analysis

### 2.5.1. Alignment

Alignments were generated using similarity calculated at the nucleotide level ("-n") with DIALIGN 2.2 (Morgenstern, 1999) and corrected manually for obvious alignment errors using MacClade v. 4.08 OSX (Maddison and Maddison, 2005) and Winclada 1.00.08 (Nixon, 2002). For EF-1 $\alpha$, the honey bee (Apis mellifera) sequence was used to establish reading frames and intron/exon boundaries. In cases where multiple sequences were available for the same species, the sequences were merged after being resolved in the same clade in preliminary analyses and resulting partial polymorphisms were kept as such.

### 2.5.2. Phylogenetic analyses using parsimony

Raw data files were edited with Winclada (Nixon, 2002) and this program was used to export to TNT version 1.1 (Goloboff et al., 2004). Sequence indels were treated as missing data. Ratchet, sectorial, drift and tree fusing with "collapse trees after search" and "find minimal length" set to 10 found the same most parsimonious trees. Symmetrical resampling (Goloboff et al., 2003) was performed on unweighted results with 10000 iterations and a probability of character weight change (up or down) of $33 \%$. Symmetric resampling allows estimation of group support without being biased by differential character (or character state) weights, which affect results obtained with jackknifing and bootstrapping (see Goloboff et al., 2003). Support is indicated on the cladograms using GC (Group supported/Contradicted). For a particular node, this

Table I. Overview of the datasets.

|  | Number of <br> characters | Informative <br> characters | Total <br> information | Information/ <br> number of characters |
| :--- | :---: | :---: | :---: | :---: |
| EF-1a exons | 1098 | 267 | 1416 | 1.29 |
| EF-1a introns | 586 | 240 | 1345 | 2.30 |
| 28S rRNA | 1565 | 135 | 655 | 0.38 |
| COI | 663 | 257 | 1490 | 2.24 |
| molecular combined | 3912 | 899 | 4906 | 1.24 |
| morphology | 248 | 425 | 2143 | 8.61 |
| COMBINED | 4160 | 1324 | 7049 | 1.68 |

calculates the difference between the frequency of the group and the most frequently found contradictory arrangement. GC values can vary from -100 to +100 , representing maximum contradiction (the alternative grouping is favored in all resampled matrices) to maximum support (the original grouping found in all resampled matrices) (Goloboff et al., 2003).

### 2.5.3. Bayesian phylogenetics

The best-fit model of evolution for each of the four partitions (introns and exons of $\mathrm{EF}-1 \alpha, 28 \mathrm{~S}$ rRNA, and COI, was statistically tested. Decision theory (DT), Akaike information content (AIC), and Bayesian information content (BIC) were employed to seek for a balance between model complexity and its suitability for each data partition. Two computer programs were used to shed light on the most appropriate model(s) for the data: (1) DTModSel (Minin et al., 2003 - DT model selection) and (2) MrAIC.pl 2.2 (Nylander, 2004 - AIC and BIC).

Bayesian searches were conducted with the serial version of MrBayes 3.1.2 (Altekar et al., 2004; Huelsenbeck and Ronquist, 2005) through the Computational Biology Service Unit at the Cornell Theory Center. Searches were run for $3 \times 10^{6}$ generations on two sets of 10 chains each. The initial 2000 trees were discarded after examining the variation in log likelihood scores over time. Convergence was also assessed using the potential scale factor for the parameters. A partitioned model for the four loci (exons and introns of EF- $1 \alpha$ treated separately) of the concatenated dataset was applied using the following unlinked models: (1) EF- $1 \alpha$, exons: HKY $+\mathrm{I}+\mathrm{G}$; (2) EF-1 $\alpha$, introns: GTR $+\mathrm{I}+\mathrm{G}$; (3) 28 S rRNA: SYM $+\mathrm{I}+\mathrm{G}$; (4) COI: GTR+G+SSI.

## 3. RESULTS

### 3.1. Data set

GenBank accession numbers for all sequences used in this study are presented in Table S3 (Supplementary Materials).

The complete combined matrix contained 4160 characters: 3912 molecular and 248 morphological. The information content (sensu Farris) was higher for the morphological component as was the mean relative information of its constituent characters, i.e. information/number of characters (Tab. I). Information of a character is a quantity defined as its maximum number of steps minus its minimum number of steps (this is also the denominator for the retention index [Farris, 1989]).

### 3.2. Phylogenetic results

The morphological data gave nine most parsimonious trees of length $1215, \mathrm{ci}=46$ and ri $=69$ (strict consensus shown in Fig. 2). All of the unresolved nodes are within the clade formed by Chilimelissa and Xeromelissa. This is not so surprising considering that the main objective of the original morphological data matrix was to assess generic level relationships within the subfamily and subgeneric relationships within Chilicola - a more extensive suite of characters for Chilimelissa would likely result in greater resolution. The new result is entirely congruent with the previous analysis.

The molecular data yields eight most parsimonious trees with length of 3703 steps, $\mathrm{ci}=49$ and ri $=62$ (strict consensus shown in Fig. 3). While the relationships among

Figure 2. Strict consensus cladogram of the nine most parsimonious trees based on the morphological matrix analyzed with equal weights; tree length $=1215$, ci $=46$, ri $=69$. Species of Xeromelissinae are marked in bold; names of colletid subfamilies sampled as outgroups for the analysis are provided after the species names.
the genera of Xeromelissinae remain congruent with those of the morphological analysis (Fig. 2), the phylogenetic pattern among outgroups and subgenera of Chilicola are different. In particular, the molecular data place the euryglossines with the scrapterines, which is congruent with previous molecular analyses (Almeida, 2007). Chilicola does not appear as monophyletic here, with Xenochilicola mamigna, Chilicola aenigma, and the clade comprised by the remaining Chilicola species forming a trichotomy. Many of the subgenera of Chilicola are also in unexpected relationships. Within the clade consisting of Chilimelissa and Xeromelissa, however, the pattern is congruent with that of the previously published result (Packer, 2008), except that Cm. rozeni and Cm. australis are now in a clade (along with three species not previously included) separate from other Chilimelissa. The Bayesian analysis of the molecular data does not support the monophyly of Chilicola
either: Xenochilicola mamigna and Chilicola aenigma form a clade, sister to the remaining Chilicola species (Fig. 4).

The total evidence analysis resulted in three equally most parsimonious trees with length of 4963 steps, ci $=48$, ri $=63$ (strict consensus shown in Fig. 5). This analysis reverses most of the unusual features of the results from molecular data to less unexpected patterns. The subfamily level result is (Paracolletinae, Colletinae (Scrapterinae (Hylaeinae (Euryglossinae + Xeromelissinae)))). Relationships among the genera are identical to that found in the morphological cladistic analysis and the Bayesian molecular analysis, except for the placement of Cc. aenigma.

## 4. DISCUSSION

Our results are largely in good agreement with the purely morphological analysis of

Figure 3. Strict consensus cladogram of the eight most parsimonious trees based on the molecular matrix analyzed with equal weights; tree length $=3703$, ci $=49$, ri $=62$. Numerals represent GC support values calculated from 10000 replications using TNT $(\mathrm{P}=33)$. Species of Xeromelissinae are marked in bold; names of colletid subfamilies sampled as outgroups for the analysis are provided after the species names.

Packer (2008). The relationships among the outgroups in our combined analysis is identical to that found in the earlier study, with one exception: the generic relationships among the ingroup are the same and the subgeneric (Chilicola) and species (Xeromelissa) phylogenetic patterns are mostly congruent.

The following points of some classificatory import can be stated more firmly than previously on the basis of the combined data:
(i) Our combined data argue against Engel's (2005) suggestion that Euryglossinae and Hylaeinae are sister groups. A larger study of colletid subfamily relationships (Almeida, 2007), as well as a recent study of family-level relationships in bees (Danforth et al., 2006b), strongly suggests that Xeromelissinae is sister to Hylaeinae.
(ii) The synonymization of Chilimelissa with Xeromelissa (Packer, 2008), the latter rendering the former paraphyletic. All
datasets tested (morphological, molecular, and combined), regardless of the kind of phylogenetic analysis performed, strongly support the paraphyly of Chilimelissa in relation to Xeromelissa. This change is being made formally by Packer (2008).
(iii) The resurrection of the subgenus Oediscelisca from synonymy with Oediscelis, from which it is distantly located on the cladogram. It also groups with Anoediscelis as in the earlier study and the resurrection is made formally in Packer (2008).
(iv) The erection of the new subgenus for Chilicola liliana Packer, Cc. olmue Toro and Moldenke, and their relatives (see Packer, 2008).
(v) The resurrection of Heteroediscelis as a subgenus distinct from Oediscelis (Packer, 2008).

The differences between the two sets of results are largely minor, involving swapping

Figure 4. Bayesian majority-rule phylogram based on partitioned model with parameters estimated separately for (1) exons of $\mathrm{EF} 1 \alpha$, (2) introns of $\mathrm{EF} 1 \alpha$, (3) 28 S rRNA, and (4) COI. Branch support is given by posterior probabilities. derived from 58000 trees; the first 2000 trees were discarded. (harmonic mean: $-\operatorname{lnL}=22713.90$ ). Species of Xeromelissinae are marked in bold; names of colletid subfamilies sampled as outgroups for the analysis are provided after the species names.
subgenera of Chilicola on adjacent nodes. Thus, the following pairs exchange places in the combined analysis in comparison to the previously published result: Oediscelis and Heteroediscelis; [Oediscelisca + Anoediscelis] and [Cc.chubutense + Pseudiscelis]; Oroediscelis and Cc. liliana (Fig. 6 ${ }^{2}$ ). Two aspects of the current result suggest more important differences from Packer's (2008) study. The first is that Xenochilicola becomes sister taxon

[^2]to Chilicola rather than to [Geodiscelis + (Chilimelissa + Xeromelissa)] (Fig. 6). This possibility was mentioned by Packer (2008) who showed that the pattern suggested here was, with the original data, actually only one step longer than the most parsimonious result obtained by morphology alone. The closer relationship of Xenochilicola to Chilicola had already been suggested by the classification in which Xeromelissinae was subdivided into Chilicolini and Xeromelissini (e.g. Michener, 1995), and by the analysis by Toro and Moldenke (1979).

The other major difference is more surprising. Packer (2008) found that Cc. aenigma was nested within the subgenus Chilioediscelis; the combined data place it as sister

Figure 5. Strict consensus cladogram of the three most parsimonious trees inferred from a combined data set composed of 248 morphological characters and molecular data from three gene loci: EF- $1 \alpha, 28 \mathrm{~S}$ rRNA, and COI.; tree length $=4963$, ci $=48$, ri $=63$. Numerals represent GC support values calculated from 10000 replications using TNT $(P=33)$. Species of Xeromelissinae are marked in bold; names of colletid subfamilies sampled as outgroups for the analysis are provided after the species names.
to all remaining Chilicola (Fig. 2) and the molecular data alone suggest that it is sister to Xenochilicola mamigna (Fig. 4). In the morphological analysis (Fig. 2), the grouping of this species within Cc. (Chilioediscelis) was supported most strongly by (1) the robust and curved hind tibial spurs; (2) the reduced inner tooth on the hind tarsal claws; and (3) the absence of corbiculate structure of the female sternal scopa. These all appeared as robust synapomorphic evidence for monophyly of the subgenus Cc. (Chiloediscelis) including Cc. aenigma in the original morphological analysis. However, Cc. aenigma is a highly autapomorphic species with numerous unique states, particularly of the male genitalia, that could not be homologized with those of any other exemplar included in the study. Furthermore, it lacked some of the synapomorphies that united Cc. (Chilioediscelis) with related
subgenera, particularly those of the male hind leg, which are considerably modified in related taxa but are not sexually dimorphic (other than for the scopal hairs) in Cc. aenigma. Assuming the close relationship of this species to Xenochilicola to be correct, it is possible to see some similarities between some of the unique states for Cc. aenigma and those found to be synapomorphic for the two species of Xenochilicola included in the morphological study. Resolution of this discrepancy will require reanalysis of the morphological traits of these bees, gathering additional molecular data and incorporation into the data matrix of a recently discovered Patagonian bee species that superficially appears somewhat intermediate between Cc. aenigma and Xenochilicola (Genaro and Packer, unpublished data).

These results suggest an interesting contrast to the long branch problem that is well

Figure 6. Summaries of phylogenetic hypotheses relationships within Xeromelissinae inferred from a morphological dataset by Packer (2008: Fig. 2): cladogram on the left; and the result of the combined matrix formed by molecular and morphological data of the present study (abridged from Fig. 5): cladogram on the right. Dashed lines represent incongruence between the two trees. Species of Chilimelissa, Geodiscelis, Xenochilicola, and Xeromelissa and subgenera of Chilicola missing from one of the original studies were removed from the summary cladograms, while preserving the relationships among the remaining taxa. Chilicola liliana and Cc. chubutense are included in the present study to represent two newly described subgenera (see Packer, 2008 and comments in the text).
known to dog molecular phylogenetic analyses (reviewed by Bergsten, 2005). Here we have a morphologically highly autapomorphic species that came out nested deeply within the phylogeny in, what we now believe to be, the wrong position, as a result of sharing a few convergences. This cautions against accepting the phylogenetic position of morphologically outlying taxa uncritically. An alternative interpretation is that the molecular data is responsible for the attraction of Cc. aenigma to be sister of Xenochilicola (Figs. 3, 4) or to the base of the Chilicola-clade (Fig. 5). The relatively long branch of Xenochilicola mamigna (Fig. 4) reflects many autapomorphies, which is the typical cause of the long-branch attraction phenomenon.

## ACKNOWLEDGEMENTS

This research was funded by Systematic Biology grants to B.N. Danforth (DEB-0211701 and DEB-0412176) and a discovery grant from the Natural Sciences and Engineering Research Council
of Canada to L. Packer. A National Geographic Grant in Aid of Research (NGS grant No. 694601) provided travel funds for the collection of some important specimens for this study. E.A.B. Almeida is grateful to Fundação de Coordenação de Aperfeiçoamento de Pessoal de Nível Inferior (CAPES: Brazilian Ministry of Education) for a Ph.D. scholarship. The following people are acknowledged for arranging loans or gifts of specimens from their collections or loans from collections under their jurisdiction, J.S. Ascher, J.M.F. Camargo, B.N. Danforth, G. Else, Z. Falin, T. Griswold, R. Hoebeke, J. Huber, C.D. Michener, J. Neff, F.D. Parker, A. Roig-Alsina, J.G. Rozen, L. Ruz, F.A. Silveira, F. Vivallo, K. Walker and the late H. Toro.

Une phylogénie des Xeromelissinae (Hymenoptera : Colletidae) basée sur les caractères morphologiques et moléculaires.

Colletidae / abeille / phylogénie / Xeromelissinae / région néotropicale
$\underset{\text { Xeromelissinae }}{\text { Zusammenfassung - Eine }}$ (Hymenoptera: Colletidae),
basierend auf morphologischen und molekularen Merkmalen. Die Xeromelissinae bilden eine Subfamilie der Colletidae. Sie umfasst etwa 200 Art mittelgrosser Bienen, die in ihrer Verbreitung alle auf die Neue Welt bechränkt sind. Wie der Namen bereits besagt, handelt es sich hierbei um Bienen, die im allgemeinen in Trockenhabitaten vorkommen, vor allem im südlichen Südamerika. Xeromelissinen sind typischerweise klein bis sehr klein und im allgemeinen von schlanker Gestalt. In der vorliegenden Arbeit präsentieren wir die Ergebnisse einer kombinierten Analyse von 248 morphologischen Merkmalen und den Sequenzen von drei Genen. Die Analyse umfasst 29 Arten, die alle Genera der Xeromelissinae repräsentieren, sowie 7 Taxa mit Vertretern der ColletidenSubfamilien Colletinae, Euryglossinae, Hylaeinae, Paracolletinae und Scrapterinae als Aussengruppen. Der molekulare Datensatz bestand aus den Sequenzen von zwei Kerngenen (Elongationsfaktor 1 alpha (F2-Kopie) und 28S rRNA) und einem mitochondrialen Gen (Cytochromoxidase 1). Die Wurzel des Stammbaums wurde mithilfe der Merkmale des Genus Trichocolletes (Paracolletinae) definiert. Die Ergebnisse stimmen in den meisten Punkten mit den Befunden einer früheren Analyse überein. Bemerkenswert sind (1) die Paraphylie von Chilimelissa in Bezug zu Xeromelissa und (2) das Fehlen einer Schwestergruppenbeziehung zwischen Hylaeinae und Xeromelissinae. Ausser kleineren Veränderungen in der Stammbaumtopologie, die aus der Verschiebung benachbarter Knotenpunkte herrühten, lag der einzige grössere Unterschied in der Positionierung einer Art des Genus Chilicola, C. aenigma. Diese gruppierte nicht mehr innerhalb von C. (Chilioediscelis), sondern erschien enger verwandt mit Xenochilicola. Neben diesen Ergebnissen diskutieren wir den Einfluss von morphologisch stark autapomorphen Taxa mit wenigen gemeinsamen Merkmalen auf die phylogenetischen Beziehungen mit anderweitig weniger aussergewöhnlichen Arten.

## APPENDIX 1.

## Justification for the use of Scrapterinae Melo and Gonçalves, 2005

In 2005, two family-group names were proposed to include the African colletid genus Scrapter Lepeletier and Serville (Ascher and Engel in Engel, 2005; and Melo and Gonçalves, 2005; the latter being published approximately two months earlier than the former; according to Ascher and Engel, 2006). Scrapter used to be traditionally included in Colletinae (sensu Michener, 2000) or in Paracolletini (Michener, 1989). Its removal from Colletinae and placement in a subfamily of its own makes the classification more concordant with the accumulating phylogenetic evidence for lack of a close relationship between Scrapter and remaining paracolletine bees (references in Melo and Gonçalves, 2005; Ascher and Engel in Engel, 2005). The two names are spelled differently, which facilitates their distinction: Melo and Gonçalves (2005) used the stem "Scrapter-", whereas Ascher and Engel (in Engel, 2005) picked "Scraptr-".

Based on the Principle of Priority (ICZN, 1999: article 23.1), the name proposed by Melo and Gonçalves (2005) is to be considered the senior synonym. However, Ascher and Engel (2006) claimed that the name based on the stem "Scrapter-" is not valid because Melo and Gonçalves did not comply with article 13.1 (ICZN, 1999) in providing an explicit diagnosis for the group. By accepting Ascher and Engel's (2006) position, Scrapterini Melo and Gonçalves is to be interpreted as nomen nudum. Nevertheless, Melo and Gonçalves (2005) listed various references that indirectly serve for the diagnosis of the group and,
therefore, comply with Article 13.1.2 of the Code (ICZN, 1999).

Because we believe the interpretation of this matter remains contentious and depends on the subjective interpretation of article 13.1, we prefer to remain neutral on this and adhere to the Principle of Priority, which favors the name by Melo and Gonçalves (2005). The name used throughout the paper hence is Scrapterinae Melo and Gonçalves.

Finally, we would like to point out that the reason for this choice does not have to do with the adoption of a more correct spelling of the stem of the family-group name based on Scrapter. Under the International Code of Zoological Nomenclature, stems of both names, i.e. Scrapter- and Scraptr-, are equally acceptable because they were proposed after 1999 (ICZN, 1999: Article 29.4.2; and, for further discussion, see Ascher and Engel, 2006: 118).

3*. S2 specialised hairs sparse
3. S4 with long erect hairs
4. S5 with long erect hairs and apical hair row
9. S6 with hairs

4*. Labrum narrowly concave apically
4. Genal margin mostly parallel to posterior margin of compound eye
5. F1 petiolate
2. Stigma absent

4*. S7 ventral lobe anteriorly directed basally, laterally directed apically
9. S7 dorsal lobe triangular

4*. S7 apical disk unique
9*. S7 apical disk unique
8. S8 apical lobe unique
3. Inner posterior margin of gonoforceps with acute process
5. Mesoventral lobe of gonoforceps broadly based, swollen
4. Membranous lobe of gonoforceps long and broadly attached
8. Gonostylus unique
3. Paraocular area with triangular pale marking
5. Metasomal terga with sparse apical bands of silver setae
4. Frontal line below broadly raised
9. Facial fovea broadly S-shaped

6*. Epipharyngeal tongs with apex unique
4. Basal articulation of cardo L-shaped
2. Premental rods of intermediate length
4. Prementum ventrally angularly convex
7. Premental lobe short, bilobed
8. Premental lobe parallel-sided basally, flared apically
9. Metapleural flange broadly convex
