Acknowledgements

We wish to thank Ademe for its financial support within the framework of the research contract n°99 66 014 "Emissions unitaires de polluants des voitures particulières – Technologies récentes et polluants non réglementés".

We wish to thank the European Commission for its financial support within the framework of the Artemis research contract n°1999-RD.10429 "Assessment and reliability of transport emission models and inventory systems", workpackage 300 "Improved methodology for emission factor building and application to passenger cars and light duty vehicles" - Project funded by the European Commission under the Competitive and sustainable growth programme of the 5th framework programme.

The authors would like to thank all the laboratories, which provided them with data. And more particularly people who sent data and comments: Mr Weilenmann from EMPA (Switzerland), Mrs Prati from Istituto Motori (Italy), Mr Laurikko from VTT (Finland) and Mr Vermeulen from TNO (The Netherlands). Their remarks were very useful to improve this document.

12 Notes			
13 Summary After a survey among 39 European laboratories, data were obtained concerning 1 766 vehicles and 35 941 measurements (1 measurement corresponds to 1 vehicle, 1 cycle and 1 pollutant). Data were measured during standardised and representative cycles. The data received were analysed in order to model cold-start-related excess emissions (defined as the difference between cold and hot emissions, for a same cycle) for 4 regulated pollutants (CO, CO ₂ , HC, NOx) and 116 unregulated pollutants as a function of various parameters: technology or emission standard, average speed, ambient temperature and travelled distance. In the second time, the model is wide from a single trip to a traffic of vehicles, characterized by the parameters traffic flow, overall traffic mean speed and environmental conditions. One uses for that of the statistical distributions, resulting from measurements, which relate the mean speed during the cold period to the overall traffic mean speed, the ambient temperature, and the distribution of mileage during the cold period according to the length of the trip, the cold start number per hour as well as the distribution of mileage after a given stop duration at a given hour. One obtains a simple model expressing a cold unit excess emission in g/km, function of mean speed, ambient temperature, hour and season. This model is provided for the current gasoline and diesel cars. The final model is included in the ARTEMIS emissions inventory model.

12 Remarques		
13 Résumé Après enquête auprès de 39 laboratoires européens, nous avons obtenu des données concernant 1 766 véhicules et 35 941 mesures (1 mesure correspond à un véhicule, un cycle et un polluant). Les données ont été obtenues lors de mesures effectuées durant des cycles normalisés et des cycles représentatifs. Nous avons analysé ces données afin de modéliser la surémission des voitures particulières lors d'un départ à froid (définie comme la différence entre l'émission à froid et l'émission à chaud, pour un même cycle) pour 4 polluants réglementés (CO, CO ₂ , HC, NOx) et 116 polluants non réglementés en fonction de divers paramètres: technologie et norme d'émission, vitesse moyenne, température ambiante et distance parcourue. Dans un deuxième temps, le modèle est étendu d'un seul trajet à un trafic de véhicules, caractérisé par les paramètres flux de trafic, vitesse moyenne, et conditions environnementales. On utilise pour cela des distributions statistiques, issues de mesures, qui concernent la vitesse moyenne à froid en fonction de la vitesse moyenne générale, la température ambiante, la distribution du kilométrage à froid selon la longueur des trajets, le nombre de départ à froid par heure ainsi que la distribution du kilométrage après un arrêt donné à une heure donnée. On obtient un modèle simple exprimant une surémission unitaire à froid en g/km, fonction de la vitesse moyenne, de la température ambiante, de l'heure et de la saison. Ce modèle est fourni pour les voitures essence et diesel actuelles.		
Le modèle final proposé fait partie du modèle ARTEMIS d'inventaire des émissions.

1. Introduction

The Artemis (Assessment and Reliability of Transport Emission Models and Inventory Systems) study is aiming at developing a harmonised emission model for road, rail, air and ship transport to provide consistent emission estimates at the national, international and regional level.

The workpackage 300 entitled "Improved methodology for emission factor building and application to passenger cars and light duty vehicles" is aiming at improving the exhaust emission factors for the passenger cars and light duty vehicles, by investigating the accuracy of the emission measurements, by enlarging the emission factor data base especially for non-regulated pollutants, recent passenger cars and light duty vehicles, and by building emission factors according to the different purposes of Artemis.

One of the sub tasks of this work package 300 is aiming at modelling the cold start excess emissions of the passenger cars. Three methods are till now available in Europe to model excess emission at start:

- The Handbook, applied mainly in Germany and Switzerland (Keller et al., 1995)
- The MEET approach, based on a synthesis of the available cold emission data in Europe (Joumard and Serié, 1999)
- The Copert III approach (Ntziachristos and Samaras, 2000), which is a mixture of the former Copert and MEET approaches.

Samaras et al. (2001) evaluated the values of excess emissions for various situations in Europe, by using the three approaches. He found that, due to the differences between the methodologies of Copert III and MEET, there are discrepancies between the predicted values of the total emissions due to cold start. These effects however are mostly exhibited at very low values of the speed and ambient temperature and become negligible when intermediate values of these parameters are approached. In general, the difference between the results obtained by Copert and those by MEET is reduced for temperatures between 15°C and 25°C and also for high values of the vehicle speed. The agreement between the results of Copert III and those of the model suggested in the German handbook is very good, especially in the case of Euro I vehicles, even though the two models exhibit several differences with respect to the methodology. All these calculations show that the excess emissions depend of course on the methodology used and on the emission data used.

The present study is using cold measurements collected during the MEET project, together with measurements collected recently, and measurements carried out specifically for the Artemis study. The aim of this study consists in modelling the cold start impact on road vehicle emissions as functions of the pollutant and the vehicle type, using all the existing data in Europe. This model is developed empirically, considering the available data for passenger cars: excess emissions indeed, but also ambient temperature, and driving behaviour statistics.

Such model is necessary for large-scale applications - national inventories for instance - but could also be used for smaller scale applications. The geographical and time limits of the applications depend on the quality of the available data and will be presented.

2. The concept of cold start excess emission

As expressed by Duboudin and Crozat (2002), as long as a vehicle does not reach its running temperature, the emissions of atmospheric pollutants (CO, HC, NOx, PM for instance) are increased. In the case of cars non equipped with a 3-way catalyst, this excess of emission comes from a non-optimal engine running. Therefore the engine temperature is the main parameter. In the case of vehicles equipped with a 3-way catalyst, the catalyst temperature determines the functioning conditions and therefore the emissions. In both cases we define the time needed by a vehicle to reach its normal running temperature, and an over emission before. The concept of over emission is defined below.

The evolution of the instantaneous emission of a vehicle along the time, for a given pollutant, an engine speed and an initial engine temperature, can be split up into a first phase with a decreasing emission due to the progressive increase of the engine or catalyst temperature, followed by a stability phase when the normal engine temperature is reached (Figure 1). The first phase corresponds to the time t_{cold} .

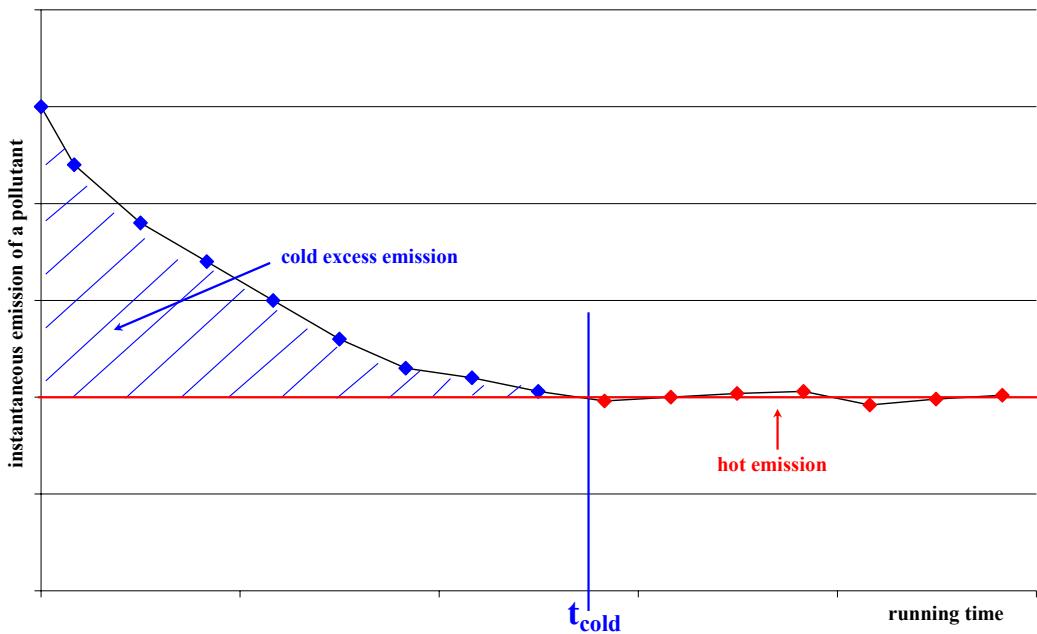

Figure 1: Evolution of the instantaneous emission of a vehicle according to time in given running conditions.

The cold excess emission is defined by the amount of pollutant emitted in excess before t_{cold} as compared the same time travelled with the normal running temperature. It is possible to transform the concept of time into the concept of distance travelled in cold condition through the average vehicle speed, again for the same engine speed (Figure 2).

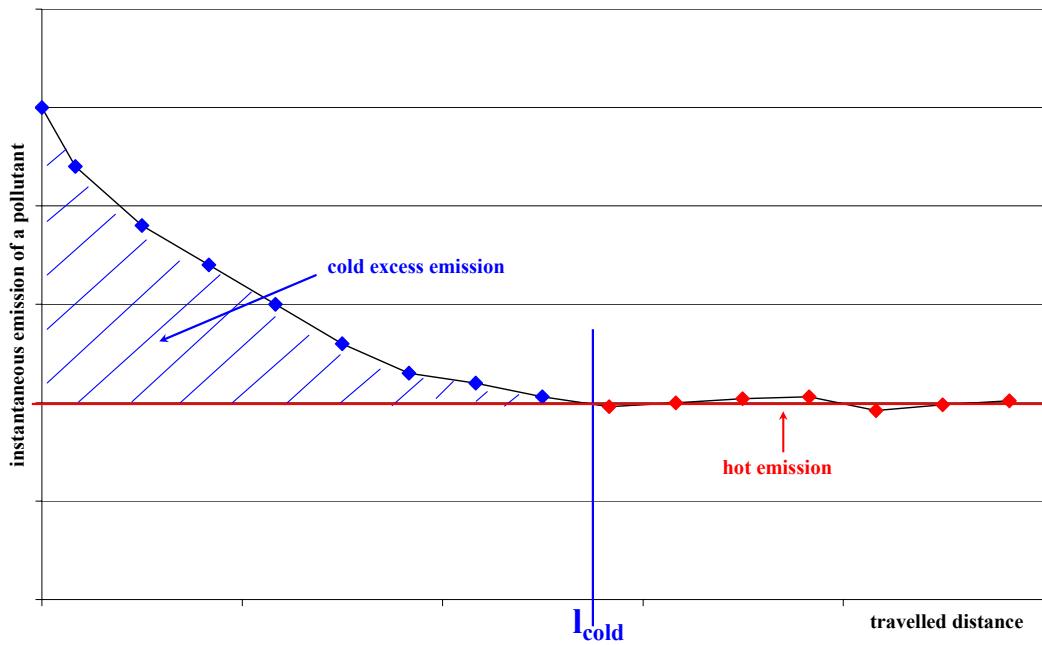

Figure 2: Evolution of the instantaneous emission of a vehicle according to travelled distance in given running conditions.

The distance needed to reach stabilised emissions is called l_{cold} .

When we consider a driving cycle, composed of a succession of different vehicle speeds and therefore different engine speeds, the instantaneous emission is much more complex and unsteady. It depends on the different running phases and on the progressive temperature increase (the Figure 3 is not really an example, but rather an illustration of that, when the engine speed variations are much quicker than the temperature increase).

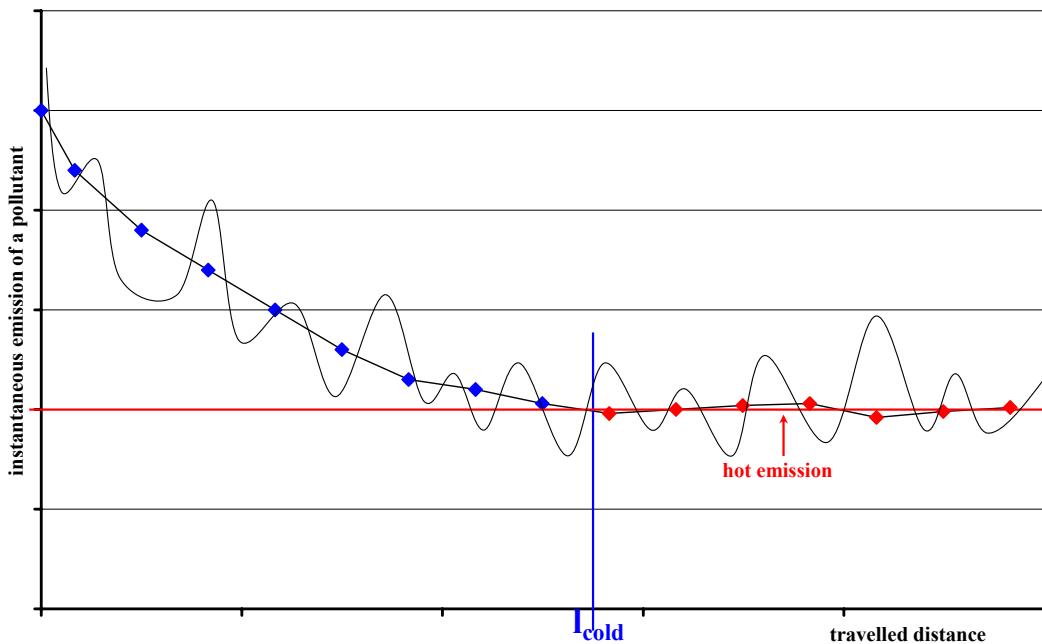

Figure 3: Evolution of the instantaneous emission of a vehicle according to travelled distance in real-world running conditions.

The total cold excess emission for a vehicle and a driving cycle is defined as the excess emission of a vehicle starting at the ambient temperature as compared to a vehicle running in hot conditions. This excess emission depends of course on the ambient temperature (more or less far from the normal running temperature). This definition is meaningful only if the variations of accelerations and decelerations within the cycle are much quicker than the vehicle temperature increase.

This total cold excess emission can be measured as the hot emissions on a vehicle bench, if the used driving cycle is long enough: the stabilisation distance must be reached. The excess emission depends on the pollutant and a priori on the driving cycle. In addition, if we want to assess the relationship between the excess emission and the driving behaviour through the driving cycles, the vehicles must follow the same driving behaviour during the cold and hot phases. To define the cold duration t_{cold} or the cold distance l_{cold} , as a function of the driving cycle, the driving cycle duration must be much shorter than t_{cold} . It is the reason why we developed short driving cycles of 100-200 sec (Joumard et al., 1995b), repeated a lot of times on the bench.

A vehicle does not start only at the ambient temperature or in hot conditions. We can therefore define a cold excess emission as a function of a start engine/catalyst temperature, which can be different from the ambient temperature.

In the same way a vehicle is not always driven during the full cold distance l_{cold} . We can therefore define a cold excess emission as a function of the distance travelled in cold conditions. The upper limit of this excess emission is the total cold excess emission already defined.

The total emission during a driving cycle of a vehicle, which does not start in hot conditions, can be calculated by the sum of the hot emission during the cycle and the cold excess emission during the same cycle:

$$E_{cold} = E_{hot} + EE_{cold}$$

The concept of the relative cold emission can be also defined. It is the ratio of the cold emission during a given driving cycle over the hot emission during the same cycle. This ratio depends on the travelled distance, as, in steady conditions, the cold emission is unsteady and the hot emission is a constant.

In fact there are five different ways of presenting cold effect results. These are:

- ✓ average cold emission factors (g/km) of the first (cold) period
- ✓ absolute emissions (g) of the cold period
- ✓ the difference of average emission factors (g/km) between cold and hot periods, i.e. a unit excess emission
- ✓ the ratio of cold and hot emissions (relative cold emission)
- ✓ absolute excess cold start emissions (g) defined as the additional emission value obtained under cold conditions compared to the emission value that could have been recorded for the same period (cycle) under hot conditions, as described above

In this report, the last excess emissions are addressed.

3. Data

3.1. Initial data

In January 1994 an inquiry was sent to various European laboratories studying vehicles emissions under cold start conditions. Data were obtained from TNO, INRETS, TU-Graz, TÜV, Politecnico di Milano, TRL, EMPA, INTA, VTT, VTI, KTI and LAT (see Annex 1 for laboratory acronyms). Information was asked about cold start tests: number of test vehicles, vehicle type and characteristics (fuel type, model year, engine capacity), driving cycle type, ambient temperature, start condition, emission measurements. Only a few number of laboratories were able to provide data relative to cold start, i.e. measuring cold and hot emissions over a same driving cycle.

16 770 emission factors measured with 1 378 passenger cars were collected. But only 15 616 emission factors measured with 1 229 passenger cars were kept for this work. The vehicles, which have no emission standard or with a "US87" emission standard, were deleted from the database, because they cannot be considered as European emission standard. Data without both hot and cold emission factors were also deleted from the database.

In December 2002, the same inquiry was sent to the same laboratories to get new data. The data from the Artemis project were also added to the existing data. The list of available data is given in Annex 2 on page 54.

Finally we process data from the following laboratories: EMPA, INRETS, IM, TNO and VTT.

A data represents one measurement for one vehicle during a cold or a hot cycle, independently of the pollutant recorded. To obtain the number of data, we have to multiply the number of vehicles by 2 for ECE-15 and FTP72-1 cycle and by 15 for IUFC and IRC cycles.

Passenger cars were divided into ten categories, for which emissions of regulated pollutants (RP) and unregulated pollutants (URP) are available:

- | | |
|---|------------------------------|
| ✓ Euro 0 gasoline without catalyst (RP & URP) | ✓ Euro 2 gasoline (RP & URP) |
| ✓ Euro 0 diesel without catalyst (RP & URP) | ✓ Euro 2 diesel (RP & URP) |
| ✓ Euro 0 gasoline with catalyst (RP) | ✓ Euro 3 gasoline (RP & URP) |
| ✓ Euro 1 gasoline (RP & URP) | ✓ Euro 3 diesel (RP & URP) |
| ✓ Euro 1 diesel (RP & URP) | ✓ Euro 4 gasoline (RP & URP) |

For each vehicle, 3 types of cold and hot cycles were possibly followed (a short description of these cycles is shown in Table 1):

- ✓ Legislative cycles: ECE-15, FTP72-1.
- ✓ Short Inrets cycles: short free-flow urban (Inrets urbain fluide court, so called IUFC) and short road (Inrets route court, so called IRC); each of these cycles was repeated 15 times. These cycles were drawn up from 23 000 travelled kilometres previously recorded all over France by 35 private cars (EUREV study, André, 1989; André, 1998; Joumard et coll., 1999).

- ✓ Artemis urban cycle (André, 2004a and b). This cycle is designed together with Artemis rural and motorway cycles within the Artemis study. The set of 3 driving cycles is designed in order to test the vehicles with driving cycles as representative of the real-world as possible.

Type	Name	Short name	Duration (s)	Distance (m)	Average speed (km/h)
Standard	FTP72-1		505	5779	41.2
	ECE-15		780	4052	18.7
Inrets	Urbain Fluide Court	IUFC	189	999	19.0
	Route Court	IRC	126	1439	41.1
Artemis	Urban	Art. urban	921	4472	17.5

Table 1: Main characteristics of the driving cycles used.

Concerning excess emission data as a function of the cycle, the total number of obtained data is 35 941, all categories and all pollutants merged, i.e. 28 337 and 8 604 data resp. for regulated and unregulated pollutants. These data were measured with 1 766 vehicles, i.e. 1 604 and 102 vehicles resp. for regulated and unregulated pollutants. All vehicle samples were selected by various laboratories, in order the vehicle distribution to be representative, to some extent, of the fleet corresponding to each country. The number of vehicles tested and the corresponding cycles are shown in Annex 2 (page 54) for the regulated pollutants, and Annex 3 (PAH: page 60) and Annex 4 (VOC: page 61) for the unregulated pollutants.

The Annex 2 (page 54, Table 10) details the number of measurements according to the mean temperature, the minimal and maximal temperatures per cycle and per laboratory.

It should be noted that:

- ✓ For Euro 0 diesel cars with oxidation catalyst, the data are rare and do not allow a full data processing, as for other vehicle categories.
- ✓ For NOx pollutant, some laboratories made standard humidity correction but not all of them. We did not take into account such a correction factor, preferring data without humidity corrections, i.e. actual emissions. Concerning these latter, Annex 5 (page 64) gives the computation of the humidity correction factor.

3.2. Methodology

Once all the data were collected, we had to take into account a number of parameters influencing the general method:

- ✓ Great variety of data:
 - As it can be seen in section 3.1, the number of vehicles analysed with standardised cycles is very significant; but such cycles are not representative since they do not reflect the reality. Comparing, for a same average speed, the standard deviation of acceleration between Inrets and standard cycles (Joumard *et al.*, 1999) yielded significantly differing results, acceleration standard deviation being lower for standardised cycles.

- The short representative cycles (real-world cycles) enabled a fine description of the emission evolution, but there were a limited number of analysed vehicles.

Cycle Name	Emission Standard	Fuel type	CO	CO ₂	HC	NOx
ECE15-1	Euro 0 w/o cat.	Gasoline	287	266	277	288
	Euro 0 cat.	Gasoline	739	739	739	739

	Euro 4	Gasoline	7	7	7	7

Table 2: Vehicle sample size distribution versus driving cycle used to calculate excess emission of regulated pollutants.

- ✓ In the Table 2, we can see that some categories (vehicle type, driving cycle) have not enough vehicles to make a good computation of the cold start influence. So we decided to merge some vehicle categories. The consequences are that some results will be the same for different vehicle categories.
- ✓ When the vehicles are tested using a standard cycle, the engine temperature is not always hot at the end of the cycle, according to Journard *et al.* (1995b). Therefore, we had to introduce a light adjustment for each pollutant. Thus we obtained excess emissions over the entire cold period for different cycles, whether standard or not. Such an adjustment is needed especially for ECE-15 cycle since it is very short. This correction is presented in section 3.3.4.1.
- ✓ The ambient temperature must be taken into account, if possible, whatever the mean speed may be. Therefore, we have to look for a relationship independent of the average speed, considering that initially the starts are made with a cold engine (engine temperature corresponds to ambient temperature at start).
- ✓ We make the following hypothesis: excess emission depends on the engine start temperature only (as temperature parameter), this one being equal to the ambient temperature (real cold start) or greater than the ambient temperature (semi-cold or semi-hot engine). This hypothesis is necessary due to the lack of data. For instance we have no data for a vehicle starting with an engine temperature of 0°C when the ambient temperature is 10°C.
- ✓ Taking into account the travelled distance after a cold start in order to decrease excess emission levels if the travelled distance is lower than the cold distance (i.e. the distance needed to stabilise the emission).
- ✓ Taking into account the parking duration before a start to decrease excess emission level if the parking duration is lower than the duration needed to completely cool the engine at the ambient temperature.

It should be noted that some measurements correspond to the same driving cycle. But, they correspond to measurements made by various laboratories using various measuring devices, in various conditions, with various car models, different vehicle ages, etc... So it results in differences for the same cycles themselves.

3.3. Cold start excess emission and distance calculation

3.3.1. Methods for regulated pollutants

We propose hereafter to analyse the different methods used, in Europe, to calculate the cold start emissions and the cold start distances, when emission factor is a continuous signal. It is the case when instantaneous emissions are available, but also when a short cycle is repeated as long as the emissions are stabilized.

3.3.1.1. First method: Standard deviation

This method was developed previously at INRETS (Joumard and Serié, 1999) and consists in calculating the standard deviation on the last two data, then on the last three, etc., then on all the following consecutive cycles. As long as the emissions are stable (i.e. hot), the variations between them occur randomly around a mean, which is the hot emission. The standard deviation is therefore a decreasing function of the number of points considered. However, the standard deviation increases rapidly as soon as cold start emission appears.

The cold start distance is determined when the standard deviation is minimal. The hot emission is calculated by incorporating the values beyond this minimum. The cold start emission is calculated by incorporating the emissions over the entire cold start distance. The cold start excess emission is calculated by subtracting the theoretical hot emission from the cold start emission throughout the cold driving period.

As an example the Figure 4 shows the graphic representation of the emission of CO for Euro 1 Diesel at 18°C. On this figure the standard deviation is also plot. The standard deviation shows that all the cycles equal or higher than the cycle 9 are hot (during the 9th to 15th cycles the average emission factor is 0.50 g/cycle or 0.30 g/km). Thus the cold distance covers 8 cycles (i.e. 13.48 km). By integrating over the 8 first cycles we obtain the cold start emission of 4.92 g, a theoretical hot emission of $8 \times 0.50 = 4.03$ g, and therefore a cold excess emission of $4.92 - 4.03 = 0.89$ g.

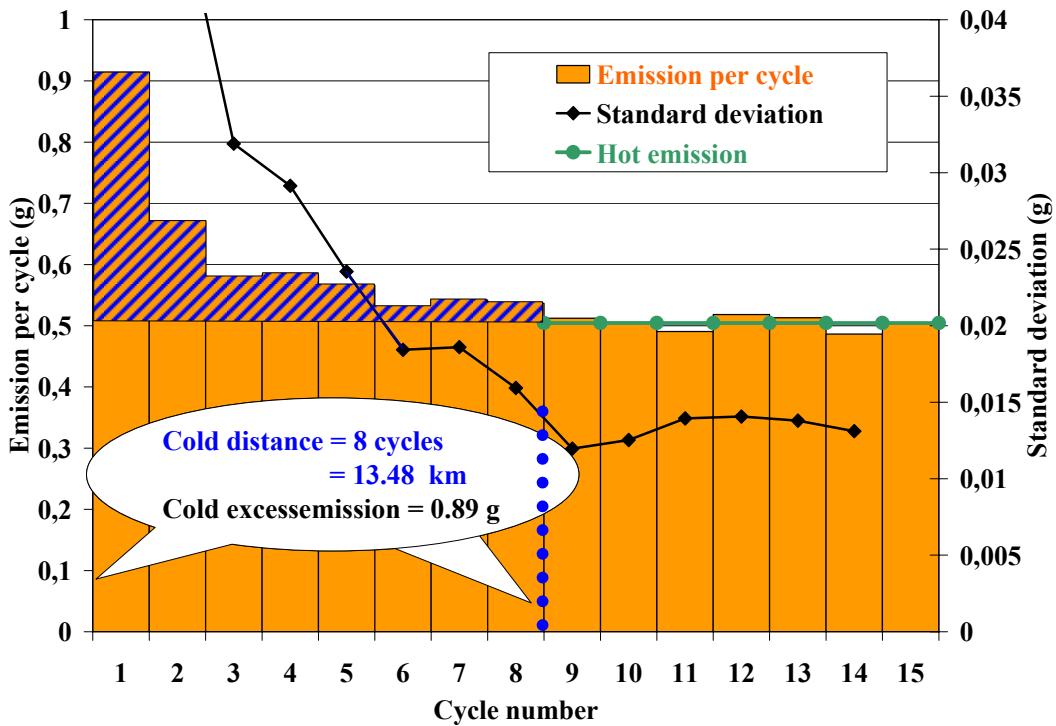

Figure 4: Standard deviation method: Example of cold start distance and emission calculation for Euro 1 diesel vehicle and CO at 18°C. The distance is in km and the emission in g per cycle.

3.3.1.2. Second method: Linear regression

This method developed at EMPA (Weilenmann, 2001) considers the continuous cumulative emission from the start. The linear regression of this cumulative emission is then calculated on the basis of the hot part alone. The regression value at the distance 0 gives the cold start emission value.

The hot/cold limit is calculated from a first rough estimation of the cold distance, and then by plotting two straight lines parallel to the linear regression during the rough hot part. They have the same slope but the constant of the first line is equal to 95% of the emission while the second is equal to 105%. The precise cold driving distance is determined by the last time the total emission falls between these two lines.

This latter method can supply slightly different results in terms of cold driving distance and cold start emission. It is based on a hypothesis on the hot part of the cycle, on which the linear regression is calculated.

As an example the Figure 5 shows us the graphic representation of the emission of CO for Euro 1 Diesel at 18°C. The data are the same than in Figure 4, but we plot in addition the cumulative emission, the cold start emission (0.89 g) calculated from the linear regression (we took the last 7 points because the cumulative emissions curve is like a straight line) and the two lines at 95% and 105% of the cold start emission. Thus the cold distance is the evaluated as 7 cycles (i.e. 10.1 km).

This second method can give slightly different results, in term of cold distance and cold excess emission. The problem of this method is the determination of the hot cycles, over which the hot linear regression is calculated.

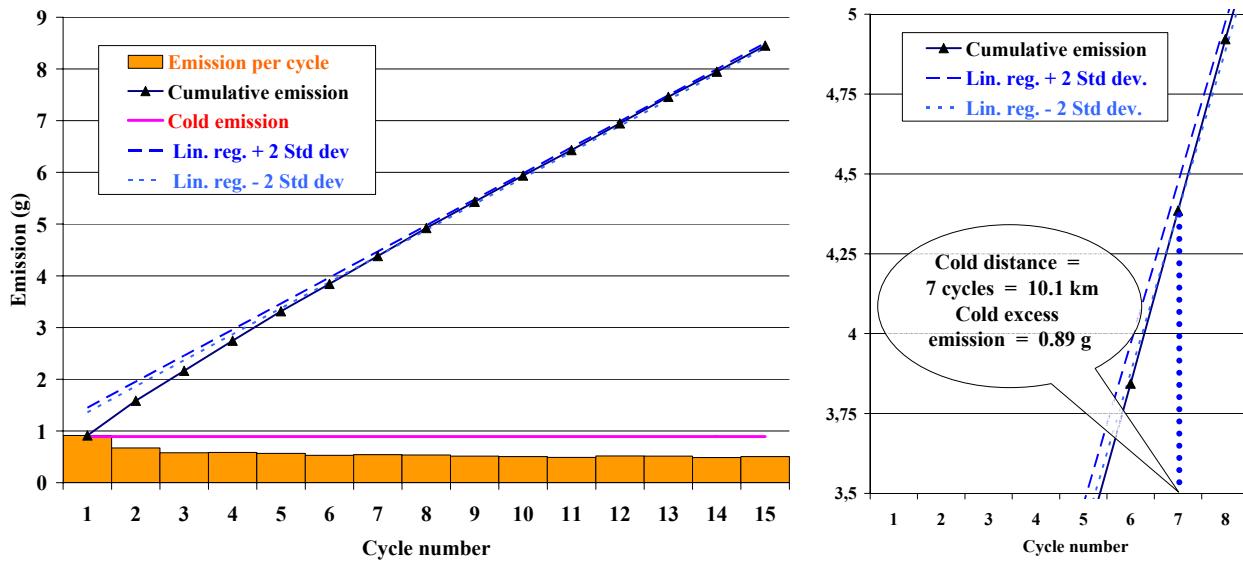

Figure 5: Linear regression method: Example of cold start distance and emission calculation.

3.3.1.3. Artemis method: Linear Regression + standard deviation

This method was specifically developed for this project, by integrating those described above. We first plot the emission per cycle and the standard deviation on the basis of the first method (see Figure 6 and Figure 7).

The rough cold start period is initially determined according to the first method, when the standard deviation is minimal: It is the first 8 cycles. This permits calculating a hot emission (along the 9th - 15th cycles in the example), and a corresponding standard deviation (of 0.017 g in the example). The exact cold driving distance is determined when the curve of the emission cycle after cycle reaches a distance of two standard deviations from the mean when hot (7.2 cycles in the example, see Figure 6). In parallel, the linear regression of the continuous emission over the rough hot start period alone gives the cold start emission at distance 0 (0.9 g in our example, see Figure 7).

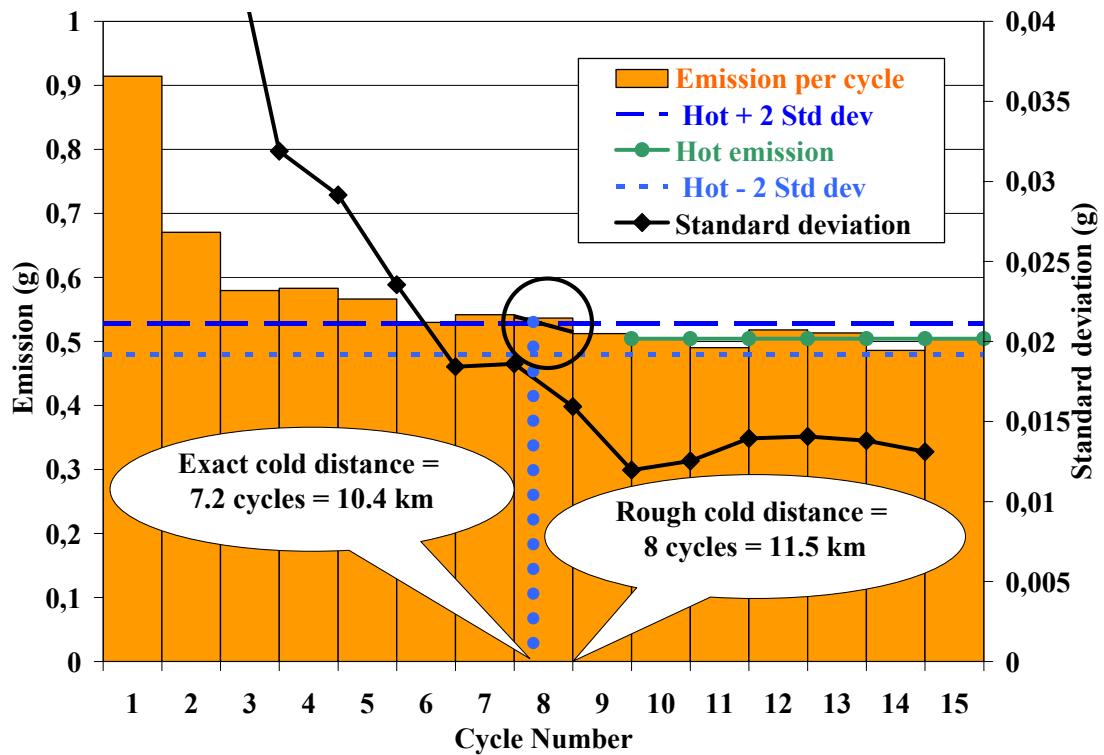

Figure 6: Artemis method: Example of calculation of the rough and exact cold start distances.

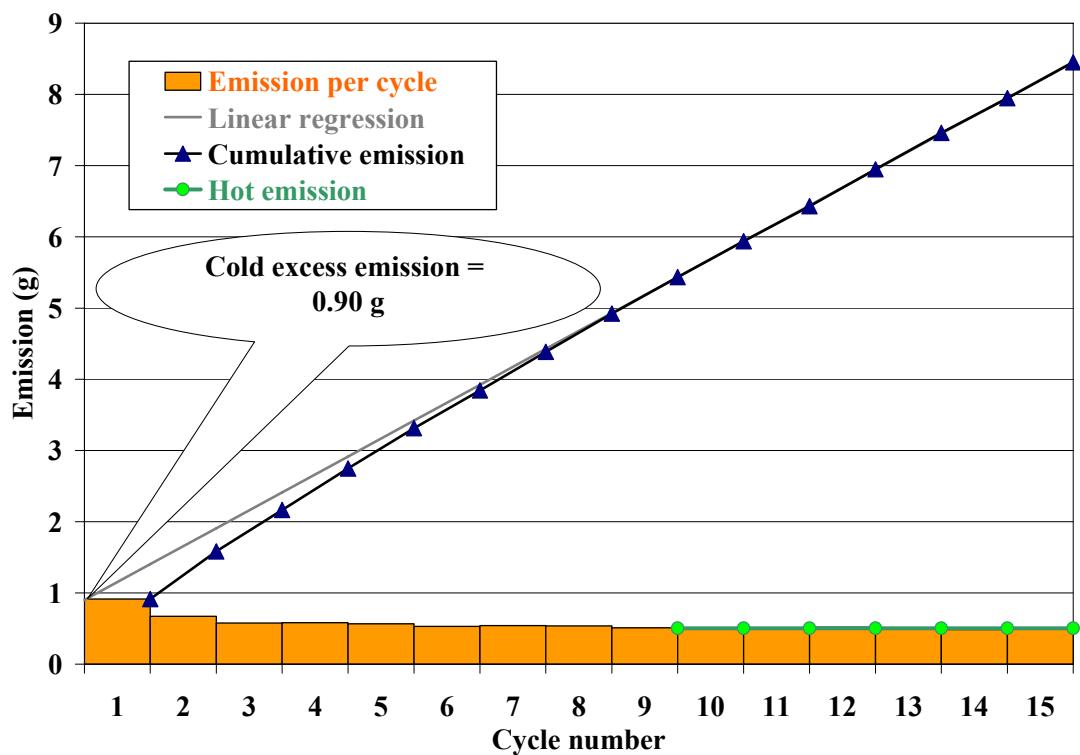

Figure 7: Artemis method: Example of cold start excess emission calculation.

3.3.1.4. Conclusion

The Table 3 shows that, for the same emission data, the three methods give nearly the same cold start excess emission, but not the same cold start distance. The difference between cold distances goes up to 25 %.

With the Artemis method, we can determine:

- ✓ When the cycle is completely hot as in the standard deviation method
- ✓ The cold start emission as in the linear regression method but with more accuracy because we applied the linear regression with the hot emissions
- ✓ The cold start distance with a better accuracy because we are searching when the hot emission cuts the emission by looking at the standard deviation of the hot part.

No assumption is necessary in the linear regression method, and it is a way to calculate the cold start distance precisely by interpolation.

Method	Standard deviation	Linear regression	Artemis
Cold distance (km)	13.48	10.1	10.4
Cold emission (g)	0.89	0.89	0.90

Table 3: Comparison of the cold start distance and the cold start emission calculated with the different methods, in the case of Figure 4 to Figure 7.

3.3.2. Methods for unregulated pollutants

The emissions factors of the unregulated pollutants for the cold start conditions were measured with the short Inrets cycles, the ECE-15 cycle and the Artemis urban cycle, but the pollutant analysis adds constraints in terms of sampling.

The short Inrets emissions were measured with two different conditions. At INRETS the unregulated pollutants emission factors were measured twice with a cold short cycle and with a hot one, both of them repeated 15 times. So the cold start excess emission is the difference between these two values because the cold short cycle is always hot at the end.

The others laboratories measured the unregulated pollutants emission factors with the same short cycle but with three measurements for the cycles 1-5, 6-10, and 11-15. So to calculate the excess emission, we consider that the cold distance is, for all the unregulated pollutants equal to the total HC one; The cold distance of HC is always less than 10 cycles (cf. Annex 6).

With this condition, the excess emission EE is:

$$\text{EE} = \text{emission(cycles 1 to 5)} - \text{emission(cycles 6 to 10)} - 2 \times \text{emission(cycles 11 to 15)}$$

The excess emission deduced from the ECE-15 and the Artemis urban cycles are calculated as for the regulated pollutant, i.e. a light adjustment for each pollutant to obtain excess emissions over the entire cold period for different cycles, whether standard or not, because the driving cycles are too short to end hot.

3.3.3. PAH in gaseous and particulate phase

At INRETS, the PAH were measured into two phase: gaseous and particulate. So it is possible to deduce from these measurements, the percentage of the total excess emission due to the gaseous and to the particulate phase (see Annex 15.2).

3.3.4. Results

3.3.4.1. ECE-15 emissions correction

A previous study (Joumard *et al.*, 1995b) showed that ECE-15 cycle could not cover entirely the cold period due to the cold start. So, we introduced a correction coefficient for this cycle to transform the measured excess emission during standard cycles into a full cold excess emission. This coefficient is deduced from measurement data recorded using IUFC cycle (because the mean speed is near the ECE-15 mean speed), which covers the whole cold period. Using this “cold” distance (see Annex 6), calculated with the Artemis method on the short Inrets cycle data, we calculate the correction coefficient to be applied to adjust the standardised cycles to the representative cycles.

For example (see Figure 8), the ECE-15 cycle corresponds to an average speed of 18.7 km/h and a distance of 4 052 m. For CO pollutant, the cold distance is equal to 8.7 km for the representative cycle with the nearest average speed, i.e. 19.0 km/h (from Annex 6). Regarding excess emission (normalised by the total excess emission) as a function of the distance, the ECE-15 cycle corresponds to 80 % of the total excess emission of the short free-flow urban cycle. Then the factor is equal to 1.25 (=1/0.8). We applied this method to all the pollutants (see Table 4). The correction factors are sometimes important (from 0.77 to 4).

The majority of the correction factors are higher than 1, but sometimes lower than 1. A coefficient lower than 1 is possible when emission partially increasing with distance (rather than always increasing). An example for correction factor lower than 1 is shown in Annex 7.

We consider here that the correction, based on INRETS data for a given temperature, can be extrapolated to other laboratories and ambient temperatures, even these assumptions are wrong. But we have no data to build better assumptions.

3.3.4.2. Cold distance and excess emissions

When applying the whole methodology, we get the cold distance for the 4 regulated pollutants, 2 driving cycles (at 19.0 and 41.1 km/h) and a number of cases (vehicle type, ambient temperature): See Annex 6. Then the excess cold start emissions are calculated from the emission measurements according to different driving cycles, for regulated and unregulated pollutants (see Annex 8 and Annex 9 resp.).

The cold distance covers a large range, from 2 to 9 km, with an average of 5.2 km at 20°C.

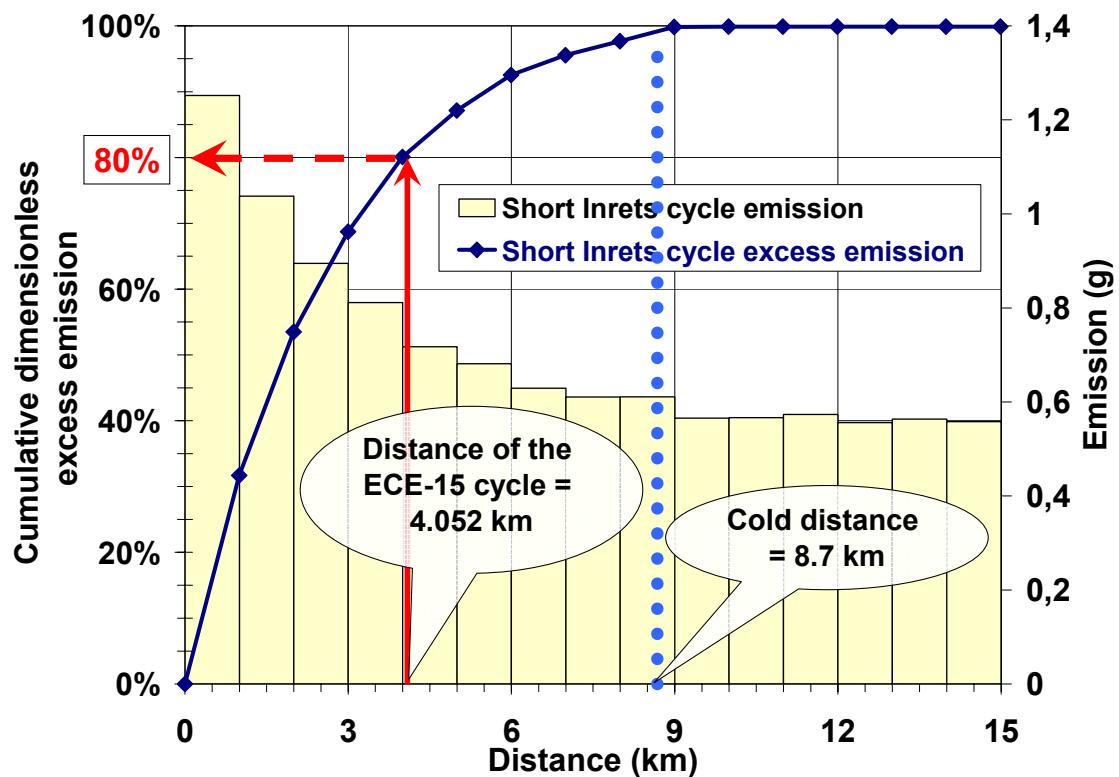

Figure 8: Cumulative dimensionless excess emission (ratio of absolute excess cold start emission to total absolute excess cold start emission) as a function of the distance (km) for the short INRETS free-flow urban cycle. Correction calculation example of ECE-15 cycle for CO pollutant and gasoline cars without catalyst.

Emission standard	Fuel type	Mean temperature	CO	CO ₂	HC	NOx

4. Influence of various parameters

In this chapter, the influence of the ambient temperature, the average speed, the distance and the parking duration on excess emissions is shown. The aim is to express the excess emission EE as:

$$EE(T, V, \delta) = \omega_{20^\circ C, 20 km/h} \cdot f(T, V) \cdot h(\delta) \cdot g(t) \quad (\text{Equation 1})$$

with:

EE (T, V, δ): excess emission in mass per start

T: temperature ($^\circ C$)

V: average speed (km/h)

$\delta = d/d_c$: dimensionless travelled distance

d: travelled distance

d_c : cold distance (km)

t: parking time

$\omega_{20^\circ C, 20 km/h}$: excess emission at $20^\circ C$ and 20 km/h

$f(T, V) = \omega(T, V) / \omega_{20^\circ C, 20 km/h}$: cycle speed and the temperature influence dimensionless function expressed in section 4.1

$h(\delta)$: distance influence function expressed in section 4.2

$g(t)$: parking-time influence function expressed in section 4.3

4.1. Excess emission as a function of the cycle speed and the temperature: $\omega(T, V)$ and $f(T, V)$

Firstly the successive corrections are calculated and applied as follows:

- ✓ Data correction for ECE-15 standard cycle, as explained in section 3.3.4.1.

Then, using the modified data, we applied a 3D linear regression in order to obtain the excess emission level $\omega(T, V)$ in g as a function of the average speed V [km/h] and the temperature T [$^\circ C$] (see Annex 10 page 75, and Table 16 and Table 17 in Annex 9). Another condition must be applied: the excess emission must tend towards zero when T increases.

To apply a 3D linear regression is an assumption quite arbitrary. For instance in Joumard and Sérié (1999), we did another assumption, summing the speed and temperature influences. The present assumption is done to represent at the best the available data, but other modelling could be used.

An example of CO₂ excess emission as a function of the mean speed and ambient temperature for Euro 2 gasoline vehicles is shown Figure 9.

It should be noticed that the regression is calculated using measurement points covering only four speeds and different temperatures (the number of measurements points are indicated Annex 10). One point in Figure 9 is the average of the excess emission for one temperature and one speed. But

the regression was made by weighting each point by the number of vehicles. Using the calculated equations, we determined the correction functions $f(T,V)$ (see Annex 10) corresponding to the functions made dimensionless by dividing them by their values calculated at 20 km/h and 20°C, i.e. $\omega(20^\circ\text{C}, 20\text{km/h})$. It should be noted that the boundaries of the measurements points for the linear regression calculation are [-20°C, +30°C] for the ambient temperature and [18 km/h, 42 km/h] for the mean speed. Outside these boundaries, the values of the regression have to be taken with care. The best way is to take the maximal (or minimal) value of the function at the boundaries outside these ones (Weilenmann, 2001), because this author showed that the speed dependence is not linear but polynomial (2nd degree).

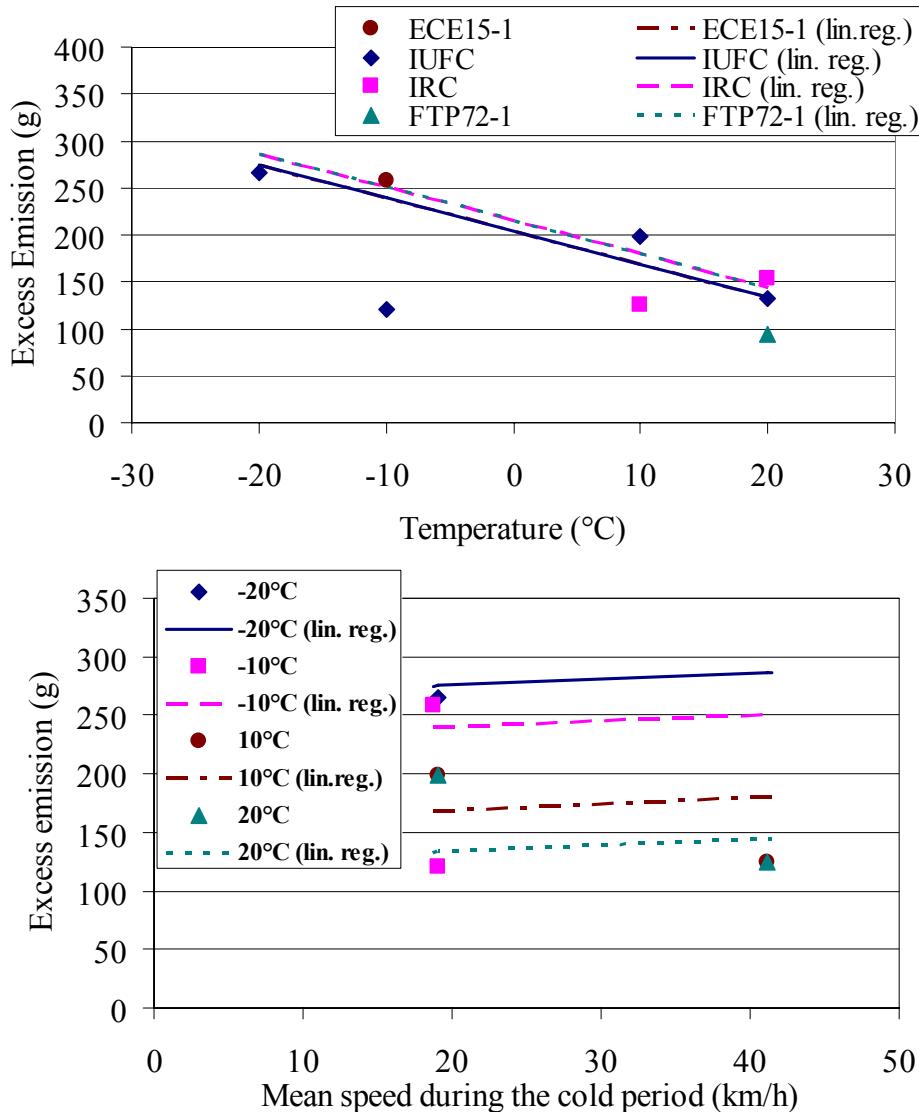

Figure 9: CO_2 excess emission of Euro 2 gasoline vehicles as a function of the mean speed and the ambient temperature.

4.2. Excess emission as a function of the travelled distance $h(\delta)$

The knowledge of the emission evolution during the cold phase, by considering the emissions measured on each Inrets short cycles, allows us to model the excess emission according to the travelled distance. The excess emission is therefore increasing till the end of the cold distance, and then equal to the cold start excess emission presented in section 4.1.

In a first step, we model the cold distance d_c as a function of the vehicle speed V and the ambient temperature T

The Figure 10 shows an example of the cold distance (see Table 5 page 31 and Table 18 and Table 19 in Annex 11 for the data and equations).

Both excess emission and cold distance are therefore expressed as function of V and T . It should be noted that the boundaries of the measurements points for the linear regression calculation are [-20°C, +30°C] for the ambient temperature and [18 km/h, 42 km/h] for the mean speed. So outside these boundaries, the values of the regression have to be taken with care. The best way is to take the maximal (or minimal) value of the function at the boundaries outside these ones.

It allows us to make dimensionless both excess emission and travelled distance (see an example Figure 11; the others ones in Annex 12) and to look at the influence of the dimensionless travelled distance $\delta=d/d_c$ on the dimensionless excess emission. We express this influence as an exponential function $h(\delta)$. It should be noted that the chosen exponential function is well representative of the majority of the data. But in some cases, especially for NOx, the shape is much more complex (as shown in Annex 12.4). As we prefer to model only the influence of the distance, we propose to use the exponential function in all the cases.

This function $h(\delta)$ could be influenced by two available parameters, i.e. the ambient temperature T and the average speed V . But in fact the influence of V and T are very low. Therefore $h(\delta)$ can be expressed as:

$$h(\delta) = \frac{1 - e^{a \cdot \delta}}{1 - e^a} \quad \text{with } \delta = \frac{d}{d_c} \quad (\text{Equation 2})$$

where a is deduced from the data. a is given in Annex 13 for the different vehicle categories.

For the unregulated pollutants, the emission evolution during the cold phase was not measured. So we will consider that the h function for the unregulated pollutants will be the h function of the HC for the same category.

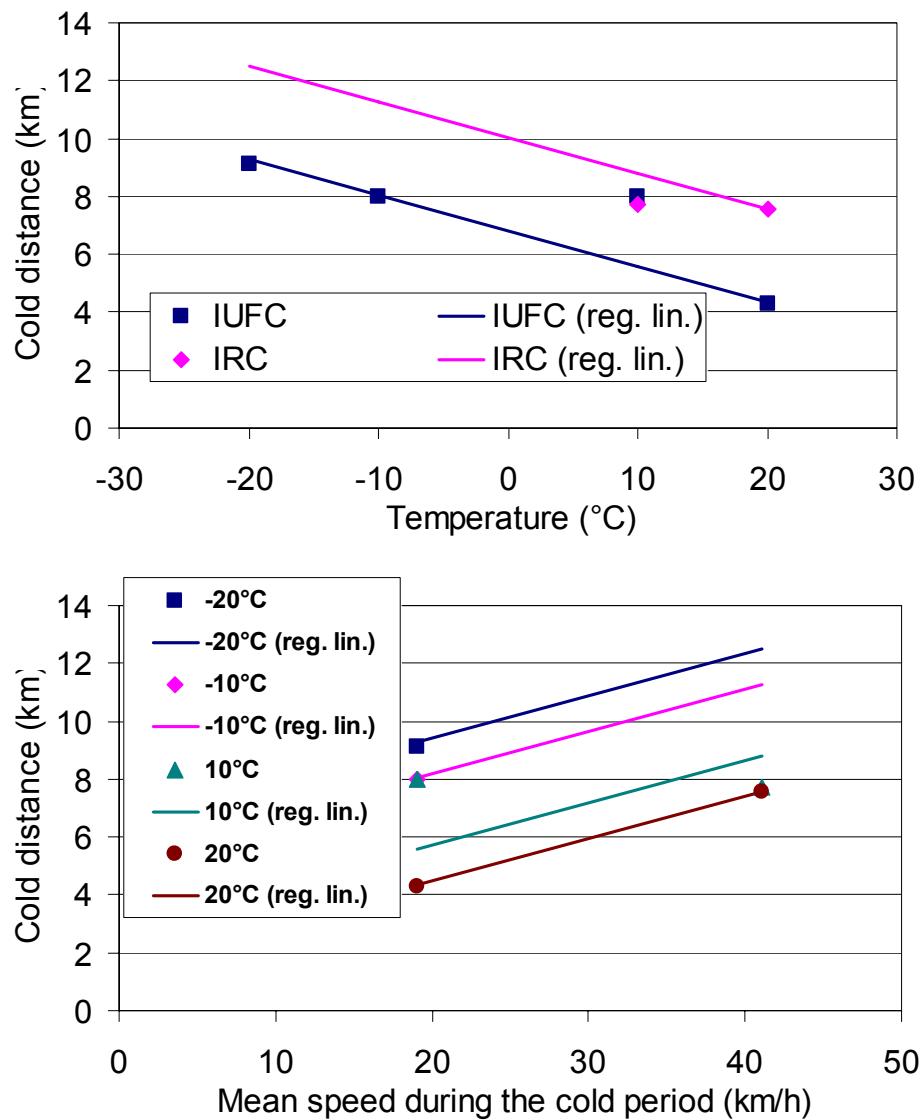

Figure 10: Cold distance d_c (km) as a function of the vehicle mean speed V (km/h) and the ambient temperature T ($^{\circ}\text{C}$) for CO_2 pollutant of Euro 2 gasoline car.

Pollutant	Emission standard	Fuel Type	# of points	$d_c(T,V)$
CO	Euro 0 w/o cat.	Diesel	27	$10.17 - 0.167*T - 0.049*V$

		Gasoline	105	$-2.515 + 0.238*V$
	Euro 3	Diesel	32	$9.809 - 0.094*V$
		Gasoline	708	$1.922 + 0.091*V$
	Euro 4	Gasoline	14	4.523

Table 5: Formula describing the cold distance d_c (km) as a function of the average speed V (km/h) and the temperature T ($^{\circ}$ C). The results of this formula must be positive.

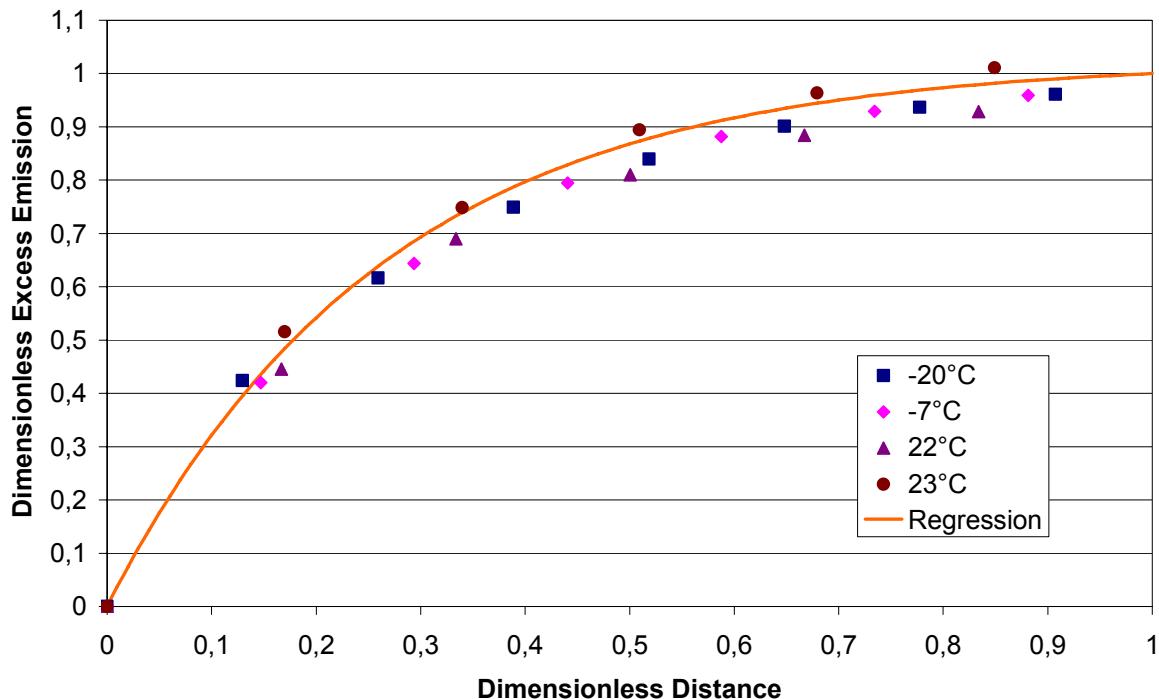

Figure 11: Dimensionless excess emission of CO_2 for Euro 2 diesel cars, according to the dimensionless distance.

4.3. Excess emission as a function of the parking time $g(t)$

As we would like to take into account the parking time, which influences the start engine temperature, we need to know the influence of the parking time on the excess emissions. But, unfortunately, such data are rare. We found only European studies from EMPA, TUG and VTI, and an American study from CARB. We propose hereafter to present these studies and to make a conclusion on the parking time influence.

4.3.1. VTI study

The VTI study (Hammarström, 2002) looks at the short parking time (10' to 60') influence on the excess exhaust emissions. The number of measured vehicles was four, all gasoline cars. Two of them have a catalyst and the two others have not catalyst.

The protocol of the study was:

- At least 12h of engine stop.
- A warm up phase made with 4xFTP72-1 cycles (but only 3 had been recorded)
- Two parts composed each of four groups:
 - Group 1
 - 10 minutes of parking time
 - 3xFTP72-1 cycles
 - Group 2
 - 20 minutes of parking time
 - 3xFTP72-1 cycles

- Group 3
 - 30 minutes of parking time
 - 3xFTP72-1 cycles
- Group 4
 - 60 minutes of parking time
 - 3xFTP72-1 cycles

The measurements were based on the following considerations:

- The fourth FTP72-1 of the warm-up phase reaches a stabilized emission level with no influence on the following measurements
- That start effects should be expected mainly from the first FTP72-1 cycle of each group and that a stabilized emission level should be reached before the third FTP72-1 cycle of each group

The statistical analyse showed that theses two hypotheses are wrong.

4.3.2. EMPA study

The EMPA study (Schweizer et al., 1997) looks at the parking time influence on the emissions by using a city-centre driving cycle T50 (distance: 6.51 km, average speed: 28 km/h). As the FTP cycle, this cycle is too short to consider that the cycle is hot at its end. This study shows that the excess emissions according to the parking time increase rapidly for short parking times and begin to be plate for parking times longer than one hour. The full cold start excess emission is reached after 12 h of parking.

4.3.3. TUG study

The TUG study (Hausberger, 1997) looks at the parking time influence on the emissions by using a driving cycle, which represents the driving behaviour in an underground parking lot.

The tests are made with 5 gasoline catalyst cars (Euro 1), 3 gasoline cars without catalyst (Euro 0 and older) and 4 diesel cars (Euro 1). The parking durations are 0.5 h, 1 h, 2 h, 4 h and 16 h.

4.3.4. CARB study

The CARB study (Sabate, 1996) looks at the parking time influence on the emissions by using a FTP cycle. The difference with the VTI study is that the cold period is defined as to be the first 100 s. Therefore the excess emission is the difference between the cumulative emission during these 100 s and the cumulative emission during the last part of the FTP cycle.

As it is known, the first part of the FTP cycle is not completely hot as the end, and it is of course much more the case after only 100 s. So these data have to be taken with care.

4.3.5. Parking time correction function

With all these studies we can calculate an average table of parking time influence for each pollutant. For that we plot all the data (see an example in Figure 12) and draw the best fit. The results are presented in Annex 14. The function $g(t)$ is equal to 1 for 12 h parking. The function $g(t)$

is equal to 1 for 12 h parking. The CARB data are excluded of the average because they do not represent the European behaviour.

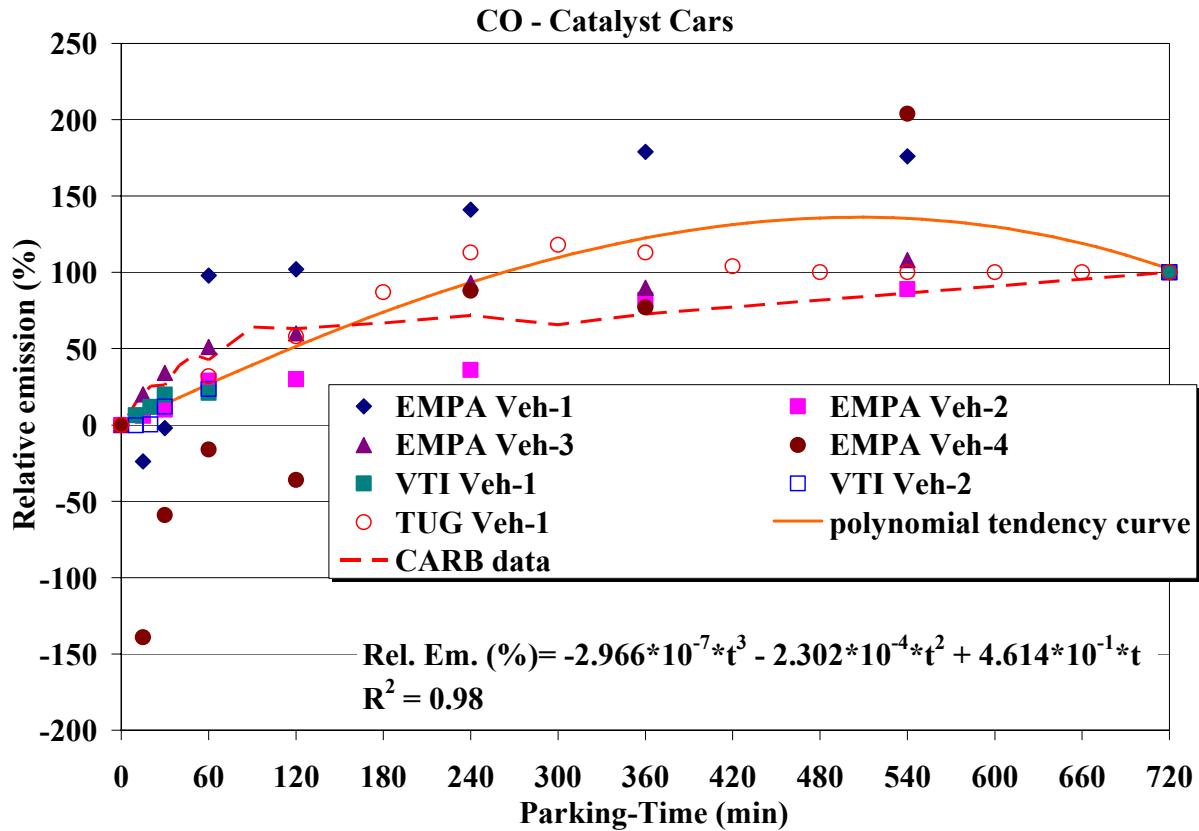

Figure 12: Parking time influence on the total excess CO emission for catalyst cars.

4.4. General formula of cold-start-related excess emissions of a trip

We assumed that the general model of the cold start emission is a function of ambient temperature, average speed, travelled distance and parking duration. Measurements were made using different cycles, these being characterised by their mean speed (see Table 1). The cycles can be characterised by other parameters such as mean product speed time acceleration (dynamics measurement), standard deviation of speed or standard deviation of the product speed time acceleration for example (Hassel and Weber, 1996). But, those parameters cannot be used in the general model due to the fact that there is no available statistics.

With the calculation made in section 4, the equation (1) can be written as:

$$EE(T, V, \delta, t) = \omega_{20^\circ C, 20 km/h} \cdot f(T, V) \cdot \left\{ \frac{1 - e^{a \cdot \delta}}{1 - e^a} \right\} \cdot g(t) \quad (\text{Equation 3})$$

where:

EE: excess emission for a trip in g

V: mean speed in km/h during the cold period

T: ambient temperature in °C

t: parking time in hours

$\delta = \frac{d}{d_c(T, V)}$: dimensionless travelled distance

d: travelled distance

$d_c(T, V)$: cold distance

$\omega_{20^\circ C, 20 km/h}$: reference excess emission (at 20 °C and 20 km/h).

The functions $\omega_{20^\circ C, 20 km/h}$, $f(T, V)$, a , $d_c(T, V)$ and $g(t)$ can be found respectively in Table 6, Annex 10, Annex 13, Table 5, and Annex 14. The function f is so that f tends toward 0 when T increases.

For example, for CO and Euro 2 gasoline cars:

- ✓ Using Table 6, $\omega_{20^\circ C, 20 km/h} = 17.060$
- ✓ Using Annex 10, $f(T, V) = 1.927 - 0.043 * T + 0.003 * V$
- ✓ Using Annex 13, $a = -9.007$
- ✓ Using Table 5, $d_c(T, V) = 4.409 - 0.002 * T + 0.024 * V$
- ✓ Using Annex 14, $g(t) = -2.916 * 10^{-7} * t^3 - 1.941 * 10^{-4} * t^2 + 4.315 * 10^{-1} * t$

and therefore δ et $h(\delta)$ can be calculated, and finally:

$$\begin{aligned}
 \text{Excess Emission}(T, V, \delta, t) = & \underbrace{17.060}_{\omega} \cdot \left[\frac{1.927 - 0.043 \cdot T + 0.003 \cdot V}{f(T, V)} \right] \cdot \left(\frac{1 - e^{-9.007 \cdot \frac{d}{4.409 - 0.002 \cdot T + 0.024 \cdot V}}}{1 - e^{-9.007}} \right) \\
 & \cdot \underbrace{\left(-2.916 \cdot 10^{-7} \cdot t^3 - 1.941 \cdot 10^{-4} \cdot t^2 + 4.315 \cdot 10^{-1} \cdot t \right)}_{g(t)}
 \end{aligned}$$

Table 6: Coefficient $\omega_{20^\circ\text{C}, 20\text{km/h}}$ corresponding to excess emission at 20 °C and 20 km/h (in g), calculated from Annex 10.

A comparison can be made between the temperature and speed influences on total excess emission (i.e. after 12h of parking time). An example of influence of temperature decrease by 30 °C (20 °C to -10 °C) and average speed increase by 30 km/h (20 km/h to 50 km/h) on the f function is shown in Table 7. The joint influence of speed and temperature is ranging from -1.2 to 31, with an average of 4.5. Thus the influence of temperature and speed is very significant, temperature influence being higher than speed influence.

The light duty vehicles (LDV) are not concerned by our data base. Therefore we could consider, if necessary, that LDV excess emissions should be the same as for passenger cars (PC) but it would be much better to build a LDV cold start model using LDV specific data base.

4.5. Near future vehicles

From the future evolution of the European standard of the vehicle emissions, the report number *** (Samaras et al., 2004) proposes cold excess emission reduction rates (see Table 8) for CO, HC, NOx and particulates for Euro 4 and 5 passenger cars.

Emission Standard	Gasoline				Diesel				
		CO	CO ₂	HC	NOx	CO	CO ₂	HC	NOx
Euro3						1	1	1	1
Euro4	No DISI	1	1	1	1	0.781	1	0.833	0.5
	DISI	1	0.9	1	1				
Euro5	No DISI	1	0.9	1	1	0.781	1	0.833	0.35
	DISI	1	0.9	1	1				

Table 8: Reduction rates to apply to the cold excess emissions for gasoline and diesel vehicles (Samaras et al., 2004).

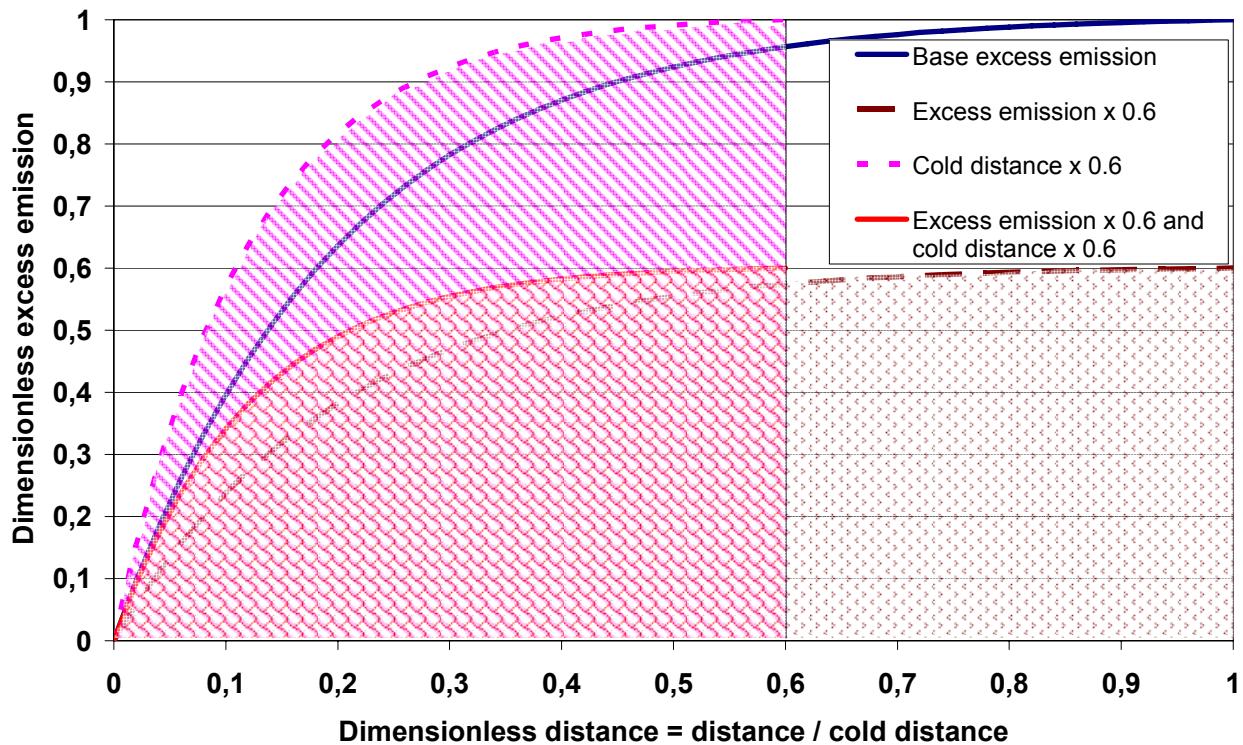

Figure 13: Comparison of ways to decrease excess emission, either by decreasing the total excess emission ω , or by decreasing also the cold distance d_c .

A decrease of the cold excess emission can come either from a decrease of the cold excess emission along the same cold distance, or from the only decrease of the cold distance, as shown Figure 13: the areas of both dotted curves are decreased by 40 % compared to the area of the base curve. Therefore both cold excess emissions ω (in g) are decreased by 64 %.

The equation of the base excess emission in the Figure 13 is defined as (if we do not take into account the parking time influence):

$$f(\delta) = \frac{\text{Excess Emission}(\delta)}{\text{Total Excess Emission}} = \frac{\omega_{20,20} \cdot f(T, V) \cdot h(\delta)}{\omega_{20,20} \cdot f(T, V) \cdot h(1)} = h(\delta)$$

- In this case $f_1 = \int_0^1 f(\delta) d\delta$ is the value of the area of the base curve
- If we apply the rate α only to the excess emission, the area of the new curve becomes:

$$f_2 = \int_0^1 \alpha \cdot f(\delta) d\delta = \alpha \cdot \int_0^1 f(\delta) d\delta = \alpha \cdot f_1$$

- If we apply the rate α only to the cold distance, the area of the new curve becomes:

$$f_3 = \int_0^\alpha f\left(\frac{\delta}{\alpha}\right) d\delta = \alpha \cdot \int_0^1 f(x) dx = \alpha \cdot f_1$$

- If we apply the rate α to the excess emission and to the cold distance, the area of the new curve becomes:

$$f_4 = \int_0^\alpha \alpha \cdot f\left(\frac{\delta}{\alpha}\right) d\delta = \alpha \cdot \int_0^1 \alpha \cdot f(x) dx = \alpha^2 \cdot f_1$$

So a decrease of 40 % applied both to the excess emission and to the cold distance, gives a total decrease of 64 %.

5. The different models

In this chapter, we propose different models to calculate the cold start excess emission with the different type of information the user could have. All the proposed models are for a pollutant and a vehicle type (i.e. for a given fuel type and a given emission standard).

5.1. Excess emission per start (model 1)

The model 1 gives an excess emission per start (i.e. per trip) in g for a car type and a given pollutant, as a function of the ambient temperature T, the mean speed during the cold period V, the travelled distance d, and the parking time t. It is presented in detail in section 4.4.

$$EE(p, T, V, \delta, t) = \omega_{20^\circ C, 20 km/h}(p) \cdot f(p, T, V) \cdot h(T, \delta(p, T, V, d)) \cdot g(p, t) \quad (\text{Equation 5})$$

with:

EE = Excess emission for a trip (g)

p = Atmospheric pollutant

T = Ambient temperature ($^\circ C$)

V = Mean speed during the cold period (km/h)

$\delta(p, T, V, d) = \frac{d}{d_c(p, T, V)}$ Dimensionless distance = $\frac{d}{d_c(p, T, V)}$

d = Travelled distance (km)

$d_c(p, T, V)$ = Cold distance (km) for the pollutant p

$\omega_{20^\circ C, 20 km/h}(p)$ = Reference excess emission (at $20^\circ C$ and 20 km/h) for a trip distance longer than the cold distance, i.e. in any case longer than 15 km (g), for the pollutant p

$f(p, T, V)$ = Plane function of the speed V and the temperature T, for the pollutant p

$h(p, \delta) = \frac{1 - e^{a(p)\delta}}{1 - e^{a(p)}}$

$a(p)$ = Constant coefficient for the pollutant p. It corresponds to the shape of the dimensionless excess emission.

$g(p, t)$ = % of excess emission at 12 h of parking as a function of the parking time t for the pollutant p

t = Parking time (h)

$\omega_{20^\circ C, 20 km/h}(p)$ and $f(p, T, V)$ are given for each pollutant, regulated or unregulated one.

$h(p, \delta)$ and $g(p, t)$ are not available for the unregulated hydrocarbons (URHC). For these components, the functions h and g specific for the total hydrocarbons THC are used:

$h(URHC, \delta) = h(THC, \delta)$ and $g(URHC, t) = g(THC, t)$

5.2. Full model of excess emission of a traffic (model 2)

In a number of cases, assessing cold-start-related excess emissions for a single trip (for some micro inventories) is sufficient, but most emission inventories require calculating cold-start-related excess emissions not for a single vehicle and over a single trip, but for the whole traffic characterised by a number of parameters such as vehicle flow, average speed and environment conditions (hour, ambient temperature...).

5.2.1. General approach

The model 1 initially applied to a single trip must be extended to the whole traffic using the available statistical data relative to traffic parameters. The excess emission of a traffic due to the cold starts reads therefore as the product of the unit excess emission for a trip EE, defined by the model 1, by the number of trips cold starting:

$$E_c = \text{Number of trips cold starting} \cdot EE$$

The number of trips cold starting is expressed globally as the ratio of the total distance started with a cold start by the average distance of the trips started with a cold start:

$$\text{Number of trips cold starting} = \frac{L_{cold\ total}}{L_{cold\ mean}}$$

$L_{cold\ total}$ is the product of the traffic flow expressed in veh.km by the percentage of mileage started at cold start. This percentage is over the year for instance 69.0 % globally but varies with the global average speed from 61.3 to 75.6 % resp. for speeds lower than 10 km/h and speeds ranging from 40 to 50 km/h (Annex 18). For a given average speed v_i of the traffic, these parameters are tf_i and $cm(v_i)$, and:

$$L_{cold\ total} = tf_i \cdot cm(v_i)$$

If we consider for instance only the cold started trips of length d_m , their number is expressed in the following way:

$$\text{Number of trips cold starting}(d_m) = L_{cold\ total} \cdot \frac{p_m}{d_m}$$

where p_m is the share of the total distance started with a cold start corresponding to trips of length d_m . 2.5 % of the mileage started with a cold start correspond for instance to trip length of 11-12 km over the year (Annex 20).

In the same way, if we consider the cold started trips with an average speed v_i , to these trips correspond a number of cold distances of average cold speed v_j .

$$\text{Number of trips cold starting}(d_m, v_i) = \sum_j L_{cold\ total} \cdot \frac{p_{m,j} \cdot p_{i,j}}{d_m}$$

where $p_{i,j}$ is the distribution (in %) of the cold started distance with an average trip speed v_i among the different speeds v_j during the cold distance. For instance 12.4 % of the mileage starting with a cold start and with an average trip speed of 60 to 70 km/h correspond to a cold speed lower than 10 km/h; this percentage varies from 0.0 to 46.0 according to the different cold and global speed ranges (Annex 19). At the same time p_m has to be related to the speed v_j , and expressed as $p_{m,j}$.

In the same way, if we consider a stop or parking duration t_n , it corresponds to a distance share p_n .

$$\text{Number of trips cold starting}(d_m, v_i, t_n) = \sum_j L_{cold}^{total} \cdot \frac{p_{m,j} \cdot p_{i,j} \cdot p_n}{d_m}$$

As we must take into account all the cold started trips lengths d_m and all parking durations t_n , the number of trips cold starting is therefore the summations over m and n of the above expression.

In addition we would like to take into account the obvious influence of the hour (in the day) on the start number and on the parking time. Therefore the traffic flow tf_i and the parking duration share p_n are functions of the hour and are transformed into $tf_{i,h}$ and $p_{n,h}$. At the same time the cold starts must be distributed along the day by introducing the relative number of cold starts of the hour h (relative to the average hourly cold start number) p_h . But for instance if between 8 and 9 o'clock we have 185 % of cold starts related to the hourly average (Annex 21), it is due to the early time when a lot of people begin the day, but at the same time to the fact that the traffic is 16 % higher than the hourly average of the day (Table 9). The only influence of the hour is 185 / 116. Generally speaking this influence is $p_h / ptf_{i,h}$, where $ptf_{i,h}$ is the relative variation of the traffic of average speed v_i for the hour h.

Finally we get the Equation 6 below, after summing on the hour h and the traffic speed range i, if necessary. For a given hour and a given speed these two summations are unnecessary, but the summations on the cold speed class j, the cold trip length class m and the parking duration class n are necessary.

5.2.2. Equation of the model 2

The model 2 gives an excess emission of a traffic in g, as a function of:

- traffic flow
- season (winter, intermediate, summer, year)
- average speed
- ambient temperature
- hour in the day

Distributions of the distance travelled according to average speed, ambient temperature and parking time are open to the user. Default values are given, but the user can enter his own distributions.

It should be noted that the distributions used in Jourard and Sérié (1999) were trip distributions, and therefore not coherent with the Equation 6. We modify them according to Duboudin and Crozat (2002).

$$E_c(p) = \sum_i \frac{cm(s, v_i)}{100} \cdot \omega_i(p) \cdot \left[\sum_h tf_{i,h} \cdot \frac{p_h}{ptf_{i,h}} \cdot \left(\sum_j \sum_m \sum_n \frac{p_{i,j} \cdot p_{m,j} \cdot p_{n,h}}{10^6 \cdot d_m} \cdot f(p, V_j, T) \cdot h(p, \delta(p, T, V_j, d_m)) \cdot g(p, t_n) \right) \right]$$

Equation 6

$E_c(p) =$	traffic excess emissions with a cold engine for the pollutant p corresponding to a traffic $tf_{i,h}$ (g)
$p =$	atmospheric pollutant
$i =$	vehicle type
$cm(s, v_i) =$	% of mileage recorded under cold start or intermediate temperature conditions for season s and overall speed v_i of vehicle type i
$s =$	season (winter, summer, intermediate, year)
$v_i =$	traffic overall average speed for the vehicle type i (km/h)
$\omega_i(p) =$	reference excess emission for the vehicle type i and the pollutant p (g)
$h =$	hour (1 to 24, day)
$tf_{i,h} =$	traffic flow for the studied vehicle type i and the hour h (km.veh)
$p_h =$	relative cold start number for the hour h (average=1)
$ptf_{i,h} =$	relative traffic for the studied vehicle type i and the hour h (average=1)
$j =$	speed class with a cold engine
$m =$	trip length class
$n =$	class of stops (0 – 1/4, 1/4 – 1/2, 1/2 – 3/4, 3/4 - 1, 1 - 2,... , >12h)
$p_{i,j} =$	% of the distance travelled at speed j with a cold engine, for the overall average speed considered, and for the studied vehicle type i (%)
$p_{m,j} =$	% of the distance started with a cold engine and distance d_m , for speed V_j with a cold engine (%)
$p_{n,h} =$	% of the distance travelled after a stop with a duration of t_n , for the hour h (%)
$d_m =$	average distance of the trips under cold start conditions of class m (km)
$f(p, V_j, T) =$	plane function of the speed V_j and the temperature T, for the pollutant p
$V_j =$	average speed with a cold engine corresponding to class j (km/h)
$T =$	ambient temperature (°C)
$h(p, \delta) =$	$\frac{1 - e^{a(p,T)\delta}}{1 - e^{a(p,T)}}$
$a(p) =$	constant coefficient for a pollutant p
$\delta(p, T, V_j, d_m) =$	Dimensionless distance = $\frac{d_m}{d_c(p, T, V)}$
$d_c(p, V_j, T) =$	cold distance for the pollutant p (km)
$g(p, t_n) =$	% of excess emission at 12h of parking as a function of the parking time t_n for the pollutant p
$t_n =$	parking time (h)

Among all these parameters, we can distinguish different types of parameters:

- some ones are purely internal and should not be modified by the user: $\omega_i(p)$, $f(p, V_j, T)$, $d_c(p, V_j, T)$ and $g(p, t_n)$. They are resp. given in Table 6, Annex 10, Table 5 and Annex 14.
- some parameters are input parameters: i , s , v_i , h , $t_{f,i,h}$, $ptf_{i,h}$ and T . An example of $ptf_{i,h}$ is given in Table 9.
- some ones are internal parameters, but could be modified by the advanced user: $cm(s, v_i)$, p_h , $p_{i,j}$, $p_{m,j}$, $p_{h,n}$, d_m and V_j . They are resp. given in Annex 18, Annex 21, Annex 19, Annex 20, Annex 22, Annex 20 and Annex 20.

$\omega_i(p)$ and $f(p, V_j, T)$ are given for each pollutant p , regulated or unregulated one.

$h(p,\delta)$ and $g(p,t_n)$ are not available for the unregulated hydrocarbons (URHC). For these components, the functions h and g specific for the total hydrocarbons THC are used:

$$h(\text{URHC}, \delta) = h(\text{THC}, \delta) \quad (\text{or } a(\text{URHC}) = a(\text{THC}))$$

$$g(\text{URHC}, t_n) = g(\text{THC}, t_n)$$

According to Duboudin and Crozat (2002), the taking into account of the average speed in the Equation 6 is problematic, because of the possible difference between the average speed during the cold period and the average speed during the whole trip. A trip with an average speed v_i is subdivided into a cold phase and a hot phase. The cold phase can have an average speed V_j different from the global speed v_i . To calculate the global emission we add a hot emission calculated with v_i and a cold excess emission calculated with V_j :

$$E_{total}(\text{trip}) = EE_{cold}(V_j) + E_{hot}(v_i) \quad \text{Equation 7}$$

It is not really coherent: if the distance travelled during the cold phase d_c corresponds to an average speed V_j different from the speed of the whole trip v_i , the travelled distance in hot conditions cannot have an average speed v_i , and the global emission should be calculated with the formula:

$$E_{total}(d_c + d_{hot}) = EE_{cold}(V_j, d_c) + E_{hot}(V_j, d_c) + E_{hot}(V_{hot}, d_{hot}) \quad \text{Equation 8}$$

where V_{hot} is the average speed of the hot distance d_{hot} .

Therefore, when we calculate the traffic emission, we should use the Equation 6, but add $(E_{hot}(V_j, d_c) - E_{hot}(v_i, d_c))$. As the difference should be quite small, we do not apply this correction.

5.3. Aggregated model of excess unit emission of a traffic (model 3)

Both models 1 and 2 are not at all easy to be used by a common user: The first model needs to be completed by a model giving the number and the characteristics of the starts. The second model is the most comprehensive and accurate model, the most open to any user data, but is especially complex to use: As a lot of necessary statistics are really not common, to use the model can lead to misunderstandings.

Therefore we apply the second model, with all its default values, and transformed the outputs into an excess emission factor in mass per travelled distance (model 3), but with only few open input data.

The model 3 gives for a given vehicle type and an atmospheric pollutant an excess unit emission of a traffic in g/km, according to the season s , the ambient temperature T , the average speed v_i , and the

hour in the day h. It is a combined table for 4 seasons (winter, summer, intermediate, whole year), 8 speed ranges (5 to 75 km/h), 7 temperature ranges (-25 to 35°C), and 25 hours (24 hours and the whole day): see Annex 20 to Annex 29.

The using of this model 3 allows us to take into account the distribution of the cold starts along the day. But the calculation of the model 3 needs a specific assumption on the relative traffic distribution along the day ($ptf_{i,h}$): we used the so-called base distribution presented in Table 9 and .

But when applying this model 3, if the actual traffic distribution is very different from this base distribution, the overall emission calculated during the day can be wrong. For instance for average traffic distributions representative of USA, Belgium and Switzerland (Table 9 and), the using of the model 3 introduces an error for the whole day between 3 and 7 %. In this case, we recommend not to use the model 3 hour per hour, but:

- ✓ Either to use the model 2: the calculation will be very precise, with a detailed distribution of the cold excess emission along the day and an accurate summation over the day,
- ✓ Or to use the model 3 for the whole day (hour = whole day): the summation over the day of the hourly cold excess emissions will be accurate, but its distribution among the hours will not be accurate.

Applying this model allows us to get, for each pollutant and each vehicle type, a matrix of cold unit excess emissions in g/km, depending on the average speed, the ambient temperature, the season and the hour. The results for the regulated pollutants are presented in Annex 23 to Annex 32 for each season and the whole day. The results for unregulated pollutants are available on demand.

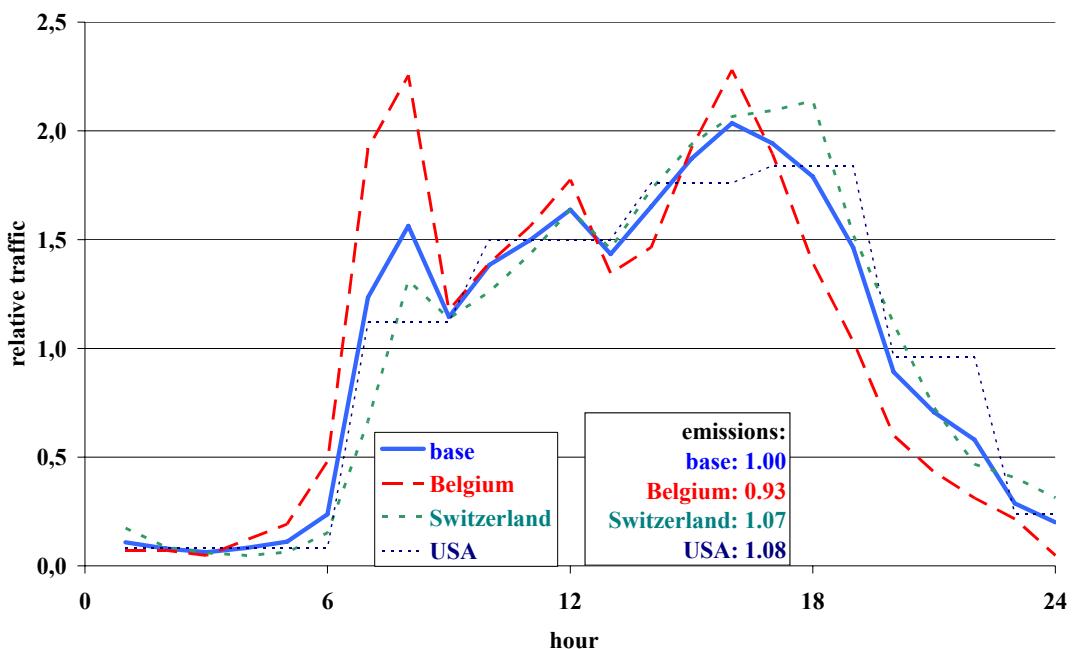

Figure 14: Average traffic distributions representative of 3 countries, and relative base distribution used in the model 3 design. Relative influence of the using of the different distributions on the daily emissions. .

In order to look at the relative influence of the different parameters, we present some illustrations on Figure 15 for the influence of the average speed and vehicle type, on Figure 16 for the influence of the ambient temperature and average speed, on Figure 17 for the season influence, and on Figure

18 for the influence of the hour. Similar results are presented in Annex 38 for PAH and in Annex 39 for VOC

<i>emission for the whole day</i>	1.03	0.93	1.04	1.00

Table 9: Relative traffic distribution $ptf_{i,h}$ along the day for 3 countries and the base distribution used in the design of the model 3, with the error of the emission calculated with the model 3 for the whole day in case of traffic distributions different from the base case.

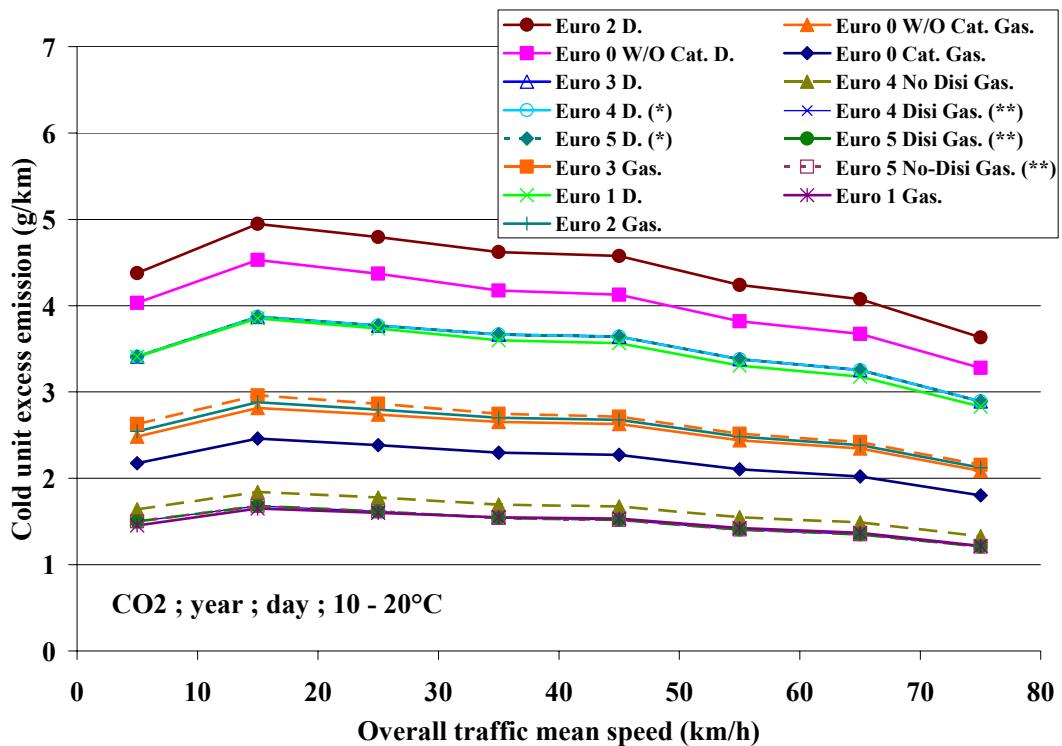

Figure 15: CO_2 cold unit excess emission according to average speed and vehicle technology (ambient temperature: 10-20°C, season: year, hour: whole day) (g/km). * Computed from Euro 3 Diesel. ** Computed from Euro 4 no DISI Gasoline.

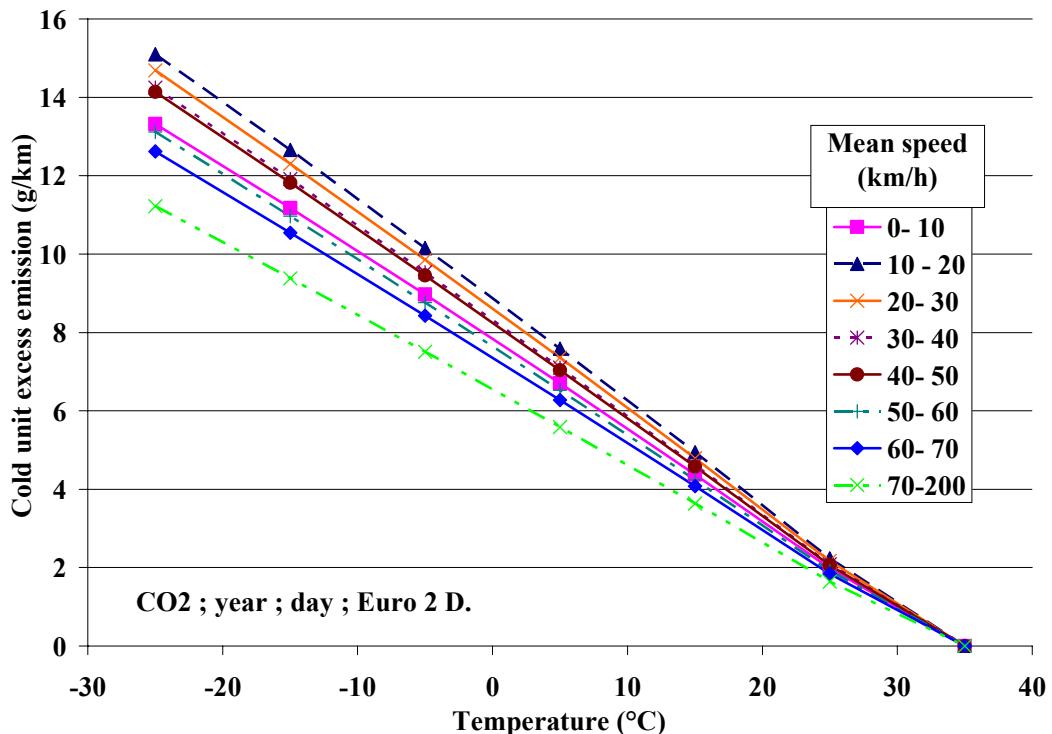

Figure 16: CO_2 cold unit excess emission according to ambient temperature and average speed for Euro 2 gasoline cars (season: year, hour: whole day) (g/km).

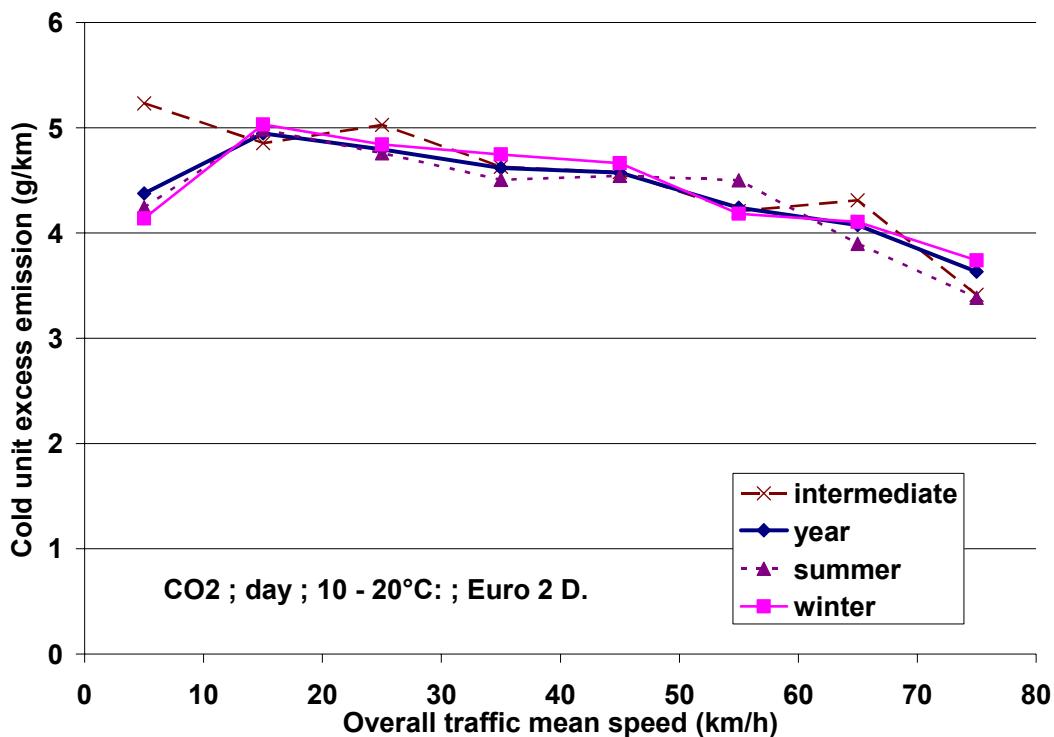

Figure 17: CO_2 cold unit excess emission according to season and average speed (ambient temperature: 10-20°C, gasoline Euro 2) (g/km).

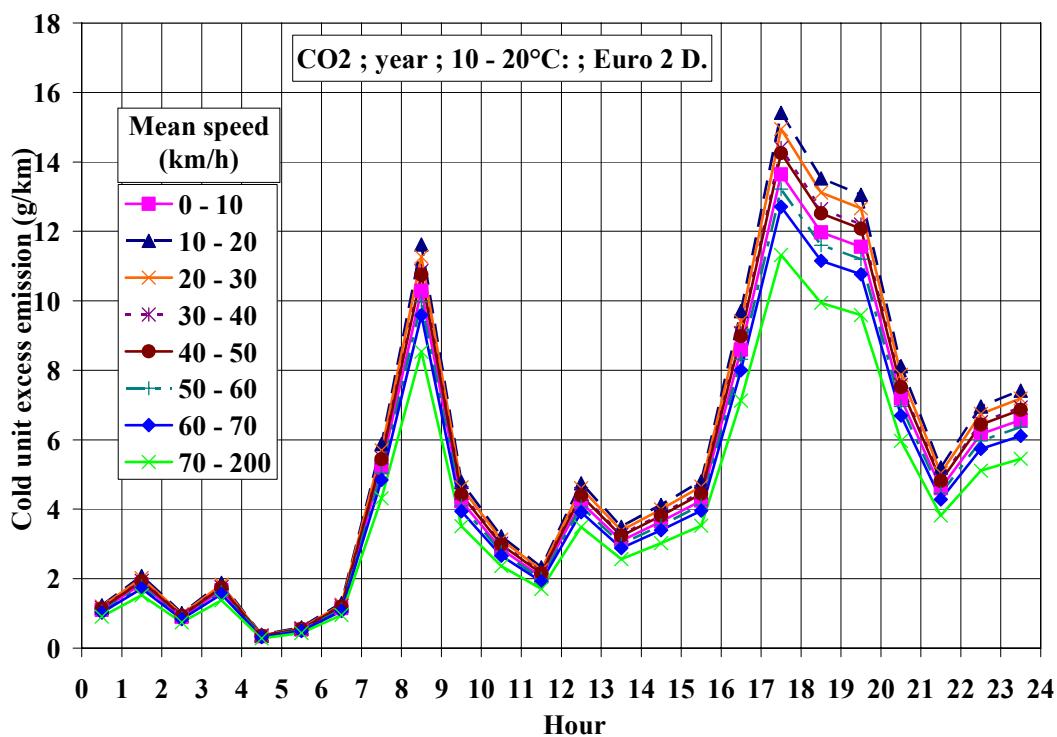

Figure 18: CO_2 cold unit excess emission according to hour and average speed (ambient temperature: 10-20°C, gasoline Euro 2) (g/km).

The influence of all these parameters depends on the pollutant considered. Nevertheless the ambient temperature, the average speed and the hour in the day play the major role. The season, for a same temperature, plays a minor role, with up to 15 % variations.

6. Conclusion

This modelling of excess emission under cold start conditions for passenger cars results from data provided by various European research organisations as part of the MEET and Artemis projects. The models take into account the average speed, ambient temperature and travelled distance, among other parameters. They are based on measurements made over 4 driving cycles at different ambient temperatures. The average speeds of these cycles range from 18.7 km/h to 41.5 km/h, and the temperatures range from -20 °C to 28 °C. The modelling counts in fact three models.

In a first model the cold excess emission is expressed in grams per start. It is given for a prescribed pollutant and a vehicle technology, i.e. for gasoline and diesel cars, from Euro 0 to Euro 4 emission standard. The general formula is written in the form of a reference excess emission multiplied by functions depending on average speed, ambient temperature, travelled distance and parking duration. The shape of the speed-temperature functions is assumed to be 3D-linear. We assumed that the influence of the travelled distance is, in order to simplify the model, an exponential function (with a temperature influence) for all the pollutants, even if the shape seems more complex for NOx.

A second model is developed to assess the excess emissions of a traffic, and no more for a single vehicle. It uses a lot of driving behaviour statistics, and is therefore very complex. It allows the very experimented user to modify all these default data, in order to model very specific situations;

The third and final model is derived from the second one and provides a unit excess emission in g/km, therefore parallel to the hot emission factor. It takes into account the average speed, the ambient temperature, the hour in the day and the season.

The three models are available for numerous vehicle technologies (fuel + emission standard) covering the European situation, and for regulated as unregulated pollutants.

The models can be applied at different geographic scales: at a macroscopic scale (national inventories) using road traffic indicators and temperature statistics, or at a microscopic scale for a vehicle and a trip. If a model user could not access to necessary statistics, it would be recommended to use the most aggregated model, i.e. the third one.

All these models are improved versions of the former MEET model. The third one should replace the Copert III cold start model within the new inventorying tool Artemis. These models are presented for gasoline and diesel vehicles, the present and the near future ones.

This study corresponds to the state-of-the-art at the present time. In the future, this model could be improved by different ways:

- By updating this model using new data when available, either for the most recent passenger cars, or the light duty vehicles, or the heavy duty vehicles.
- It would be much more precise to have crossed distributions for different speeds and ambient temperatures.
- The number of analysed data has to be increased, especially for different speeds, low or high temperatures, and unregulated pollutants.

Table 15: Number of vehicles per driving cycle (defined in Table 1), unregulated pollutant (VOC) pollutant, vehicle category and mean ambient temperature (°C) of the measurements.

Annex 5: Standard correction of NOx emission according to humidity

According to E.P.A. (1976) and Lenner (1994), we present here the standard method to correct NOx emission according to air humidity.

In order to define the hygrometric state of the atmosphere, the mixing ratio r can be used, expressed in grams of water vapour per kilogram of dry air. This ratio depends on the atmospheric humidity, the temperature and the total pressure:

$$r = 6.2198 \cdot \frac{U \cdot e'_w}{P - U \cdot e'_w \cdot 10^{-2}}$$

with

$$\begin{cases} U : \text{relative humidity in \%} \\ P : \text{atmospheric pressure in kPa} \\ e'_w : \text{saturated vapour pressure in kPa ; } e'_w = 0.61121 \cdot \exp \left[\frac{\left(18.729 - \frac{T}{227.3} \right) \cdot T}{T + 257.87} \right] \\ T : \text{temperature in } ^\circ\text{C} \end{cases}$$

In order to compute the correction factor, we have to multiply the emission by the factor K_H equal to:

$$K_H = \frac{1}{1 - 0.0266 \cdot (r - 10.71)} \text{ for FTP cycle}$$

$$K_H = \frac{1}{1 - 0.0329 \cdot (r - 10.71)} \text{ for ECE-15 cycle}$$

The first equation (FTP cycle) is valid for mixing ratio ranging between 2.86 g and 20.00 g of water vapour per kg of dry air, whereas, the second equation (ECE-15 cycle) is valid for ambient temperature between 20 °C and 30 °C and mixing ratio between 5.0 g and 12.2 g of water vapour per kg of dry air.

New correction factors are proposed within the Artemis project, different from the standard ones.

Annex 7: Example of dimensionless excess emissions versus distance (km)

The figure below shows the cumulative dimensionless excess emission (ratio of absolute excess cold start emission to total absolute excess cold start emission) as a function of the distance (km) for short Inrets free-flow urban cycle (IUFC).

This graphic explains why sometimes the correction factor can be less than 1. In this case the emission per cycle is firstly very high then very low, i.e. lower than the hot emission, then increases, and finally decreases. Therefore the excess cold emission is sometimes negative.

Correction calculation: Example of ECE-15 cycle for NOx pollutant on Euro 3 Gasoline cars (at -19°C).

Annex 8: Cold start excess emission (g) according to the driving cycle for regulated pollutants

Table 17: Excess emission (in g) as calculated from regression per pollutant, per vehicle type, per cycle speed and per temperature. The number between brackets is the relative error between measurement and regression.

Annex 10: Equation of the excess emission $\omega(T,V)$ and correction coefficients $f(V,T)$

The equation describes the influence of the mean speed V [km/h] and the ambient temperature T [°C] on excess emission $\omega(T,V)$ [g] and the associated dimensionless correction coefficients $f(V,T)$. This equation results in a 3D linear regression (best fitted plan).

Annex 28: Cold excess unit emission according to average speed and ambient temperature for Euro 2 diesel cars according to the season

Cold excess unit emission in g/km, average speed in km/h, ambient temperature in °C.

season: year

Hour: day
