Abstract: This paper shows the validity of experimental designs as an efficient on-site tuning tool for fuzzy controllers, dedicated to electrical engineering applications with multi-objective criteria. Our purpose is to improve the input and output system characteristics that is to say the global quality of the electrical power in a boost rectifier with unity power factor correction. The desirability notion combines here time dynamic and harmonic criteria, it illustrates the trade-off that has to be satisfied between the different properties.

Keywords: fuzzy control, experimental designs, tuning methodology, multi-objective criterion, boost rectifier, power factor correction, desirability.

1. INTRODUCTION

Our work deals with the tuning of fuzzy controller in order to improve the control of electric systems. Fuzzy-logic-based controllers are used in various applications, mainly because of advantages such as the dynamic performance, the robustness or the possibility to take into account an experimental knowledge of the process.

Nevertheless, some drawbacks have to be underlined: first, the huge number of parameters that have to be tuned even for a very simple fuzzy structure and the lack of an efficient on-site tuning strategy for all these parameters. The fuzzy controller parameters could of course be tuned through trial-and-error procedure, but it could be quite long and rather delicate. On the other hand, some methods have already been proposed, for the tuning of fuzzy controllers, using adaptive algorithms (Barrero, 1995) and (Kang et al, 1992), additional fuzzy rules (Takagi, 1992), neural networks (Perneel et al, 1995), H_∞ and LMI methods (Liu et al, 2001) and (Park, 2004) or genetic algorithms (Hoffmann, 2001). These tuning methods are successful but are generally far from simple.

Besides, a simple tuning methodology based upon experimental on-line designs for all the parameters of a PID-like-fuzzy-logic controller have already been proposed (Hissel et al., 1999) few years ago. This method, based on time criterion only, for fuzzy controller tuning gave experimental and simple pre-established settings just like the well-known Ziegler-Nichols methods for the classical PID controllers.

Our aim is now to show that experimental designs methodology could be an efficient tool in order to tune fuzzy controllers for applications that require multi-objective criteria. In this paper, the methodology will be applied to a single phase boost rectifier with unity power factor correction. This kind of converter is strongly nonlinear, it means that linear controllers are not truly efficient, especially when sudden and hard parameter variations due to high load variations occur. Then a fuzzy controller should be an efficient solution for the control of such a converter. Two criteria have to be regarded: a time-response-based criterion on the output voltage and an harmonic criterion based on the input current distortion on the grid. Fuzzy controllers have already been used for this system control (Yu et al. 1996), (Henry et al., 1999), (Pires et al., 1999) and (Mattavelli et al., 1995), and the harmonic reduction by fuzzy control has been shown in (Palandöken, 2003) but there is still a lack of efficient tuning methodology. This paper will show how the experimental designs could be an efficient tool, in simulation or on the experimental process, for the on-site tuning of a nonlinear controller under those specific constraints. This is the main contribution of our work.

Section 2 describes the system and its classical linear control is presented in section 3. The structure of the fuzzy controller is given by section 4 while section 5 describes the experimental design methodology, applied in section 6 for the tuning of the fuzzy controller. Simulation results are presented in section 7, experimental results in section 8 and their comparison in section 9. Finally, section 10 concludes the paper and gives some trends for future works.

2. SYSTEM DESCRIPTION

2.1 System description

The system is a single phase boost rectifier with unity power factor correction and 1kW nominal power. In a classical solution with a diode bridge rectifier, an additional capacitor reduces the voltage ripple. However, this capacitor also reduces the diode conduction angles and generates harmonic distortion on the electrical network described by V_n (network voltage) and L_n (network inductance). In order to solve these problems, a boost converter is added to the

system. The capacitor C_{out} is the output filter for the load that needs a constant voltage. The values of these different components are given in table 1.

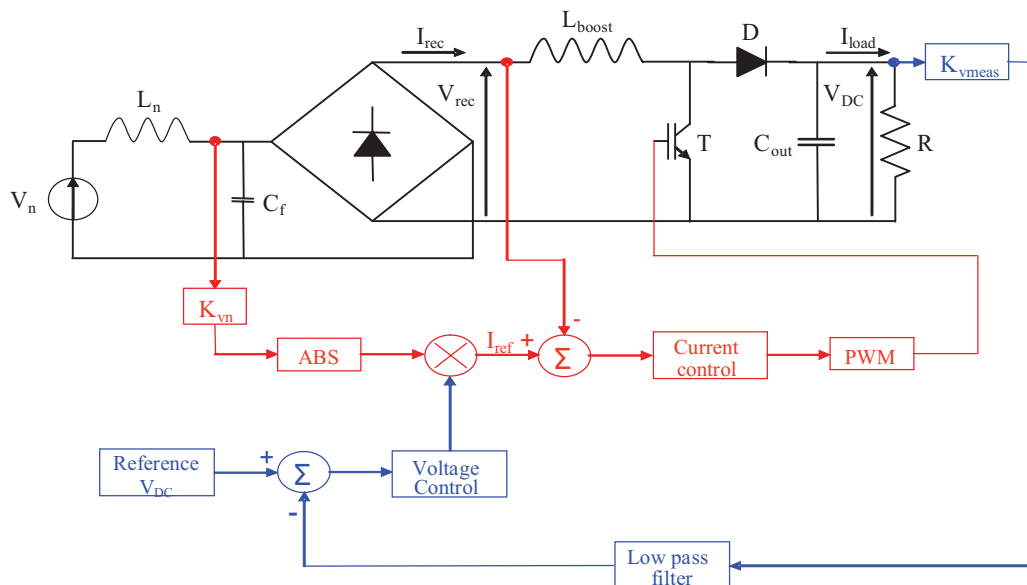

Fig. 1. System structure

V_n	325V	R_{load}	100 Ω
L_n	0.1 mH	R_0	2000 Ω
C_f	25 μ F	K_{vmeas}	1/100
L_{boost}	4 mH	K_{vn}	1/325
C_{out}	500 μ F	Ref V_{DC}	4 V

Tab. 1. System parameters values

Hard and sudden load variations are applied to the system in order to evaluate the performance of the control strategy. The benchmark test is the following: from steady-state operation under no load conditions ($R = R_0$) to sudden maximum load connection ($R=R_{load}$), and sudden disconnection. In addition, it is important to notice that capacitor C_f prevents high frequency harmonics from going back to the network. A cut-off frequency F_c chosen above the higher frequency (the 100 Hz frequency of the rectified voltage V_{rec}) and around one decade below the switching frequency (20 kHz) is suitable. We fix $C_f = 25 \mu$ F, that means $F_c = 500$ Hz (1).

$$F_c = \frac{1}{2\pi\sqrt{L_f.C_f}} \quad (1)$$

A complementary study shows that this C_f value also reduces the current distortion under no load conditions.

2.2 Behaviour requirement

The boost rectifier has some characteristics that impose a constraint on the output voltage. When transistor T is ON, the diode D is OFF ($V_D = -V_{DC}$) and :

$$\frac{dI_{rec}}{dt} = \frac{V_{rec}}{L_{boost}} > 0 \quad (2)$$

When transistor T is OFF, the diode D is ON ($I_D = I_{rec}$) and :

$$\frac{dI_{rec}}{dt} = \frac{V_{rec} - V_{DC}}{L_{boost}} > 0 \quad (3)$$

Thus, whatever the state of the transistor, while $V_{DC} < V_{rec}$, $\frac{dI_{rec}}{dt} > 0$. In such a configuration, the system is not controllable until $V_{DC} = V_{rec}$. In conclusion, this system requires that $V_{DC} > V_{rec}$, that is why it is called ‘‘boost’’.

3. LINEAR CONTROL

The control of this kind of system is usually done by linear controllers. Performance of such controllers will be the reference for a comparison with the fuzzy controllers and also their initial parameter values. There are two control loops (figure 1), one for the dc output voltage and the other for the rectified input current.

3.1 Current loop

The objective of this “fast” loop is to get a sinusoidal current in phase with the electrical grid voltage. Thus, it reduces the harmonic rejection and maintains a unity power factor. A linear PI controller is used in combination with a PWM module. The high frequency harmonics are then reduced with this kind of control. The shape of the current reference is generated from the network voltage (via K_{vn}) and its amplitude from the DC voltage (via the voltage controller) as shown in figure 1. The transfer function of the PI current controller is:

$$H_{current}(p) = G_c \cdot \frac{(1 + p.T_{ic})}{p.T_{ic}} \quad (4) \quad \text{and} \quad s^3 + 1.75 \omega_n s^2 + 3.25 s \omega_n^2 + \omega_n^3 \quad (5)$$

The PI controller is tuned according to (Dorf, 1990), in order to make the denominator of the current closed loop transfer function fit a specific equation (5) that minimizes the ITAE criterion. These considerations lead to the following coefficients (6) :

$$G_c = 2.1 \quad \text{and} \quad T_{ic} = 0,28 \text{ ms} \quad (6)$$

Figure 2 shows the simulation results with the PI controller. One can check the efficiency since the rectified current is closed to its reference and contains very few low frequency harmonics.

Fig. 2. Current control: I_{rec} and I_{ref}

Fig. 3. Criterion measurement and benchmark test.

3.2 Voltage loop

This “slow” loop must control the output voltage V_{DC} with respect to load, input voltage and input current variations. A classical PI controller tuning is based on the average model of the system. This method relies on the equilibrium of the instantaneous powers between the output of the rectifier and the DC part (Yu, 1996). If the current loop is fast enough compared to the voltage loop, approximation (7) could be done, and the transfer function is given by (8).

$$\frac{V_{DC}(p)}{I_{rec}(p)} \approx \frac{V_{DC}(p)}{I_{ref}(p)} \quad (7)$$

$$\frac{V_{DC}(p)}{I_{ref}} = \frac{V_{rec}}{4.\bar{V}} \cdot \frac{R_{load}}{1 + p \cdot \frac{R_{load} \cdot C_{out}}{2}} \quad (8)$$

where \bar{V} is the V_{DC} average value. As the transfer function of the voltage controller is given by equation (9), optimum symmetrical methodology leads to the following coefficients (10).

$$H_{voltage}(p) = G_v \cdot \frac{(1 + p.T_{iv})}{p.T_{iv}} \quad (9) \quad \begin{cases} G_v = 7.5 \\ T_{iv} = 0.062 \end{cases} \quad (10)$$

3.3 Different tuning criteria

The control quality for the whole system will be evaluated through two criteria. The first one is the IAE (integral of absolute error, expression (11)). This criterion applied to V_{DC} will show the robustness and the dynamic performance of the controller. In addition, a second criterion, the harmonic distortion rate (THD) in (12), represents the harmonic rejection quality at the input.

$$IAE = \int |e(t)|.dt \quad (11)$$

$$THD_{\%} = \frac{\sqrt{\sum_{k=2}^{39} I_k}}{\sqrt{\sum_{k=1}^{39} I_k}} \cdot 100 \quad (12)$$

The CEI 61000-3-2 international standard defines the electromagnetic compatibility and limits the harmonic current emissions for the 39 first harmonics. It gives the maximum allowable current amplitude for each harmonic. Figure 3 shows how and when the two different criteria are calculated during the benchmark test. The IAE criterion is taken into account throughout the test. The harmonic distortion is only computed during steady-state operation under rated load condition, i.e. rated current.

4. FUZZY CONTROLLER

A fuzzy controller will be used in the rest of this paper in order to improve the dynamic performance. The controller is a PI-like fuzzy controller (FLC) (see figure 4). This structure was chosen because the error's second derivative does not have to be calculated. Indeed, its value could be important as it may amplify noise. The inherent difficulty of such a kind of controller is the huge number of parameters. The fuzzy part consists into two inputs / one output Sugeno FLC (Hissel et al. 1999) with seven triangular membership functions on each input and seven singletons at the output. There is a normalisation factor for each input (em for the error signal and dem for the error derivative) and for the output (gm).

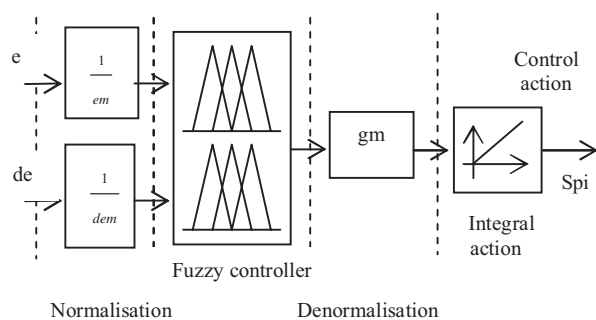

Fig. 4. Fuzzy controller structure.

Experiment number	Factor 1	Factor 2	Interaction 12	Criterion
1	-	-	+	y1
2	+	-	-	y2
3	-	+	-	y3
4	+	+	+	y4

Effects	E_1	E_2	E_{12}

Fig 5 : Example of an experimental table

A zero-symmetry is imposed for both triangular membership functions and singletons in order to provide a similar response for positive and negative inputs. A classical anti-diagonal rule table, with fixed parameters, is used. By fixing em to the reference value, only 8 parameters have to be tuned among the initial 73 ones (7*7 rules, 3*7 membership functions and 3 gains). The tuning parameters are: dem , gm , PSe and $PVSe$ (membership functions on error), $PSde$ and $PVSde$ (membership functions on error derivative), given by figure 6 and PSs and $PVSs$ (output singletons), given by figure 7. For example, PSe is the label of the Positive Small membership function on the error and $PVSde$ is the label of the Positive Small membership function on the derivative of the error. The positions of these membership functions have to be tuned. Anyway, the tuning problem remains effective as 8 control parameters are to be tuned according to two criteria.

Fig. 6. Membership functions for error and derivative of error inputs

Fig. 7 : Output singletons

Fuzzy logic is only used for the PI like controller on the voltage loop. Due to frequency limitation of our DSP, the current loop must be continuous (the sampling period is $Te = 1.10^{-4} s$). Moreover, two fuzzy controllers for the same system would dramatically increase the number of parameters that have to be tuned.

5. EXPERIMENTAL DESIGNS PRINCIPLES

The history of experimental designs began in the 30's in England with M. Fisher, (Fisher, 1935) but it had an increasing development since Taguchi published predefined tables (Taguchi, 1987). This methodology realizes a schedule of the experiments in order to obtain the most accurate information for a specific problem with a minimum number of experiments (Dey et al., 1999). The idea is to modify the level of each factor for each experiment according to a specific procedure. It allows a drastic reduction of the number of experiments, an increase in the number of parameters, the detection of interactions between factors and gives an optimized solution.

Considering for example only two levels for each of the 8 factors described above, the classical experimental tuning method that consists in varying one of the parameters when all the others are maintained constant, leads to $2^8=256$ required experiments. With experimental designs methodology, only 16 experiments out of 256 are necessary to find the suitable combination for the 8 factor levels in order to minimize the selected criterion

We use centred reduced variables, i.e. -1 for the low level and +1 for the high level of each factor. Then, an experimental table, as shown in figure 5, could be used. Each line represents an experiment and each column is a factor, an input MF, an output singleton position or a gain. For each experiment, the criterion is calculated through simulation or measured during experiments.

$$E_1 = \frac{-y_1 + y_2 - y_3 + y_4}{4} \quad (13)$$

$$E_{12} = \frac{y_1 - y_2 - y_3 + y_4}{4} \quad (14)$$

According to the experimental design methodology (Dey et al., 1999), the effect of a factor is obtained through equation (13). For example, $E_1 = 0.12$ means that factor 1 at high level has an effect of +0.12 on the criterion. Moreover, the effect of interactions between factors can also be investigated with this methodology. Expression (14) leads to the effect of interaction E_{12} between factor 1 and 2, on the desired criterion. Furthermore, the same column could also be used to study a third factor. From these effects, an optimal tuning could be reached, with a last experiment in order to confirm the design. If the results are irrelevant, then the hypotheses must be reconsidered.

The experiment table is built like an Hadamard matrix (Droesbeke, 1997) that verifies equation (15), where n is the number of experiments. Such a structure gives the best accuracy on effects. Indeed, the standard deviation on the effect (σ_E) is a fraction of the standard deviation on the criterion (σ_y), as shown in equation (16) :

$$X^t . X = nI \quad (15) \quad \sigma_E = \frac{\sigma_y}{\sqrt{n}} \quad (16) \quad s_i^2 = \frac{1}{N-1} \sum_{j=1}^N \left(y_{i,j} - \bar{y}_i \right)^2 \quad (17)$$

A major problem is the determination of the experimental error. The accuracy of the estimation s , the experimental standard deviation on the criterion σ_y , depends on the number of experiments. By repeating N times each experiment of the design table, the estimation s_i for each experiment is improved. $y_{i,j}$ is the j^{th} repetition of the i^{th} experiment and \bar{y}_i is the average of the N repetitions of the i^{th} experiment. The variance is given by equation (17). The classical isovariance assumption is considered and equation (18) can be written. Afterwards the estimation of the experimental standard deviation on the effect, s_E , is expressed in (19).

$$s = \sqrt{s_i^2} = \sqrt{\frac{\sum_{i=1}^n s_i^2}{n}} \quad (18) \quad s_E = \frac{s}{\sqrt{N.n}} \quad (19)$$

The confidence interval is thus balanced by the variable of Student $t_{\alpha}^{n.(N-1)}$ at $n.(N-1)$ degrees of freedom with the probability α to be exceeded in absolute value. As a consequence the confidence interval for a probability α is $\pm t_{\alpha}^{n.(N-1)} \times s_E$ around the average effect value.

6. TUNING METHODOLOGY

6.1 Parameter values

In this controller, 8 parameters have to be tuned. The initial levels of parameters are always difficult to choose, an accurate expertise on the system is required. The values of the continuous PI controller parameters will be used as

initial values. Regarding S_{PI} as the fuzzy controller output, on figure 4, equation 20 can be defined. k_p is the proportional gain and k_d is the derivative one of the first part of the fuzzy controller.

$$S_{PI} = \int (k_p(e, de).e + k_d(e, de).de) dt$$

$$S_{PI} = gm \cdot \int \frac{1}{em} e(t).k_1(e, de).dt + gm \cdot \int \frac{1}{dem} \cdot \frac{de(t)}{dt} .k_2(e, de).dt \quad (20)$$

$$S_{PI} = \frac{gm}{em} \cdot \int e(t).k_1(e, de).dt + \frac{gm}{dem} \cdot \int \frac{de(t)}{dt} .k_2(e, de).dt$$

Then, equation 20 reveals two different actions: integral and proportional of the complete PI-like-fuzzy controller which can be used for initial tuning. If the error is sampled at the sampling period T_e , expressions (21) can be written, and from the transfer function $H_{voltage}$, it comes (22) :

$$\begin{cases} e(t) \Rightarrow e(k) \\ de(t) \Rightarrow \frac{e(k) - e(k-1)}{T_e} \end{cases} \quad (21)$$

$$\begin{cases} \frac{gm}{em} = \frac{G_v}{T_{iv}} \\ \frac{gm.T_e}{dem} = G_v \end{cases} \quad (22)$$

The levels of the membership functions are chosen on both sides of the values of the equi-distributed membership function positions. Similar choices are made for gm and dem coefficients.

6.2. Experimental table

As there are 8 parameters, a 2^{8-4}_{IV} Hadamard experimental table is used, which implies only 16 experiments. Table 2 presents the experimental designs table.

exp	F1 PS _e	F2 PVS _e	F3 PS _{de}	F 4 PVS _{de}	F5=234 and PS _s	F 6=134 and PVS _s	F7=123 and g _m	F 8=124 and de _m

Tab. 2. First set of factors levels in a 2^{8-4}_{IV} experimental table

The two criteria (IAE and THD) are calculated during simulations or measured during the experiments. It is important to notice that each experiment is run once in simulation but has to be repeated during experimental tests, in order to reduce the experimental standard deviation on the effect, as seen in section 5.

6.3 Desirability

The desirability notion was introduced by E.C. Harrington (Harrington, 1965). It combines several different properties Y_i with different scales and units (Derringer et al. 1994). Each of them is transformed in an elementary desirability function di , as seen in equation (23). A desirability function is ranged between zero and one.

A zero level corresponds to an unacceptable value for the criterion while a desirability of one represents the maximum desired performance. Many different transformations could be chosen. The most classical one was adopted due to its simplicity, it is described below. The value of $Y_{i,p}$ is the minimum acceptable value for Y_i and $Y_{i,c}$ is the value above whom an amelioration of Y_i is not very interesting.

$$di = \begin{cases} 0 \Leftrightarrow Y_i \leq Y_{i,p} \\ \left[\frac{Y_i - Y_{i,p}}{Y_{i,c} - Y_{i,p}} \right]^{ri} \Leftrightarrow Y_{i,p} < Y_i < Y_{i,c} \\ 1 \Leftrightarrow Y_i \geq Y_{i,c} \end{cases} \quad (23)$$

$$D = \left[\prod di^{wi} \right]^{\frac{1}{\sum wi}} \quad (24)$$

The parameters ri balance the importance of the increase of the property on the elementary desirability (Fig. 7). Then, all the elementary desirabilities are combined into a composite desirability such as in equation (24) :

Fig.8 Elementary desirability

Fig.9 Simulated output voltage responses

7. SIMULATION RESULTS

Two successive designs are carried out in simulation using desirability in order to combine the dynamic and the harmonic criteria. The first one is a global and “rough” design which gives significant levels for the tuning parameters, the second one improves the tuning. The experimental design, described in table 2 gives then interesting results.

Fig.10 Experimental output voltage responses

Fig.11 Input currents with fuzzy control

Figure 9 shows the simulation results for the fuzzy controller and the continuous PI. Giving parameter levels, this tuning, set0, is tested also on the experimental process, leading to experimental output responses, figure 10 and 11. Dynamic performance with the fuzzy controller is improved and the harmonic distortion remains low, cf table 8. Only 2 sets of 16 experiments are necessary during this optimization procedure based on the model of the system. But it can be seen that there are some important differences between simulation and experimental results for a single set of parameters (oscillations remains during steady state and the overshoot with experimental fuzzy PI controller is not negligible).

In fact, the model of the system which was used for the simulations tests was not a very fine model and some additional components should be added in order to improve it. But there is another way to improve performance: an

on-site and experimental tuning of the controller on the system itself, according to experimental designs methodology. The price to pay is an increased number of experiments in order to improve accuracy.

8. EXPERIMENTAL RESULTS

Instead of system model improvement for a better controller tuning, we applied the experimental designs method directly to the system, with all its characteristics. The whole methodology is detailed hereafter.

8.1 Single criterion

The tuning procedure is then realized on the experimental process. Two successive sets of experiments are again carried out. Parameters of the first “rough” design are given in Tab. 3 from values of the continuous PI controller:

PSe	0.6	PSs	0.6
PVSE	0.3	PVSs	0.3
PSde	0.6	Gm	486
PVSde	0.3	dem	6.5e-3

Tab. 3. Initial fuzzy parameter values

The factor levels are chosen on both sides of initial parameter values:

PSe	0.5 - 0.7	PSs	0.5 - 0.7
PVSe	0.2 - 0.4	PVSs	0.2 - 0.4
PSde	0.5 - 0.7	Gm	490 - 570
PVSde	0.2 - 0.4	dem	5.5e-3 - 7.5e-3

Tab. 4. First set of factor levels.

Considering both criteria in desirability, the experimental design methodology leads to the following set of “roughly optimized” parameters, in Tab.5 :

PSe	0.5	PSs	0.7
PVSE	0.2	PVSs	0.4
PSde	0.7	Gm	530
PVSde	0.2	dem	5.5e-3

Tab. 5. First set of “roughly optimized” parameters

The factor levels for the second and “fine” design are given by Tab. 6 after the first design results.

PSe	0.4 - 0.6	PSs	0.6 - 0.8
PVSe	0.1 - 0.3	PVSs	0.3 - 0.5
PSde	0.6 - 0.8	Gm	490 - 570
PVSde	0.1 - 0.3	dem	45e-4 - 65e-4

Tab. 6. Second set of factors levels.

The two criteria (IAE and TDH) are measured for each experiment. The latter is repeated three times for accuracy improvement, (confidence interval defined as 99.9%. Factor effects are given by Table 7. Interaction effects are less influent than main parameter effects and are not given here.

	IAE*10 ⁻² V.s	TDH*100 %		IAE*10 ⁻² V.s	TDH*100 %
PSe	1.4	-3.1	PSs	-2	-3.2
PVSe	3.9	-2.9	PVSs	-2.5	8.6
PSde	0.7	-4.3	Gm	-2.2	1.5
PVSde	5.6	-21	dem	2.9	-7.2
Average	22.5	364	Confidence interval	0.27	4.04

Tab. 7. Factor effects on both criteria

It appears that the factor effects are strongly different for each criterion. The factor *PVSde* is always the dominant one and its influence is opposite for each criterion, as shown by Table 7. From the factor effects given by the experimental design, a set of optimal parameters for the fuzzy controller can be defined for each criterion: the first one, Set 1, for the IAE criterion only and the second, Set 2, for the harmonic criterion only. Figure 12 presents the

output voltage V_{DC} for the two optimal settings and figure 13 depicts the input current for the second setting only. The criteria values are given in table 8.

Fig. 12. Experimental output voltage responses for set 1 and set 2

Fig. 13. Experimental input currents for Set 2 only

From these criteria, experimental designs can not give a composite optimal tuning. The solution may consist in a combination of the criteria in a composite criterion with the desirability notion.

8.2 Composite criterion

From the given results, the main difference between harmonic rejection for Set 1 and Set 2 is the value of the third harmonic (0.325 A for Set 1 and 0.113 A for Set 2), the others remaining equivalent. This preponderant harmonic amplitude is then transformed into elementary desirability dh_3 . Values $Y_{h_{3,c}}$ and $Y_{h_{3,p}}$ are equal to Set 1 and Set 2 results with $rh_3 = 0.1$, increasing the penalty for low values. IAE is also transformed into an elementary desirability d_{IAE} , with $r_{IAE} = 1$ and $Y_{IAE,c} = 0$ while $Y_{IAE,p}$ is chosen slightly higher than the worst value of the experimental designs. Finally, the harmonic values of the other ranks i are transformed into elementary desirabilities dh_i ($i \in [2,39], i \neq 3$) with $Y_{h_{i,c}} = 0$ as the objective is to reject harmonic distortion. $Y_{h_{i,p}}$ is equal to the CEI 61000-3-2 standard limit value so as to respect it. We fix $rhi = 0.01 \ll 1$ so that the sensibility of elementary desirabilities for harmonic rejection is improved near the standard values. Giving more importance to the IAE criterion and to the third harmonic amplitude through w_i parameters, the final criterion Y (25) is therefore:

$$Y = \left(d_{IAE}^5 \cdot d_{h3}^5 \cdot \prod_{\substack{i=2 \\ i \neq 3}}^{39} dh_i \right)^{\frac{1}{47}} \quad (25)$$

The new tuning, Set 3, gives results shown in fig 14 and in Table 8. It appears that the THD benefit is equal to a third of the difference between the best and the worst tunings while keeping a really good dynamic behavior.

Fig. 14. Experimental output voltages with set 3 and linear PI

	Fuzzy Controller				Linear PI
	Set 1	Set 2	Set 3	Set 0	
IAE voltage (0.01V.s)	9.6	47.1	10.1	10.9	53.1
TDH (%)	3.7	2.8	3.4	3.8	4.1
Load connection:					
Tr 5% (ms)	57	173	56	67	193
V_{DC} min (V)	369	338	370	367	335
Load disconnection:					
Tr 5% (ms)	118	1078	134	169	1236
V_{DC} max (V)	432	476	434	439	485
V_{DC} min (V)	390	350	388	384	344

Tab. 8. Experimental results

9. COMPARISON

All experimental results are summarized in Table 8. Linear controller performance is quite bad and the comparison illustrates the validity of using FLC. Experimental design analysis allows to explore several tuning settings giving more influence to one or two criteria.

It is important to notice that the grid voltage THD itself is 2.6%. Then, the THD for the optimal setting is really close to this network's value. It underlines the really good performance of the fuzzy controller with respect to harmonic rejection. The dynamic improvement under such important load variations is significant in comparison with linear PI. FLC tuning given through simulation, set 0, is here worse in term of global performance in comparison with results given by the experimental study but is cheaper in term of number of experiments. Moreover, the dynamic performance is improved with respect to linear PI controller.

10. CONCLUSION

It has been shown in this paper that the experimental designs methodology is an efficient tool for on-line tuning of fuzzy controller according to either simple criterion or multi-objective criteria. The controllers were first tuned through simulations and showed some interesting performance but some differences with experimentations appear due to some modelling offsets. Although the system is non linear, experimental on-site tuning on the real process is possible through this method and leads to a clear performance improvement. Consequently, there are two possibilities: get a fine model of the system and run the experimental designs in simulation (one experiment for each of the 16 tested combinations) or run 3 times more experiments on the real system but without any need of a fine model. The next step will consist in using the experimental response surface methodology for global performance improvement.
