Glass reinforced composites are used in many structural applications. Their fibre content can vary considerably according to the manufacturing route, typically from 30% to 70% by volume. This paper presents results from an experimental study of the influence of fibre volume fraction on the mode II interlaminar fracture toughness, G_{IIc} , using the 4ENF (four point end notched flexure) specimen. Results show that G_{IIc} increases with decreasing fibre content. This effect is caused by plastic deformation energy dissipation in the thicker resin-rich interlaminar layer in lower fibre content composites.

Keyword: Fracture testing

1. Introduction

Despite efforts to develop composites with throughthickness reinforcements most composites currently in service contain only two-dimensional (in-plane) reinforcement. Delamination fracture remains an important failure mode in such composites. The development of standardised test methods to characterise the resistance to interlaminar crack propagation, is essential for two main reasons. First, such tests offer the possibility to compare existing and new materials on the same basis. Second, models for prediction of damage development and damage tolerance are becoming increasingly accessible to designers of composite structures, and such models require reliable input data. While an international standard test method now exists for the mode I interlaminar fracture testing of composite materials (ISO 15024) it has proved more difficult to reach agreement for mode II (shear). An obstacle to the most widely-used test, the end notch flexure (ENF) specimen, is that crack propagation is inherently unstable [1-3]. An alternative mode II configuration, shown in Fig. 1, was proposed by Martin and Davidson [4], called the 4ENF (four point end notched flexure) test. This test is potentially very attractive, as the geometry encourages stable crack propagation so that an experimental compliance calibration can be applied for data reduction of the fracture toughness, and a mode II resistance curve may be established. The 4ENF test employs a four-point flexure rig allowing rotation of the upper loading points. A draft mode II 4ENF test protocol [5] was prepared in 1998 for an international round robin exercise [6], but frictional effects have retarded its acceptance as a standard test [7].

Apart from the studies described above, very little work has been published on the 4ENF specimen to date, and most of the published work has involved carbon fibre reinforced epoxy composites [8]. Carbon composites

Fig. 1. Mode II 4ENF loading fixture, dimensions in mm.

are primarily used for high performance applications based on prepreg, and fibre contents are usually close to 60% by volume. There is also considerable interest in obtaining valid mode II fracture toughness values for more flexible composites. Glass reinforced composites are manufactured using a wide range of methods, including hand lay-up, resin infusion and filament winding and these processes result in widely different fibre contents, from 30% to 70%. It is therefore important to determine the influence of glass fibre content on the mode II interlaminar fracture toughness.

Fibre content has been shown to have a significant effect on mode I delamination toughness. For example Hunston et al. [9] showed much higher G_{Ic} values for a composite which was resin rich than for the same material with a lower resin content. Similarly, recent tests using the edge cracked torsion (ECT) specimen show a strong influence of fibre content on the mode III fracture toughness [10].

In this paper, we will examine the mode II fracture toughness of glass fibre composites over a large range of fibre contents using the 4ENF test. The fracture surfaces of the specimens will be analyzed in optical and scanning electron microscopes (SEMs) to examine the microscopic mechanisms responsible for the macroscopic toughness.

2. Experimental

2.1. Materials

The material studied here is a quasi-unidirectional glass/epoxy composite. This consists of 300 g/m^2 layers

of E-glass fibres impregnated by hand lay-up with an epoxy resin (HY5052), then compression moulded between steel plates. An 8 μ m thick polypropylene film, was inserted at mid-thickness during fabrication to act as a starter crack. The reinforcement is described as quasi-unidirectional because there is a small amount (1 g/m²) of 90° polyester fibres which maintain the cohesion of the unidirectional glass fibres and facilitate handling during lay-up. The epoxy is a room temperature cure system but a post-cure (5 h at 90 °C) was applied to stabilise the matrix properties.

Seven glass/epoxy panels were produced. The panels contained 20, 26, 30, 36 and 40 plies. Specimen thickness was varied by placing different thickness metallic spacer shims to fix the distance between the steel plates in the press. Large ranges of specimen thicknesses and fibre volume fractions were achieved in this manner. Fibre contents were determined on samples cut from each individual 4ENF test specimen, by resin burn-off at 500 °C for 24 h and weighing. A range of fibre volume fractions from 42% to 65% was achieved. The number of plies, thicknesses and fibre volume fractions of these composites are presented in Table 1. Notice also that specimen thickness and fibre volume fraction were designed to be uncorrelated to minimize possible thickness influence on the results. The glass transition temperature of the matrix, T_{g} was determined by differential scanning calorimetry (DSC) on two samples from each panel (TAI modulated DSC 2920, heating rate 5 °C/min). T_{g} values varied in a narrow range (71-78 °C) for all panels.

2.2. Test fixtures and procedures

Short beam shear tests were performed on three specimens cut from each panel, according to ASTM D2344 with a ratio of span to thickness of 5, at a cross head rate of 5 mm/min. These tests were intended to check panel quality.

The mode II test fixture consists of an upper loading part with a central roller 40 mm above the two loading points, (distance d) Fig. 1. This distance is less than the maximum value (50 mm) according to the draft 4ENF protocol [5]. The specimen is supported at two points

Mean values (SD).

and the initial crack length (a_0) is 35 mm measured from the left outer loading point.

All tests were performed at displacement rate of 1 mm/min, on a test frame with a 10 kN capacity load cell. The machine crosshead displacement transducer was used to record upper loading point displacements, while crack length measurements were made visually. In addition, two digital cameras were set up to view the edges of the specimen to record the global displacement field of the specimen and follow crack propagation. Fig. 2 is a photograph of a deformed specimen which shows the asymmetric displacement of the specimen. The cameras allowed non-contact measurements of deflections with a resolution of 0.2 mm, and crack lengths with a resolution of 0.1 mm, and were used to check the displacement transducer and visual crack length measurements. For some of the glass/epoxy composites, which are transparent, a third digital camera was also employed, viewing the top surface of the specimen to detect the crack advance with back lighting. This indicated that the crack front was straight, Fig. 3, so measurements on specimen edges were considered to be reliable.

Before each test an initial compliance calibration was performed (measuring compliance over a range of crack lengths), by sliding the specimen along the fixture, to vary the crack length in 5 mm steps over the range $a_0 = 20-45$ mm. Load–unload cycles were performed in the elastic range at each crack length. Then each specimen was loaded once to propagate a short mode II crack from the starter film, unloaded and reloaded until the crack propagated to the loading roller. After this crack propagation, a second compliance calibration was made over the range of crack lengths from 35 to 80 mm.

2.3. Data reduction for G_{IIc}

The mode II interlaminar fracture toughness, G_{IIc} , was reduced from 4ENF test data using an experimental compliance calibration method with the compliance expression [5]

$$C = C_0 + ma,\tag{1}$$

where *C* is the specimen compliance, and *a* is the crack length. The fracture toughness, G_{IIC} , is

$$G_{\rm IIc} = \frac{P_{\rm c}^2 m}{2B},\tag{2}$$

Fig. 3. View through specimen showing straight crack front.

where $P_{\rm c}$ is the critical load, *m* is the slope of the compliance versus crack length plot, and B is the specimen width. $G_{\rm IIc}$ was determined for each crack length using the onset of non-linearity on the load-displacement plot, and a compliance versus crack length plot determined for each specimen. Fig. 4 shows an example of a compliance calibration plot established from measurements before crack propagation (sliding) and during the fracture test (propagation). The slopes (m) measured using both methods are indicated in Fig. 4. The small difference in slope may be due to a difference in crack length measurement as the true position of the crack tip after crack propagation was obscured by the damage zone formed near the front. All G_{IIc} values reported herein were determined using the slope (m) measured during propagation.

3. Results and discussion

Short-beam shear strength data are shown in Fig. 5. The interlaminar shear strength does not depend on fibre volume fraction, a consequence of its dependence on the fibre/matrix shear strength.

Seventeen mode II specimens cut from the panels presented in Table 1 were tested. Examples of load-displacement plots from the first tests, performed on panels with 20 and 30 plies, are shown in Fig. 6. Two plots are given for each specimen, one corresponding to the first loading to generate a short shear crack from the insert film, and the second loading to propagate the crack. These plots indicate essentially linear behaviour up to crack initiation. For each specimen two initiation values were determined, one from the initial starter film and one from the mode II precrack. Then 7-10 propagation values were recorded. Fig. 7 shows examples of mode II interlaminar toughness versus crack length curves (resistance curves) at fibre volume fractions of 52% and 62%. For each composite the toughness increases somewhat during crack propagation. The variations are typical for hand laid up composites, but may also arise from the periodic 90° polyester fibres.

Fig. 7. G_{IIc} resistance curves for the specimens in Fig. 6.

Fracture toughnesses determined for all test specimens are plotted versus fibre content in Figs. 8 and 9. The toughness decreases quite substantially with increasing fibre content. Furthermore, initiation values determined by propagation from shear precracks exceed those determined by propagation direction from the insert film, Fig. 8. This increase could be due to accumulated plasticity effects for the shear precracked specimens. At high fibre contents the toughness levels off to assume a plateau level apparently dominated by fiber/matrix interfacial adhesion rather than matrix plasticity at the closed-packed fibre configurations ap-

proached at these high fibre volume fractions. Table 2 summarises the values for the low and high fibre contents. It is clearly observed that there is a strong effect of fibre volume fraction on the initiation and propagation toughnesses.

There are a number of possible explanations for the large influence of fibre volume fraction on the mode II delamination toughness. First, it may simply be that the extent of cure of the resin in the panels with the lowest fibre contents differs from that in those at higher fibre contents. The measured glass transition temperatures reported earlier, however, indicate that this is not the case. Another possibility is that the specimen stiffness (thick-

Fig. 10. Scanning electron micrographs of specimen edge in the starter film region: (a) $V_f = 42\%$; (b) $V_f = 62\%$.

ness) affects measured toughness but no correlation was noted. For example, the specimens with the lowest fibre contents were not the thickest ones.

A more plausible reason for the high toughness of the low fibre content specimens is crack tip plasticity effects [9]. To examine this factor in more detail, the specimen edges near the crack front, and fracture surfaces were examined in a SEM. Starter film regions of polished edges of specimens were examined in the SEM detailing the film insert region where crack propagation begins. Fig. 10 shows the edge views of the insert region for vertically arranged low and high fibre volume fraction specimens. For the lowest fibre content composites the resin rich layer extends about 50 µm on both sides of the insert film, see Fig. 10(a). Resin rich regions occur at all the regions between reinforcement layers. At high fibre contents the insert film is closely surrounded by fibres and the resin rich region is less than 10 μ m thick, see Fig. 10(b). The thickness of this resin layer is a striking difference between the low and high fibre content composites ($V_{\rm f} = 40-45\%$ and $V_{\rm f} = 50-68\%$, respectively).

The fracture surfaces near the insert region, Fig. 11, reveal that the presence of the matrix rich region in the low fibre volume fraction composite, Fig. 11(a), allows the development of a damage zone involving plastically deformed and micro-cracked matrix material near the tip of the insert film. This observation could explain the more extensive energy dissipation in this

Fig. 11. Scanning electron micrographs of fracture surfaces, initiation region: (a) $V_f = 42\%$; (b) $V_f = 62\%$.

Fig. 12. Scanning electron micrographs of fracture surfaces, propagation region: (a) $V_{\rm f} = 42^{\circ}$; (b) $V_{\rm f} = 62^{\circ}$.

composite. No such matrix region is observed in the high volume fraction composite, Fig. 11(b). Closer examination of the fracture surfaces in the propagation region, Fig. 12, reveals a large amount of shear microcracks that extend through the resin rich region in the low fibre content specimen, Fig. 12(a). For the higher fibre content specimen, Fig. 12(b), shear cracks also initiate but cannot develop as they impinge on the fibre/ matrix interface much sooner and the delamination crack becomes trapped in a narrow region around the ply interface. This results in much less matrix deformation and clean fibres seen on the fracture surfaces. It is interesting to note that Chai [11] conducted shear fracture tests on adhesively bonded metal specimens and found a strong increase in mode II toughness as the adhesive layer thickness was increased. Similarly, Carlsson [12] showed a strong effect of resin film thickness on delamination toughness of interleaved carbon fibre composites.

4. Conclusions

This paper shows that the 4ENF specimen is wellsuited to measuring mode II delamination toughness in glass/epoxy composites, providing full resistance curves. Initiation values fall significantly below the propagation values and the minimum initiation values are measured from propagation directly from the insert film as opposed to propagation from a short mode II precrack. A study of the influence of fibre content on the delamination toughness, $G_{\rm IIC}$, revealed that the toughness is high for resin rich composites and this is attributed to the importance of a thick interlaminar resin rich layer in the low fibre content composites that allows plastic deformation to extend over a larger volume than in the high fibre content composites.
