11	Abstract
12	The characterisation of soil surface roughness is a key requirement for the correct analysis of
13	radar backscattering behaviour. It is noteworthy that an increase in the number of surface
14	roughness parameters in a model also increases the difficulty with which data can be inverted
15	for the purposes of estimating soil parameters. In this paper, a new description of soil surface
16	roughness is proposed for microwave applications. This is based on an original roughness
17	parameter, $Zg$ , which combines the three most commonly used soil parameters: root mean
18	surface height, correlation length, and correlation function shape, into just one parameter.
19	Numerical modelling, based on the moment method and integral equations, is used to evaluate
20	the relevance of this approach. It is applied over a broad dataset of numerically generated
21	surfaces characterised by a large range of surface roughness parameters. A strong correlation
22	is observed between this new parameter and the radar backscattering simulations, for the HH
23	and VV polarizations in the C and X bands. It is proposed to validate this approach using data
24	acquired in the C and X bands, at several agricultural sites in France. It was found that the
25	parameter $Zg$ has a high potential for the analysis of surface roughness using radar

26 measurements. An empirical model is proposed for the simulation of backscattered radar27 signals over bare soil.

30 **1. Introduction** 

Soil moisture and roughness parameters play a key role in hydrological and climate studies. In 31 recent years, various efforts have been devoted to the analysis of the backscattering 32 33 characteristics of bare soils. Initially, different backscattering models (theoretical, semiempirical and empirical) were developed (Ulaby et al., 1986, Fung et al., 1992, Oh et al., 34 1992, Dubois et al., 1995, Chen et al., 2003, Zribi et al., 2008). More recently, several studies 35 have proposed various approaches for the improvement of roughness descriptions (Oh et al., 36 1998, Mattia et al., 1999, Zribi et al., 2000, Davison et al., 2000, Li et al., 2002, Callens et al., 37 38 2006, Verhoest et al., 2008, Bretard et al., 2013), which are essential to the accurate analysis 39 and interpretation of backscattering behaviour and soil moisture estimation (Lievens et al., 2009). An analysis based on a fractal representation has been proposed (Rouvier et al., 1997; 40 41 Zribi et al., 2000) allowing a multi-scale description, which is not limited to the use of a single scale based on the correlation length parameter. Zribi et al. (2000) introduced fractal 42 and Brownian approaches to describe the correlation function, whereas Li et al. (2002) 43 proposed a general power law description of roughness spectra. Fung et al. (1994), Shi et al. 44 45 (1997) and Zribi et al. (2005) have proposed different types of analytical correlation function, 46 used to fit the experimental data. Although all of these studies have led to improvements in the direct backscattering simulations, the availability of a limited number of radar 47 configurations makes it generally impossible to retrieve the volumetric soil moisture with all 48 49 of the roughness parameters. In this context, Zribi and Dechambre (2003) introduced a description based on the parameter  $Zs = s^2/l$ , where s is the rms surface height and l is the 50

correlation length (Bretard et al., 2013, Lawrence et al., 2013). Baghdadi et al. (2004, 2006, 51 52 2011) proposed an empirical correlation length, computed as a function of the rms height, radar frequency, incidence angle and polarization, in order to obtain a better fit between 53 Integral Equation Model (Fung et al., 1992) simulations and radar observations. Lievens et al. 54 (2011) show that roughness parameters differ between SAR acquisitions, as they are related to 55 the observed backscatter coefficients and variations in local incidence angle. A statistical 56 57 model was thus developed, to allow the effective roughness parameters to be estimated from microwave backscattering observations. Despite these contributions, the influence of 58 roughness is still poorly modelled in currently known inversion techniques. 59

In the present study, a new surface description is proposed, in which the analysis uses the 60 moment method to numerically simulate the backscattering integral equations. Our paper is 61 organised into five sections, of which Section 2 presents the principles of the numerical 62 backscattering simulations, Section 3 discusses the influence of roughness on the 63 backscattering simulations and introduces the new roughness parameter, Zg. Section 4 64 describes the potential of this parameter, through the use of experimental analyses based on 65 66 different types of ground and radar measurements. Finally, our conclusions are presented in 67 Section 5.

68

#### 2. Numerical backscattering simulations - methodology

A numerical backscattering model based on the moment method is used to simulate radar signals over bare soils (Harrington, 1968, Chen et al., 1990, Johnson et al., 1996, Mattia et al., 2000, Soriano et al., 2002, Zribi et al., 2010). With this approach, the computations are made using simulated surfaces, with various roughness and soil moisture characteristics. The first step in this process thus involves the generation of soil roughness profiles.

74 2.1 Roughness profile generation for different types of correlation function

In this section, it is proposed to generate soil surfaces with different correlation functions  $\rho(x) = \exp\left(-\left(\frac{x}{l}\right)^{\alpha}\right)$ , in which the parameter  $\alpha$  can range between 1 and 2 (Li et al., 2002),

with these extremes corresponding to exponential and Gaussian functions, respectively (Fung
et al., 1985). The approach described by (Fung et al, 1985) is used as follows:

79 The surface heights are written as:

80 
$$h(k) = \sum_{i=-M}^{i=M} W(i)X(i+k)$$
 (1)

81 where X(i) is a Gaussian random variable N(0,1), and W(i) is the weighting function given by

82  $W(i) = F^{-1} \left[ \sqrt{F[C(i)]} \right]$ , in which C(i) is the correlation function and F[] denotes the Fourier 83 transform operator. In the numerical simulations, a Fast Fourier Transformation (FFT) is used 84 to compute the corresponding values of W(i).

Fig. 1 shows three soil profiles generated using different values of  $\alpha$  ( $\alpha$ =1,  $\alpha$ =1.5 and  $\alpha$ =2). In this case, the rms surface height is equal to 0.6 cm and the correlation length is equal to 6 cm. It can be clearly seen that a decrease in the value of  $\alpha$  leads to an increase in the presence of high frequency structures.

#### 892.2 Moment Method simulations

In this section, a limited description of the moment method, used to compute radar backscattering over generated surfaces, is proposed. The analyses presented here make use of two-dimensional simulations, which are adequate for the purposes of the present study, and are based on the use of isotropic surfaces only (Chen et al., 1994, Fung, 1994). The backscattering computation is based on the numerical resolution of integral equations, in which the medium is considered to be air (Chen et al., 1990):

96 
$$\vec{n} \times \vec{E}^i(\vec{r}) = -\frac{1}{2}\vec{K} + \vec{n} \times \int_c \left[ j\omega\mu_0 G_1\vec{J} - \vec{K} \times \nabla G_1 - \frac{\nabla'.\vec{J}}{j\omega\varepsilon_1}\nabla G_1 \right] dl'$$

97 
$$\vec{n} \times \vec{H}^{i}(\vec{r}) = -\frac{1}{2}\vec{J} + \vec{n} \times \int_{c} \left[ j\omega\varepsilon_{1}G_{1}\vec{K} + \vec{J} \times \nabla G_{1} - \frac{\nabla'.\vec{K}}{j\omega\mu_{0}}\nabla G_{1} \right] dl'$$
 (2)

98 When the medium is soil rather than air, the corresponding integral equations are:

99 
$$0 = -\frac{1}{2}\vec{K} - \vec{n} \times \int_{C} \left[ j\omega\mu_0 G_2 \vec{J} - \vec{K} \times \nabla G_2 - \frac{\nabla' \cdot \vec{K}}{j\omega\varepsilon_2} \nabla G_2 \right] dl'$$

100 
$$0 = -\frac{1}{2}\vec{J} - \vec{n} \times \int_{c} \left[ j\omega\varepsilon_{0}G_{2}\vec{K} + \vec{J} \times \nabla G_{2} - \frac{\nabla'.\vec{K}}{j\omega\varepsilon_{2}}\nabla G_{2} \right] dl'$$
(3)

101 where  $\mu_0$  is the permeability of air,  $\varepsilon_1$  and  $\varepsilon_2$  are the dielectric constants of air and soil, 102 respectively, and  $\vec{n}$  is the unit outward normal to the surface.  $\vec{J} = \vec{n} \times \vec{H}$  is the equivalent 103 surface electric current density, and  $\vec{J} = -\vec{n} \times \vec{E}$  is the equivalent surface magnetic current 104 density.

105 The Green functions are defined in cylindrical coordinates, by the zeroth order Hankel106 function of the second kind, as:

107 
$$G_i = -\frac{j}{4} H_0^{(2)} (k_i | \vec{\rho} - \vec{\rho} |), i = 1, 2$$
 (4)

In this paper, we present integral equations and method of resolution only for horizontal
polarisation. For vertical polarisation, the approach is similar with just minor modifications
(Chen et al., 1990).

111 For the horizontal polarisation, the incident electric and magnetic fields are written as:

112 
$$\vec{E}^i = -\vec{y} e^{jk_1(x\sin\theta + z\cos\theta)}$$

113 
$$\vec{H}^{i} = \frac{1}{\eta} \left( -\vec{x}\cos\theta + \vec{z}\sin\theta \right) e^{jk_{1}(x\sin\theta + z\cos\theta)}$$
(5)

114 With  $\vec{J} = \vec{y} J(l')$  and then  $\nabla' \cdot \vec{J} = 0$ 

115 The integral equations could be written as:

116 
$$\vec{n} \times \vec{E}^{i}(\vec{r}) = -\frac{1}{2}\vec{K} + \vec{n} \times \int_{c} \left[j\omega\mu_{0}G_{1}\vec{J} - \vec{K} \times \nabla G_{1}\right]dl'$$

117 
$$0 = -\frac{1}{2}\vec{K} - \vec{n} \times \int_{c} \left[j\omega\mu_{0}G_{2}\vec{J} - \vec{K} \times \nabla G_{2}\right] dl'$$
(6)

118 where:

119 
$$\vec{K} \times \nabla G_i = (-\vec{n} \times \vec{E}) \times \nabla G_i = -\vec{E} (\vec{n} \cdot \nabla G_i), \quad i = 1, 2$$

120 The integral equations can then be simplified to:

121 
$$E_{y}^{i}(\vec{\rho}) = \frac{1}{2}E_{y}(\vec{\rho}) + \int_{c} \left[j\omega\mu_{0}G_{1}J_{y} + E_{y}(\vec{n}'.\nabla G_{1})\right]dl'$$

122 
$$0 = \frac{1}{2} E_y(\vec{\rho}) - \int_C \left[ j \omega \mu_0 G_2 J_y + E_y(\vec{n}' \cdot \nabla G_2) \right] dl'$$
(7)

123 These equations can then be rewritten in the form of a matrix system:

124 
$$\begin{bmatrix} Q^{11} & Q^{12} \\ Q^{21} & Q^{22} \end{bmatrix} \begin{bmatrix} E_y \\ J_y \end{bmatrix} = \begin{bmatrix} E_y^i \\ 0 \end{bmatrix}$$
(8)

125 The details of the different terms in these matrices are described in (Chen et al., 1989).

126 The solution for this system allows the electric field and electric field density to be estimated

127 over the studied surface. The backscattered field can then computed as:

128 
$$E_y^s = -\int_c \left[ j\omega \,\mu_0 G_1 J_y + E_y (\vec{n}' \cdot \nabla G_1) \right] \, dl'$$
 (9)

129 This leads to the following expression for the backscattered signal:

130 
$$\sigma^{0} = \frac{2\pi\rho}{PL_{eff}} \left[ \sum_{j=1}^{P} \left| E_{j}^{s} \right|^{2} - \frac{1}{P} \left| \sum_{j=1}^{P} E_{j}^{s} \right|^{2} \right]$$
(10)

131 Where  $L_{eff}$  is the effective illumination length of Gaussian antenna pattern.

132 On the basis of the outcome of several convergence tests, the profile length was set to 1 m and 133 the number of profiles as taken to be 100. For each profile, the size of the cells was taken to 134 be  $\lambda/10$ , where  $\lambda$  is the wavelength of the radar signal.

#### 135 **3.** Analysis of simulated radar backscattering as a function of roughness

#### 136 *3.1 Influence of roughness on the backscattering simulations*

In order to study the influence of the soil roughness parameters on radar signal backscattering, 137 Moment Method (MM) simulations were run in the HH and VV polarizations, at 20 and 40° 138 incidence angles, and at three different values of soil moisture: 10%, 20% and 30%. The 139 results shown in Figs. 2, 3, 4 and 5 were computed at a 40° incidence angle, since the radar 140 141 signals are known to be more sensitive to roughness at higher incidence angles (Fung, 1994, Zribi et al., 1997). Various surface parameters were used: rms heights s=0.4 cm, s=0.6 cm, s=0.6142 =0.8 cm, s = 1 cm, s = 1.2 cm, s = 1.4 cm, s = 1.6 cm; correlation lengths l=4 cm, l=6 cm, l=8143 cm and l = 10 cm;  $\alpha$  parameter  $\alpha = 1$ ,  $\alpha = 1.25$ ,  $\alpha = 1.5$  and  $\alpha = 1.75$ . The latter range (for the 144 145 parameter  $\alpha$ ) was based on the values retrieved during various experimental campaigns (Zribi 146 et al., 2005).

Fig. 2 shows the simulated backscattered signal, for the *HH* polarization, assuming volumetric 147 moisture conditions of 10% and 30% in the C and X bands at 40° incidence, for all of the 148 above roughness configurations, plotted as a function of the rms surface height. These 149 simulations show that the backscattered signal is moderately well correlated with the rms 150 surface height (in the C band,  $R^2$  is equal to 0.65 and 0.66, and in the X band it is equal to 151 0.58 and 0.51, for volumetric moistures of 10% and 30%, respectively). This outcome is 152 influenced, in particular, by the correlation length, which is not taken into account in the 153 above relationships. Fig. 3 plots the simulated backscattered radar signals for the HH 154 polarization, for volumetric moistures of 10% and 30%, in the C and X bands at 40° 155 incidence, for all of the above roughness configurations, plotted as a function of the parameter 156 Zs. Since the latter parameter is defined as  $Zs = s^2/l$  (Zribi and Dechambre, 2003), it combines 157 the influence of both the soil's rms height and its correlation length: it is in effect given by the 158 159 product of the *rms* height *s*, which is related to the power of the surface height variations, and the ratio s/l, which represents the local slope of the soil. The underlying motivation for the 160 introduction of Zs was to introduce the influence of slope, which is an important soil feature 161 in the estimation of  $\sigma^{\circ}$ . It can clearly be seen that the simulated backscattering is more 162 strongly correlated with Zs ( $R^2 = 0.82$ , 0.81 in the C band, and  $R^2 = 0.71$ , 0.62 in the X band, 163 for volumetric moistures of 10% and 30%, respectively), than with the rms height. When the 164 exponential correlation function is considered alone, the correlation between Zs and the 165 simulated backscattered signal is very high ( $R^2 > 0.9$ ). When different function shapes are 166 considered, corresponding to different values of  $\alpha$  (1, 1.25, 1.5 and 1.75), the correlation 167 coefficient decreases, as shown in Fig. 3. This outcome could be explained by the influence of 168 the slope component (s/l) on backscattering, which depends on the shape of the correlation 169 170 function.

171 *3.2 Generating the Zg parameter* 

173 The parameter Zs was initially proposed for use with an exponential correlation (Zribi and Dechambre, 2003), and weaker correlations are observed between Zs and the simulated 174 backscattering when other correlation function shapes are considered. However, with 175 agricultural and natural soils, differing correlation function shapes are retrieved during the 176 same period. In practice, new tillage is often associated with an exponential function, whereas 177 178 rain-eroded and ploughed soils are often found to have correlation functions with a shape lying between that of an exponential and a Gaussian function (Zribi et al., 1997, Zribi et al., 179 2005). For these reasons, the use of a single roughness parameter, with an rms height, 180 181 correlation length and correlation function shape, could be very useful for inversion studies based on the analysis of radar measurements, which generally make use of a small number of 182 radar configurations. 183

Since the contribution of the ratio s/l must be different from one correlation shape to another, as a result of differences in the high frequency spectrum of the soil profile, we propose to introduce a new parameter, which is a global representation of the *Zs* parameter, written as:

187 
$$Zg = s \cdot \left(\frac{s}{l}\right)^{g(\alpha)}$$
(11)

188

189 where  $g(\alpha)$  is a power function accounting for the influence of the ratio (s/l) on Zg, and  $\alpha$  is 190 the power of the correlation function.

191 In the following, it is assumed that  $g(\alpha)$  can be written as:

192 
$$g(\alpha) = a \alpha + b$$

193 where *a* and *b* are constants.

All of the backscattering simulations made in the C- and X- bands, using three values of volumetric moisture (10%, 20% and 30%), a large range of values of rms height (from 0.4 to 1.6 cm), correlation length (from 4 cm to 10 cm), and  $\alpha$  (from 1 to 1.75), were reviewed. The 197 best correlation between the global roughness parameter Zg and the simulations was 198 determined by least squares regression. This is obtained when the function g is written as:

199 
$$g(\alpha) \approx \alpha$$
 (12)

such that (from Eq. 11):

201 
$$Z_g = s \left( \frac{s}{l} \right)^{\alpha}$$
(13)

In Zribi and Dechambre (2003), it was proposed to use a roughness parameter Zs = (s.s/l), in the case of simulations corresponding to the special case of an exponential correlation function ( $\alpha$ =1).

205 For a fixed value of  $\alpha$ , small values of Zg correspond to small values of s and/or large values of l, whereas large values of Zg correspond to large values of s or small values of l. In the case 206 207 of a fixed correlation length, small values of Zg correspond to small values of s and/or large values of  $\alpha$ , whereas large values of Zg correspond to large values of s or small values of  $\alpha$ . A 208 smooth soil surface (without clods) is generally characterised by a small value of s and a 209 medium to large value of l, thus to a small value of Zg. Ploughed soil, corresponding to new 210 211 tillage, is generally associated with a large value of s, a medium to large value of l, and a value of  $\alpha$  close to 1, and thus to a large value of Zg. Ploughed surfaces, corresponding to 212 213 eroded soils, are often characterised by a large value of s, a medium to large value of l and a value of  $\alpha$  close to 2, thus to a medium value of Zg. Even when its rms height (s) is small, a 214 cloddy soil is characterised by a very small value of l and a value of  $\alpha$  close to 1, thus leading 215 to large values of Zg (Zribi et al., 1997, zribi et al., 2005). 216

Fig. 4 shows a plot of simulated backscattered signals as a function of Zg, for various ranges of roughness and four correlation function shapes ( $\alpha$ =1,  $\alpha$  =1.25,  $\alpha$  =1.5,  $\alpha$  =1.75), in the C and X bands and for the *HH* polarization, with volumetric moisture values of 10% and 30%.

Firstly, it can be seen that the simulated backscattering increases with Zg, and that there is a 220 221 strong correlation between the backscattering and Zg, equal to 0.97 and 0.97 for 10% and 30% volumetric moistures in the C-band and equal to 0.97 and 0.93 for 10% and 30% 222 volumetric moistures in the X-band. A high dynamic range can be observed at small values of 223 Zg, and near saturation can be seen when Zg reaches approximately 0.3-0.35. The highest 224 values of  $\alpha$  produce the weakest backscattering. From this initial result, Zg appears to be a 225 226 useful parameter for the characterization of surface roughness, in the case of a given (fixed) radar configuration. This result can be explained by the fact that Zg takes the influence on 227 228 radar backscattering behaviour of s, l and the correlation function shape into account.

Table 1 provides a summary of the correlations determined from backscattering simulations, using different roughness parameters (s, Zs and Zg), for all combined conditions of incidence angle, moisture, polarisation, and frequency. It can be seen that under almost all conditions of radar transmission, the strongest correlations are obtained with the parameter Zg, rather than with s or Zs. This conclusion is not completely verified in the C-band, in the case of a 20° incidence angle, for which the empirical logarithmic relationship can be seen to less well correlated.

To simplify the combination of backscattering simulations made at different radar frequencies, the former were considered as a function of electromagnetic roughness, written in the form: k.Zg (k: radar wave number). Fig. 5 plots the simulated backscattered signals as a function of k.Zg, in the *HH* and *VV* polarizations, at a 40° incidence angle, and with the volumetric moisture equal to 10% and 30%, thus allowing all roughness conditions and Cand X-band simulations to be combined.

A least squares approach was then used to establish an empirical relationship between k.Zgand the backscattered signals, taking the form:

244 
$$\sigma^0 = \alpha + \beta \left( 1 - e^{-\mu \, k \, Zg} \right) \tag{14}$$

245 where  $\sigma^0$  is expressed in dB, k in cm<sup>-1</sup>, and Zg in cm.

The backscattered signals can be seen to be strongly correlated with *k.Zg*. Table 2 lists the coefficients  $\alpha$ ,  $\beta$  and  $\mu$ , together with  $R^2$  and the RMS error, for different moisture conditions (*Mv*=10%, 20% and 30%), two incidence angles, 20° and 40°, and for the *HH* and *VV* polarisations. All of these configurations are characterised by a strong correlation between *k.Zg* and the radar simulations (greater than 0.77).

#### 251 **4. Experimental analysis**

In this study, we use data acquired over agricultural watersheds, during the course of three 252 253 experimental campaigns (Orgeval'94, Pays de Caux'94, Villamblain'2003) (Fig. 6). For each of these campaigns, radar data (SIRC, ERASME, ASAR/ENVISAT) was acquired with 254 different configurations (Table 3). Simultaneously to the radar acquisitions, ground 255 measurements were carried out in a large number of test fields: the soil moisture was 256 measured within the top 5 cm soil using a gravimetric method and/or a TDR probe, and 257 roughness measurements were made using a pin-profiler (total length equal to 2 m, resolution 258 equal to 10 mm). 259

260 *4.1 Description of the database* 

**261** • *Orgeval'94* 

The Orgeval watershed is located to the East of Paris (France). An experimental campaign was conducted during the SIRC/XSAR mission in April 1994 (Zribi et al., 1997). The soil texture is relatively constant over the whole basin: clay 17%, silt 78%, sand 5%. Ground measurements (roughness and moisture) were made in 5 fields.

**266** • *Pays de Caux '94* 

This test site corresponds to the Blosseville watershed, located in the Pays de Caux in Northern France (49°47' N; 0°50' W). The loamy soils of the northern European loess belt are sensitive mainly to soil structure degradation, and are commonly exposed to erosion caused by concentrated runoff. The site's soil is characterized by a very homogenous loamy texture (13% clay, 65% loam, and 22.5% sand). ERASME FM-CW scatterometer airborne measurements were recorded in 1994, over 10 large test fields.

**273** • *Villamblain'2003* 

This site is located approximately 80 km west of Paris (48°10'N; 01°48'E), and is characterized by large agricultural fields, which are mainly bare soil fields with a homogenous soil composed of approximately 60% loam, 30% clay and 10% sand. Simultaneously to the radar measurements acquired by the ASAR-ENVISAT radar in 2003, ground measurements were made over a large number of bare soil test fields.

279 • Soil moisture measurements

The mean volumetric moisture (Mv) was estimated for each test field, within the top 5 cm, and using a gravimetric method. As a result of relatively rainy winters, this parameter remained high and nearly constant (approximately 0.3 cm<sup>3</sup>/cm<sup>3</sup>), at all three sites.

**283** • Soil roughness measurements

Roughness measurements were made using a pin profiler (with a total length of 2 m and a resolution of 1 cm). Ten surface profiles were taken for each test field, in order to ensure that roughness parameters were determined with sufficient statistical accuracy. For each profile, we computed the correlation function (Ogilvy, 1991), as well as the two statistical parameters, the rms height (*s*) and the correlation length (*l*). The parameter  $\alpha$ , corresponding to the shape of the correlation function, is computed for the first scales up to the correlation length from experimental functions, using a least squares optimisation approach. Fig. 7-a plots the parameter  $\alpha$ , corresponding to the correlation function shapes retrieved for all test fields, as a function of the *rms* soil height, showing a moderate degree of correlation. In general, the value of  $\alpha$  is found to be close to 1 for smooth soils, and higher for ploughed soils. This type of relationship was also observed by (Zribi et al., 2005). The measured values of Zg (Fig.7-b) ranged between 0.01 and 0.03 for smooth soils. In the case of cloddy soils, Zg ranged between approximately 0.04 and 0.2, and for ploughed soils it ranged between 0.2 and 0.62 (Zribi et al., 2005).

#### 298 4.2 Comparing backscattering simulations with radar signal data

In Figs. 8-a and 8-b, the results derived from the moment method simulations made in two 299 300 dimensions are compared with real radar data, for the HH and VV polarizations, respectively. Two-dimensional (rather than three-dimensional) simulations were used, since the analysed 301 302 experimental fields had very little directional structure. For each individual test field, ground measurements (*rms* height, correlation length,  $\alpha$  parameter, soil moisture) were used as input 303 for the radar backscattering simulations. Fig. 8-a shows the HH polarization data obtained 304 from several different configurations: C and X bands, and five different incidence angles: 20°, 305 25°, 30°, 35° and 44°, whereas Fig. 8-b shows VV polarization results for the same set of 306 307 configurations. In the HH polarization, the simulations can be seen to deviate from the radar 308 measurements, with an RMSE equal to 3.34 dB. In the VV polarization, a good agreement can be observed, with an RMSE equal to 1.62 dB. These results illustrate some of the limitations 309 310 encountered, particularly in the HH polarization, when the MM model is used to simulate all surface conditions. This is probably due to the greater sensitivity of HH polarization to soil 311 roughness (Fung, 1994, Zribi et al., 1997). In the following section, it is proposed to use 312 empirical relationships to express the backscattered radar signals as a function of the surface 313 314 parameters.

315 *4.3 Analysis of the relationship between roughness and radar data* 

All of the ground data analysed in the present study was acquired under very similar soil moisture conditions (close to 30%). Fig. 9 shows the radar signals measured over the test fields, as a function of kZg, for various configurations (both polarizations and several incidence angles). As in the case of the simulations described in section 3, the radar signals are characterized by a high dynamic range at small values of kZg, and near saturation can be observed when kZg reaches approximately 0.3-0.35.

Figs. 9a, 9b, 9c, 9d, 9e, and 9f correspond to observations made at the Pays de Caux site, using the ERASME airborne FM-CW scatterometer. This data was acquired in the *HH* and *VV* polarizations, in the C-and X-bands at 20°, 25°, 30° and 35° incidence. In both polarizations, the roughness parameter kZg and the radar measurements are strongly correlated.

Fig. 9g corresponds to data acquired by SIR-C and ASAR-ENVISAT over the Orgeval and Villamblain sites, at *HH* polarization in the C band and an incidence of approximately 44°. These radar measurements are also found to be strongly correlated with kZg. Empirical relationships can be used to express the backscattered radar signals as a function of k.Zg, for various multi-incidence and polarization configurations. These are written:

332 
$$\sigma_{p\theta}^{0} = \alpha_{p\theta} + \beta_{p\theta} \left( 1 - e^{-\mu_{p\theta} k Z_g} \right)$$
(15)

where the coefficients  $\alpha_{p\theta}$ ,  $\beta_{p\theta}$  and  $\mu_{p\theta}$  are adjusted using a least squares optimisation, *p* is the polarization and  $\theta$  is the incidence angle. Table 2 lists the values of  $\alpha_{p\theta}$ ,  $\beta_{p\theta}$  and  $\mu_{p\theta}$ , together with the statistical parameters  $R^2$  and RMSE, for the nine configurations analysed in this study.

Table 5 indicates the general improvement found in the statistical parameters ( $R^2$  and RMSE) when *k.Zg* is used, rather than *k.Zs*, in the same empirical model. Only the last configuration (*HH* polarization at 44°) leads to better results with the parameter *k.Zs*. From the empirical relationships established for the nine radar configurations, a general empirical model is proposed, in which the radar signal is expressed as a function of kZg,  $\theta$  and the radar polarisation:

343 
$$\sigma_p^0 = \left(a_p \ \theta + b_p\right) + \left(c_p \theta + d_p\right) \times \left(1 - e^{\left(e_p \ \theta^2 + f_p \ \theta + g_p\right)k \ Zg}\right)$$
(16)

This model is found to be valid when  $\theta$  lies between 20° and 44°.

The values of the parameters used in Eq. 16 are listed, for the *HH* and *VV* polarizations, in Table 6.

In Fig. 10, the radar signal levels predicted by the model are compared with the measured data, over the full range of experimental incidence angles. The modelled and measured signals are found to be strongly correlated, with  $R^2$  equal to 0.79 and 0.88 and the *RMSE* equal to 1.42 dB and 1.19 dB, in the *HH* and *VV* polarizations, respectively.

#### 351 **5. Conclusion**

It is very difficult to separately estimate the influences of rms height (s), correlation length (l) and correlation function shape, on the backscattering behaviour of a rough soil surface. In practice, the availability of only a limited number of radar configurations can make it impossible to retrieve all of these parameters with soil moisture.

In the present study, a new approach is proposed for the description of surface roughness and its influence on the backscattering behaviour of radar signals. The resulting expressions make use of a numerical backscattering algorithm based on the moment method, applied to synthetically generated surfaces and assuming a correlation function described by

360  $\rho(x) = \exp\left(-\left(\frac{x}{l}\right)^{\alpha}\right)$ . The correlation between the simulated and measured rms soil heights is

weak, as a consequence of influences related to the correlation length of the surface roughnessand the shape of the correlation function. These influences must be accounted for, in order to

retrieve accurate surface roughness or moisture estimations. The parameter Zs, which allows 363 364 the influence of soil surface height and slope to be taken into account, can be used to improve the correlation strength. Nevertheless, the simulated radar signals are still affected by strong 365 fluctuations, resulting from variations in the shape of the correlation function. By introducing 366 a new roughness parameter (Zg), written in the form  $Z_g = s \left( \frac{s}{l} \right)^{\alpha}$ , the influence of the *rms* 367 surface height, the slope of the soil surface, and a third parameter  $\alpha$  related to the shape of the 368 correlation function, can be taken into account. A very good correlation is then observed 369 between k.Zg and the simulated radar signals in the C and X bands, with  $R^2$  equal to 0.93 and 370 0.9 at 40° incidence for the HH and VV polarizations, respectively. Empirical functions are 371 proposed to describe these relationships. The usefulness of this new parameter is 372 373 demonstrated through the analysis of radar signal data acquired at three experimental sites in 374 France (Orgeval, Pays de Caux and Villamblain). In the case of smooth soils, Zg is found to range between 0.01 and 0.03. In the case of cloddy soils, Zg lies between approximately 0.04 375 and 0.45, and in the case of ploughed soils, it ranges between 0.2 and 0.62. A high correlation 376  $(R^2>0.7 \text{ and } RMSE<1.54 \text{ dB})$  is observed between kZg and the experimental radar signals 377 acquired in the C and X bands, at incidence angles ranging between 20° and 44°. An 378 379 empirical model is proposed for the relationship observed between the measured radar signals and kZg,  $\theta$ , and the polarization parameters. This is found to be in excellent agreement with 380 the radar measurements, with the RMSE equal to 1.42 dB and 1.19 dB in the HH and VV 381 polarizations, respectively. These results are particularly useful for the improvement of 382 empirical or semi-empirical inversion models used in soil moisture estimations. In the past, 383 these models were often based on the rms height roughness parameter only, leading to a high 384 level of noise and a lower accuracy in the soil moisture estimation, resulting from the 385 influence of the correlation length and shape of the correlation function. 386
