Abstract. Here we develop from a first work the effect of missing data in hierarchical classification of variables according to the following factors: amount of missing data, imputation techniques, similarity coefficient, and aggregation criterion. We have used two methods of imputation, a regression method using an OLS method and an EM algorithm. For the similarity matrices we have used the basic affinity coefficient and the Pearson's correlation coefficient. As aggregation criteria we apply average linkage, single linkage and complete linkage methods. To compare the structure of the hierarchical classifications the Spearman's coefficient between the associated ultrametrics has been used. We present here simulation experiments in five multivariate normal cases.

1 Introduction

The missing data problem has been dealt in a large number of papers and books where several methods to minimise missing data effect have been developed (Rubin(1974), Little and Rubin(1987), Dempster, Laird and Rubin(1977), Orchard and Woodbury(1972), Beale and Little(1975) among others).

When one wants to classify variables, for instance in marketing analysis and social sciences, one frequently finds missing data. We are interested in analysing the effect of missing data in some particular (originally complete) hierarchical classification structures of variables, as well the results of imputation methods in those cases. In the present work we consider hierarchical clustering models based on two similarity coefficients - basic affinity, (Bacelar-Nicolau(1981,1988,2000), Matusita(1955), Nicolau(1998) among others) and Pearson's correlation - and three classical aggregation criteria. We use two types of imputation methods in simulation studies with different percentage

of missing data at random. The data are issued from multinormal populations (Saporta(1990)).

2 Hierarchical cluster analysis

In this work we are interested in the classification of variables. We use the following hierarchical aggregation criteria:
Average linkage (AL): $C(A,B) = \frac{1}{(\#A)\times(\#B)} \sum c(X_j, X_{j'})$, $X_j \in A, X_{j'} \in B$
Single linkage (SL): $C(A,B) = max\{\, c(X_j, X_{j'}) \;, X_j \in A, X_{j'} \in B \,\}$ and
Complete linkage (CL): $C(A,B) = min\{\; c(X_j, X_{j'}) \;, X_j \in A, X_{j'} \in B \quad \}$
where A and B represent two clusters and c is a similarity coefficient between two variables ($X_j, X_{j'}$are $(n \times 1)$ variables) which can be one of the two following:

The (unweighted) basic affinity coefficient $\sum_{i=1}^{n} \sqrt{\frac{x_{ij}}{x_{.j}} \frac{x_{ij'}}{x_{.j'}}}$, where $x_{.j} = \sum_{i=1}^{n} x_{ij}$ and $x_{.j'} = \sum_{i=1}^{n} x_{ij'}$, as defined in Bacelar-Nicolau(2000).
The Bravais-Pearson correlation coefficient $c_p = \frac{\sum_{i=1}^{n} \left(x_{ij} - \overline{x}^{j}\right)\left(x_{ij'} - \overline{x}^{j'}\right)}{s_{x^j}\, s_{x^{j'}}}$
and C is the respective extension to the clusters. In order to compare hierarchical classification models, we will use the Spearman's coefficient-c_s-between the ultrametric matrices, based on pairs of observations with the usual correction for ties.

3 The missing data - MAR

The data are said that missing at random if its missingness does not depend of the values assumed on the variables having missing values, but depends on the values observed in other completely observed variables. The expression of the general notion of MAR can be then written as: $Prob(R|X_{obs}, X_{miss}) = Prob(R|X_{obs})$, were X_{obs} represents the observed values of $X_{n\times p}, X_{miss}$ the missing values of$X_{n\times p}$ and $R = [R_{ij}]$ is a missing data indicator,

$$R_{ij} = \begin{cases} 1, \text{ if } x_{ij} \text{ observed} \\ 0, \text{ if } x_{ij} \text{ missing} \end{cases}$$

4 The imputation methods

An ordinary least square regression method (OLS) is used: is defined as usually, β_1, β_2 are estimated over the observed values of the dependent variable,$X_{obs} = \beta_1 + \beta_2 X'_{obs}$($X'_{obs}$ is a "sample"of X corresponding to the observed values of X - X_{obs}) and then the missing values of X (X_{miss}) are imputed by the regression on X'_{miss}(those are observed values coresponding to the missing dependent values of under the estimated model $X_{miss} = \beta_1 + \beta_2 X'_{miss}$.
An EM algorithm has been used as follows:
At the E step of the algorithm (at the tth iteration),

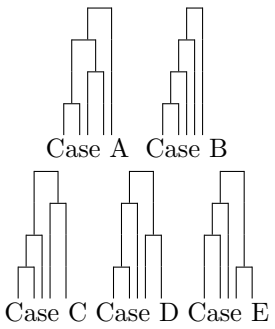
$x_{ij}^t = \begin{cases} x_{ij}\ , & \text{if } x_{ij} \text{ is observed} \\ \hat{x_{ij}}, & \text{if } x_{ij} \text{ is missing} \end{cases}$

"The E step imputes the best linear predictors of the missing values, using current estimates bof the parameters available so taht a suitable choice can be made. It also calculates the adjustments c_{jk} to the estimated covariance matrix needed to allow for imputation of missing values" Little and Rubin(1987) At the M step
$\mu^{(t+1)} = \left[n^{-1} \sum_{i=1}^{n} x_{ij}\right]$,
$\sigma_{jk}^{(t+1)} = (n-1)^{-1} E\left(\sum_{i=1}^{n} x_{ij} x_{ik} | X_{obs}\right) - \mu_j^{t+1} \mu_k^{t+1}, j, k = 1, ...p$. We consider missing values over a dependent variable.

5 Numerical Experiments

In order to study the performance of the affinity and the Pearson's correlation coefficients as measures of similarity between variables, in hierarchical classification and in presence of missing data, we use here the three classical hierarchical clustering methods AL, SL and CL: in the cases of complete data; in MAR case - 10%, 15% and 20% (over the total of the data - each 1000×5 matrices); and when the missing data are filled-in using the two imputation methods as mentioned in **4.**.

One hundred samples have been generated of each type of simulated data set, from five normal multivariate populations: Cases A, B, C, D and E, such as: $X_i \tilde{} N(\mu_i, \Sigma_i), i = 1, ..., 5$,and are 1000×5 matrices($\mu_1 = \mu_2 = \mu_3 = \mu_4 = \mu_5$).
The values of the variance-covariance matrices have been chosen with the aim of obtaining specific hierarchical structures:



(order of variables:X_1, X_2, X_3, X_4, X_5)

Note that cases C, D and E, have the same topology but they have different agreggation levels. In order to have missing data at random MAR we

have deleted (10%, 15% and 20%) values at random from variables X_1 and X_2.

In the following we present the results of the simulations, respectively in all the cases, by increasing order of the percentages of missing data (MD), according to the similarity coefficients, the agglomerative methods and the imputation methods. In each case we compare the ultrametrics associated to the originally complete data with the ultrametric matrices associated to the incomplete and the reconstructed data respectively(imputed data - ID).
The comparison between ultrametrics is obtained using a 5% Spearman's bilateral test (the critical value is $c'_s = 0,684$, see for instance Saporta (1990)).
In presence of MD, the classification is obtained by a listwise method i.e. we have only considered for the analysis the complete rows (by eliminating the rows with MD). In analysis of cases A,B,C,D and E,$c_s = 1$,$|c_s| > c'_s$,$|c_s| < c'_s$ mean that:
$c_s = 1$ the general "structure" of the two hierarchical classifications being compared is the same, that is the two associated ultrametrics are "ordinal equivalent" (each pair of ranked trees give the same "ordinal" structure).
$|c_s| > c'_s$the two hierarchical classification structures are not the same, but the two ultrametrics are "significantly correlated" (at 5%).
$|c_s| < c'_s$the two hierarchical classification structures are "significantly different"
The percentages of cases and $c_s = 1$,$|c_s| > c'_s$ and $|c_s| < c'_s$ are also indicated in each cell of the tables.

All the simulated complete data reproduced the same general hierarchical structure using both coefficients - Affinity and Pearson's correlation - and the three hierarchical methods, AL, SL and CL.

Table 5. results after using OLS method -Case B

Better results are obtained in presence of MD, than after the application of both imputation methods.

When using the imputation methods in case C both imputation methods gave the same results, and also that the affinity coefficient performs better than the Pearson's coefficient. In cases A, D and E the results are different when using the two imputation methods, some times the least squares method performs better, others, is with the EM algorithm that we obtain better performance. We have obtained similar results in a study with Personality development data, in presence of seven variables(Silva et al.(2001))
