We have calculated accurate quantum reactive and elastic cross sections for the prototypical barrierless reaction  $D^+ + H_2(v = 0, j = 0)$  using a modified hyperspherical scattering method. The considered kinetic energy ranges from the ultracold to the Langevin regimes. A reaction rate coefficient practically constant in no less than eight orders of magnitude is obtained. The availability of accurate results for this system allows one to test the quantum theory by Jachymski et al. [K. Jachymski, M. Krych, P. S. Julienne, and Z. Idziaszek, Phys. Rev. Lett. 110, 213202 (2013)] in a nonuniversal case. The short-range reaction probability is rationalized using statistical model assumptions and related to a statistical factor. This provides a means to estimate one of the parameters that characterizes ultracold processes from first principles.

DOI: 10.1103/PhysRevA.00.000700 PACS number(s): 34.10.+x, 34.50.Lf

The increasing availability of cold and ultracold samples of atoms and molecules has sprung great interest in chemical reactions at very low temperatures [1–5]. Although new experimental approaches [5] appear highly promising, advances in the field are hampered by technical problems in producing most molecules at low temperatures and high enough densities. In contrast to neutral species, ions can be easily trapped and cooled. The technology of Coulomb crystals in radiofrequency ion traps [6] and the possibility of combining them with traps for neutrals or with slow molecular beams [7,8] promise great progress in the analysis of ion-neutral reactions in the near future.

Theoretical simulations employing standard ab initio approaches are not feasible for most of the systems thus far considered. For heavy systems (more convenient experimentally) there are no potential energy surfaces (PESs) accurate enough to describe processes near thresholds. Additionally, most of exact dynamical treatments face insurmountable problems in such regimes. However, in contrast to short-range (SR) chemical interactions, those occurring at long range (LR) can be more easily calculated. Moreover, theoretical approaches based only on the knowledge of the LR part of the PES have been able to describe recent experimental findings nearly quantitatively [1,9]. Indeed, processes at very low collision energies favor LR interactions, leading to the idea of *universality* in extreme cases [10]: the result of the collision depends exclusively on the LR behavior and not on the details of the PES. In this regard, recently proposed LR parametrization procedures [9,11–13] are very appealing.

Fitting experimental data, these models are able to predict 51 nonmeasured values providing some insight into the under- 52 lying interactions. In particular, the approach by Jachymski 53 et al., based on multichannel quantum-defect theory (MQDT), 54 provides analytical expressions which can be easily compared 55 with experimental data [9,14,15]. The model has been recently 56 applied to a variety of systems [9,16,17]. In particular, for the 57 Penning ionization of Ar by He(<sup>3</sup>S) [5], the rate coefficients 58 have been fitted in a wide range of collision energies using only 59 two parameters [9]. However, the parameters of the model are 60 phenomenological and they had not been determined before 61 from first principles.

In this work, we present accurate calculations for the reac- 63 tive collision D<sup>+</sup> + H<sub>2</sub>(v = 0, j = 0) using the hyperspherical 64 reactive scattering method [18]. We consider collision energies 65 that range from the ultracold regime, where only one partial 66 wave is open, to the Langevin regime where many of them 67 contribute. These calculations allow us to test the model 68 by Jachymsky et al. [9,14] by comparison with accurate 69 theoretical results in a realistic atom + diatom system, 70 providing a way to estimate one of the parameters using simple 71 statistical model assumptions, which do not require performing 72 any quantum reactive scattering calculation.

The  $H^+ + H_2$  system is the prototype of ion-molecule 74 reactions, which are usually nearly barrierless and exhibit large 75 cross sections due to their LR,  $\propto -C_n/R^n$ , n=4, potentials. 76 At energies below  $\approx 1.7$  eV, the proton exchange is the only reactive channel, and the process can be described on the 78 ground adiabatic PES [19–22]. Since the PES is characterized 79 by a deep well or complex (≈4.5 eV), as illustrated in 80 Fig. 1, rigorous statistical models [23,24] have been applied 81 to this reaction and isotopic variants in the low and thermal 82 energy regimes [20,24-27] in good agreement with accurate 83

LARA, JAMBRINA, LAUNAY, AND AOIZ

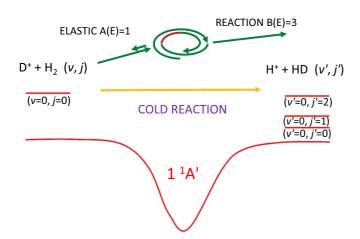

FIG. 1. (Color online) Sketch of the intrinsic reaction path and the rovibrational states involved in the reaction at the studied energies. A(E) and B(E) are the number of incoming and outgoing channels, respectively (1 and 3 for J = 0).

calculations. Specifically, the  $D^+ + H_2 \rightarrow H^+ + HD$  reaction features a small exoergicity (difference of zero-point energies). Experiments to determine state-specific rate coefficients at energies as low as 12 K [28] have been carried out, and lower temperatures are expected to be feasible soon [29].

The deep ultracold regime, governed by Wigner laws [30], is described in terms of the scattering length. The latter largely varies with slight changes of the interaction potential. Due to inaccuracies in the state-of-the-art electronic calculations, only for very particular atom + atom systems [31–33] has it been possible to reproduce the experimental scattering length theoretically. As atom + diatom systems are even more complicated, it is difficult to assess the accuracy of calculations for ultracold energies. In the spirit of the work by Gribakin et al. [34], we can consider our study as an effort to determine a "characteristic" scattering length. Besides, assuming that the interaction of the system is reasonably described by the current PES, we can use our results to test recent methodologies, like the approach in Refs. [9,14].

In the (ultra)cold regime both accurate descriptions of the LR interactions and dynamical propagations up to very large distances are two strict requirements. The PES by Velilla et al. [35], which includes the LR interactions in the functional form, satisfies the first requirement. The dominant contributions involve the charge quadrupole,  $\propto -R^{-3}$ , and the charge-induced dipole,  $\propto -R^{-4}$ , interactions. However, only the latter contributes to collisions in j = 0.1 The second requirement is fully satisfied by the hyperspherical quantum reactive scattering method developed by Launay et al. [18,36], recently modified to allow the inclusion of LR interactions [37,38]. These modifications are used here for the first time allowing the propagations up to  $10^5-10^6$  a.u. which are required for a n = 4 potential.

The reaction cross section,  $\sigma_{\rm r}(E)$ , in the  $10^{-7}$ –150 K energy range is plotted in Fig. 2 and compared with the Langevin

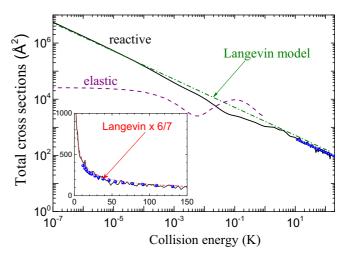

FIG. 2. (Color online) Calculated reaction and elastic total cross section for the collision  $D^+ + H_2 (v = 0, j = 0)$  compared with the Langevin prediction. The inset shows the comparison of the reaction cross sections with the experimental data [28] and the result of the statistically corrected Langevin model.

model (LM) expression for the cross section,  $\sigma_L(E) = 119$  $2\pi (C_4/E)^{1/2}$ . The LM is commonly used to rationalize 120 collisions in the regime where many partial waves are open. We 121 have determined the value  $C_4 = 2.71$  a.u. using the effective 122 potential as a function of R which results from averaging 123 the PES  $V(R,r,\theta)$  over r and  $\theta$  Jacobi coordinates, with the (v = 0, j = 0) probability distribution. The LM implies here that once the centrifugal barrier is overcome, the system is 126 captured in the complex which subsequently decomposes into 127 the  $\mathrm{H^{+}}$  + HD arrangement channel with unit probability. The 128 LM regime can be associated with the high energy part of the 129 plot (above 1 K, with five partial waves opened). The calculated 130 cross sections are found smaller than the LM prediction in 131 this energy range. Indeed, only a fraction of the complexes 132 decompose into the products.

We can improve the LM using statistical model arguments, 134 which are being revisited in the field of cold collisions [39,40]. 135 In complex mediated reactions, the statistical ansatz [23,24],  $P_r^J(E) \approx P_{\text{capt}}^J(E) \times P_{\rightarrow \text{prod}}(E)$ , can be applied, where  $P_r^J(E)$  137 is the reaction probability for a given initial rovibrational state 138 and total angular momentum, J (orbital, l, plus rotational, 139 j),  $P_{\text{capt}}^{J}(E)$  is the probability for the reagents to be captured 140 in the complex, and  $P_{\rightarrow prod}(E)$  is the *statistical factor*, i.e., 141 the probability of emerging into the product arrangement 142 channel when the complex decomposes. If there is a complete 143 randomization of the energy in the complex, the statistical 144 factor will be independent of the initial state of the reagents, only subject to conservation of energy, J, and parity. Roughly speaking, the fraction of complexes which decompose into the reactants or products is proportional to the respective 148 number of scattering channels energetically available, denoted with A(E) and B(E), respectively, considering all of them 150 as equiprobable. Accordingly, the statistical factor can be approximated by  $P_{\rightarrow \text{prod}}(E) = B(E)/[A(E) + B(E)]$ . At the considered energies, only three HD rovibrational states are 153 open, as shown in Fig. 1, and for  $J \ge 2$  we find that A(E) = 1and B(E)=6, and  $P_{\rightarrow \text{prod}}=6/7(\approx 86\%)$ . For J=0 and 155 J=1 the statistical factors are 3/4 (75%) and 5/6 ( $\approx$ 83%), 156

<sup>&</sup>lt;sup>1</sup>The integral  $\langle j = 0 | P_2 | j = 0 \rangle$  is null, and the contributions from  $\sim R^{-3}$  and anisotropic polarization terms vanish [35].

BEYOND UNIVERSALITY: PARAMETRIZING ULTRACOLD ...

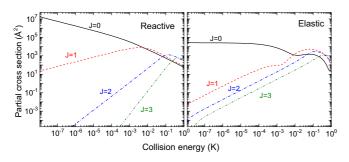

FIG. 3. (Color online) Reaction and elastic partial cross sections at the indicated J(=l) values for the  $D^+ + H_2$  (v = 0, j = 0)collision in the cold and ultracold regimes.

respectively. If the collision energy is high enough for many partial waves to contribute but low enough for the total number of channels to stay the same,  $P_{\rightarrow \text{prod}}(E) \approx 6/7$ , and

$$\sigma_{\rm r}(E) \approx P_{\rightarrow {\rm prod}} \, \sigma_{\rm L}(E).$$
 (1)

Therefore, 6/7 appears naturally as a statistical factor to correct the LM expression. When the number of product channels is large enough,  $B \gg A$ , then  $P_{\rightarrow \text{prod}} \approx 1$  and the result is  $\sigma_L(E)$ . More accurate statistical implementations, which evaluate A(E) and B(E) as capture probabilities [23,24], lead to similar conclusions.

The inset of Fig. 2 compares the calculated reaction cross section with the experimental data from Ref. [28]. The corrected LM result is also shown and found to be in very good agreement with both the experiment and the present calculations. The similarity of the theoretical results with the experiment is remarkable considering that the latter was performed with  $n-H_2$  [21] and lends credence to the predictive power of QM calculations on state-of-the-art PESs for atom + diatom systems ab initio in the Langevin regime.

The cross sections at much lower kinetic energies are also shown in Fig. 2. In the zero-energy limit, Wigner threshold laws [30,41] state that the elastic and the total-loss (inelastic + reaction) cross sections associated with each partial wave, l, vary  $\sim E^{2l}$  and  $\sim E^{l-1/2}$ , respectively. However, for a potential with n = 4, the threshold law for elastic scattering becomes  $\sim E$  for any l > 0 [30,41,42]. The ultracold cross sections, shown in Fig. 3 for the four lowest partial waves, comply with these laws (there are no open inelastic channels). The limiting behaviors for l = 0 are reflected in the total reaction ( $\sim E^{-1/2}$ ) and total elastic (constant) cross sections in the lowest energy region of Fig. 2, where only the s wave is open.

For n = 4 the energy dependence of the LM coincides with the Wigner threshold law ( $\sim E^{-1/2}$ ). Remarkably, the absolute values of accurate and LM cross sections in the ultracold limit are nearly the same,  $\sigma_{\rm r} \approx 1.07 \sigma_{\rm L}(E)$ . Therefore, the reaction rate coefficient (not shown) is practically constant in no less than eight orders of magnitude, and small variations can be further smoothed out with the Boltzmann averaging. In what follows, we will try to rationalize this classical Langevin behavior in the ultracold regime.

Very recently, quantal versions of the LM have been proposed [14,43] under the assumption that all the flux that reaches the SR region leads to reaction. In the n = 4 case, these

universal models conclude that the zero-energy limit of  $\sigma_r$  is 200 given by  $2\sigma_L(E)$ , and not by  $\sigma_L(E)$  as we have approximately 201 obtained. Therefore our system is not universal. The formalism 202 in Ref. [9] is able to deal with systems where the short-range 203 reaction probability, Pre, is <1. It provides expressions for 204 the complex (energy-dependent) scattering length  $\tilde{a}_l(k) = 205$  $\alpha_l(k) - i\beta_l(k)$  in terms of the MODT functions (where k is 206 the relative wave number). This allows us to parametrize 207  $\tilde{a}_l(k)$  using two real parameters, y and s, together with 208 the mean scattering length [34],  $\bar{a}=(2\mu C_4)^{1/2}/\hbar$  ( $\approx$ 99.7 a<sub>0</sub> 209 in this case). Specifically, the dimensionless parameter  $0 \leqslant 210$  $y \le 1$  characterizes the flux that is lost from the incoming 211 channel at SR, according to  $P^{re} = 4y/(1+y)^2$ . The Langevin 212 assumption or *universal case* corresponds to y = 1. The 213 dimensionless scattering length  $s = \tan(\phi)$  is related to an 214 entrance channel phase  $\phi$  [9,14,42].

In terms of these parameters, the small k behavior of the 216 real and imaginary parts of the complex scattering length for 217 the lowest partial waves (l = 0-3) is given by<sup>2</sup>

$$\alpha_0(k) \to \bar{a} \frac{s(1-y^2)}{1+s^2y^2}, \quad \beta_0(k) \to \frac{y(1+s^2)\bar{a}}{1+s^2y^2},$$
 (2)

$$\alpha_1(k) \to -k\bar{a}^2 \frac{\pi}{15}, \quad \beta_1(k) \to \frac{y(1+s^2)k^2\bar{a}^3}{9(s^2+y^2)},$$
 (3)

$$\alpha_2(k) \to -k\bar{a}^2 \frac{\pi}{105}, \quad \beta_2(k) \to \frac{y(1+s^2)k^4\bar{a}^5}{2025(1+s^2v^2)},$$
 (4)

$$\alpha_3(k) \to -k\bar{a}^2 \frac{\pi}{315}, \quad \beta_3(k) \to \frac{y(1+s^2)k^6\bar{a}^7}{2480625(s^2+y^2)}.$$
 (5)

Our calculations yield the S matrix as a function of the 219 energy for each total angular momentum J and hence l (for 220 j=0), which allows us to calculate directly  $\tilde{a}_l(k)$  using the 221 elastic element of the S matrix [44].

Figure 4 depicts the energy dependence of  $\alpha$  and  $\beta$  for 223 J = 0–3. The limiting behaviors are in perfect agreement with 224 the threshold laws and the power of the dependence on k in 225 Eqs. (2)–(5).

To extract the model parameters s and y from the scattering 227 results, let us consider first the case l=0. Using the values 228  $\alpha_0$  and  $\beta_0$  at the lowest energy given by our calculations 229 and solving Eqs. (2) for y and s, we obtain y(l = 0) = 0.35 230 and s(l = 0) = -0.82, which leads to  $P^{re}(l = 0) = 77\%$ . The 231 parametrization for higher values of l is not straightforward. 232 The real part,  $\alpha_l(k)$ , is independent on s(l) and y(l), and with 233 the sole expression of  $\beta_l(k)$  it is not possible to solve for the 234 values of the two parameters.

Analogous to the procedure of Ref. [9], assuming that y 236 and s do not depend on l, we can introduce y(l = 0) and 237 s(l=0) in Eqs. (3)–(5) and compare the resulting values of  $\beta_l$  238 with those obtained in the scattering calculations. The ratios of 239 the calculated and parametrized values of  $\beta_l$  are 0.4, 1.4, and 240 0.7 for l = 1, l = 2, and l = 3, respectively. The agreement 241 can be considered good on average, taken into account the 242

<sup>&</sup>lt;sup>2</sup>Equations (2) and (3) were kindly provided by the authors of Ref. [9]; Eqs. (4) and (5) were deduced by the authors of this work following Refs. [9,42].

LARA, JAMBRINA, LAUNAY, AND AOIZ

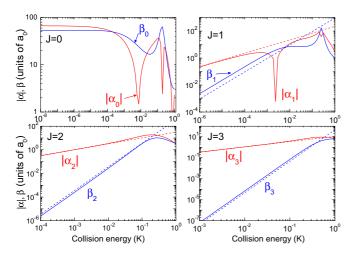

FIG. 4. (Color online) Real and imaginary parts of the scattering length,  $\tilde{a}_l(k) = \alpha_l(k) - i\beta_l(k)$ , obtained in the calculations for the four lowest partial waves. The absolute value of  $\alpha$ , mostly negative, is plotted. The values for J = 1, 2, and 3 (in continuous lines) are compared with the predictions from the model in Ref. [9] (in dashed lines), calculated using Eqs. (3)–(5), assuming for s and y the same values that have been obtained for J = 0.

oscillations of this ratio about 1. As for the real parts  $\alpha_l$ , given by Eqs. (3)–(5), they can be directly compared with our scattering results. The agreement (within 1%) is very good, which can be deemed as a test of the theory and serves to ensure the convergence of the scattering calculations. These expressions depend only on  $\bar{a}$  (not on s or y) and they can be considered as really universal.

According to Ref. [9], when the dependence of  $P^{re}$  with the energy and l is weak, the expression

$$\sigma_{\rm r}(E) \approx P^{\rm re} \sigma_{\rm L}(E)$$
 (6)

is valid in the Langevin regime,  $P^{re}$  being the same value which governs the ultracold behavior. The fact that  $\sigma_r(E)/\sigma_L(E)$  has an average value of 0.78 in the range 1-150 K, very close to 254 the  $P^{\rm re}(l=0)=0.77$  obtained at ultracold energies, indicates 255 a weak dependence of  $P^{\text{re}}$  with l and energy and hence the 256 validity of the assumption of constant parameters made above. 257

Therefore, Eq. (1), obtained from the statistical hypothesis, 258 and Eq. (6), from Ref. [9], are both valid in the Langevin 259 regime. This leads to the equivalence of the fraction of captured 260 flux that reacts,  $P^{\text{re}}$ , and the fraction of formed complexes 261 which decompose to give the products,  $P_{
ightarrow prod}$ , and thus a 262 way to estimate the  $P^{\text{re}}$ . In fact, 6/7 ( $\approx 86\%$ ) is a rough 263 estimate of  $P^{\text{re}} = 77\%$ , and only requires counting states. A 264 more accurate estimate can be obtained using the ab initio 265 QM values of  $\sigma_r(E)$  in the Langevin region to calculate 266  $\sigma_{\rm r}(E)/\sigma_{\rm L}(E)$ . This second way to estimate  $P^{\rm re}$  does not require 267 the system to behave statistically and is more general. Finally, 268 the fact that our calculations are expected to be quantitative 269 in the Langevin regime leads to an interesting conclusion: we 270 have found a way to estimate  $P^{re}$ , and through it y, one of 271 the parameters which characterize the experimental ultracold 272 behavior, while working at much higher energies where 273 state-of-the-art ab initio reaction dynamics is quantitative and 274 require less demanding QM calculations.

In summary, accurate scattering calculations have allowed 276 us to test the quantum theory by Jachymsky et al. [9,14,15]. 277 On average, the same  $P^{re}$  describes the ultracold and the 278 Langevin regimes. We have found a link between  $P^{re}$  and the 279 statistical factor of the statistical approach to reactions [23]. 280 Apart from physical insight, our analysis provides ways to 281 estimate the parameter y, which characterizes the experimental 282 ultracold behavior, using ab initio reaction dynamics at much 283 higher energies, where such methodology is assumed to be 284 quantitative.

The authors are greatly indebted to K. Jachymski, A. 286 Simoni, and T. González-Lezana for fruitful discussions. The 287FQ Spanish Ministry of Economy and Competitiveness (Grants 288 CSD2009-00038, and CTQ2012-37404-C02) are gratefully 289 acknowledged. 290
