Abstract: Small pelagic fish represent an essential link between lower and upper trophic levels in marine pelagic ecosystems and often support important fisheries. In the Bay of Biscay in the north-east Atlantic, no obvious controlling factors have yet been described that explain observed fluctuations in European sardine *Sardina pilchardus* and European anchovy *Engraulis encrasicolus* stocks, in contrast to other systems. The aim of this study was therefore to investigate to which extent these fluctuations could be trophodynamically mediated. The trophic ecology of both fish species was characterised over three contrasting periods (spring 2010 and 2011 and autumn 2011) in the area, in relation to potential variation in the abundance and composition of the mesozooplankton resource. Stable isotope analyses of carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) were performed on potential mesozooplanktonic prey items and in the muscle of adult fish, as well as in the liver whenever available, and mixing models were applied. In both springs, the mesozooplankton resource was abundant but qualitatively different. During this period of the year, results based on muscle isotope values in particular showed that *S. pilchardus* and *E. encrasicolus* likely do not compete strongly for food. On the medium term, *E. encrasicolus* always presented a greater trophic plasticity than *S. pilchardus*, both in terms of feeding areas and in the size of the mesozooplanktonic prey consumed. In autumn, mesozooplankton abundances were lower, and it was likely that *S. pilchardus* and *E. encrasicolus* share food resources during this period. No clear links between the variation in the mesozooplanktonic resource and the trophic segregation maintained between adults of both fish species in spring could be made. Although a certain potential exists for trophodynamically mediated fluctuations of both species under specific abiotic conditions (i.e. due to the existing trophic segregation in spring in particular), the overall results suggest that fluctuations in abundance of both fish species are probably not directly linked to their trophic ecology in the Bay of Biscay, at least at the level of adult individuals.

Keywords: plankton-feeding fish; mesozooplankton; copepods; stable isotopes; trophic interactions; temperate ecosystem

1. Introduction

Forage fish such as sardines and anchovies have a key role in marine pelagic ecosystems, representing the main pathway by which energy and nutrients are transported from lower (i.e. plankton) to upper trophic levels (i.e. marine mammals, large fish and seabirds) (Cury et al. 2000). However, the stocks of these small pelagic fish can be highly variable over time (e.g. Schwartzlose et al. 1999). These fluctuations can lead to considerable changes in the structure and function of marine ecosystems and in turn impact fisheries (FAO 2012). Understanding the processes involved in the fluctuations of forage fish abundance therefore appears critical to maintain marine ecosystem services.

For many years, in several marine ecosystems and notably those subjected to upwelling events where sardines and anchovies cohabit (e.g. Benguela Current ecosystem on the South African coast or Humboldt Current ecosystem on the Peruvian coast), alternative abundance fluctuations in the populations of both species have been reported (e.g. Lluch-Belda et al. 1989; Barange et al. 2009). Several hypotheses have been proposed to explain these sardine-anchovy fluctuations. Some of these hypotheses rely on the effects of physical, atmospheric and oceanographic regime such as climatic oscillations that potentially control the survival and/or recruitment of one of the other species (e.g. Lluch-Belda et al. 1992; Chavez et al. 2003; Alheit et al. 2012). Takasuka et al. (2007) also proposed that both species display differential ‘optimal growth temperatures’, so that different climatic conditions can favour one species or the other during early life stages. This hypothesis extends the ‘optimal environmental window’ theory of Cury and Roy (1989), establishing the conditions for the recruitment success of pelagic fish in upwelling areas. Other hypotheses proposed for explaining sardine-anchovy alternations include biological controlling factors, such as intra-guild predation (e.g. Irigoien and De Roos 2011), or trophodynamically mediated fluctuations with the resource’s variability favouring one

species or the other (e.g. Van der Lingen et al. 2006). Some studies that have investigated the diet of both species simultaneously (e.g. Louw et al. 1998; Van der Lingen et al. 2006; Espinoza et al. 2009) have effectively demonstrated that sardines and anchovies (generally adult individuals) show distinct feeding strategies, especially in terms of the size of copepod they preferentially consume. Hence, warmer or cooler oceanographic regimes would favour the development of small or larger planktonic prey species, and thus one or other small pelagic predator. Simply determining the effects of abiotic factors influencing both the recruitment and survival of early life stages is thus not sufficient to understand fluctuations in the abundance of small pelagic fish. The knowledge of trophic interactions between species as well as fluctuations in food resource and their impact on trophic interactions also appears a crucial step.

Stable isotope analysis (SIA) of carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$) of the tissues of consumers and their putative prey has proven to be a powerful tool to describe the trophic ecology of marine organisms, representing an alternative or complementary tool to the traditional methods of dietary studies such as the analysis of stomach contents (Michener and Kaufman 2007). Primary producers of an ecosystem generally display different isotopic compositions (Peterson and Fry 1987; France 1995), and the enrichment in ^{13}C and ^{15}N between a source and its consumer (also called trophic enrichment factor, TEF) is relatively predictable. This enrichment is less important in ^{13}C (≤ 1 ‰) than in ^{15}N (3.4 ‰ on average) (De Niro and Epstein 1978, 1981; Post 2002). Hence, $\delta^{13}\text{C}$ values are generally considered as a conservative tracer of the primary producer at the base of the food web supporting consumers, and consequently a tracer of their foraging habitat (France 1995; Hobson 1999). Alternatively, $\delta^{15}\text{N}$ values are generally used as a proxy of their trophic position (Vander Zanden et al. 1997; Post 2002). Furthermore, for some years, mixing models integrating $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of prey and predators have proved their utility to decipher the contribution of different prey items in the diet of a predator (Parnell et al. 2010, 2013; Phillips et al. 2014). This may be particularly

useful when studying the trophic links between plankton and small pelagic planktivorous fish (e.g. Costalago et al. 2012), because of the peculiar difficulty in observing direct interactions between these organisms in the open water environment, and because the small size of plankton can make stomach content analysis particularly difficult. Moreover, isotope values provide information on the food assimilated at a time scale that depends on the turnover of the tissue analysed (Tieszen et al. 1983; Hobson and Clark 1992; Sponheimer et al. 2006). For instance, carbon and nitrogen half-lives in fish tissues were shown to vary from 5–14 days in the liver to 19–21 days in the muscle of the juvenile Japanese bass *Lateolabrax japonicus* (Suzuki et al. 2005), from 3–9 days in the liver to 25–28 days in the muscle of the juvenile sand goby *Pomatoschistus minutus* (Guelinckx et al. 2007) and from 10–20 days in the liver to 49–107 days in the muscle of the flat fish *Paralichthys dentatus* (Buchheister and Latour 2010).

The Bay of Biscay is a very large bay located in the north-east Atlantic Ocean. It supports a rich fauna including many protected species, e.g. marine mammals, seabirds, sharks and rays, and is subjected to numerous anthropogenic activities including important fisheries (Lorance et al. 2009; OSPAR 2010). In particular, European sardine (*Sardina pilchardus*) and European anchovy (*Engraulis encrasicolus*) fisheries are of major importance in the area (ICES 2010a). No quota currently exists for sardine despite an observed decrease in their catches in this area (OSPAR 2010). Conversely, a decrease in anchovy stocks during the 2000s led to the closing of its fishery in 2005. The moratorium ended in 2010 and finally resulted in the establishment of quotas for this species (ICES 2010a, b). In the Bay of Biscay, strong fluctuations in the abundance of small pelagic fish such as sardines and anchovies have been observed for several years (ICES 2010a). However, in contrast to upwelling areas where alternative abundance fluctuations have been demonstrated and/or linked to climatic events or biological controlling factors (see above), no clear relationships between both fish species have yet been shown in the Bay of Biscay ecosystem. Sardine and anchovy have always

demonstrated both alternation and co-occurrence in spring-survey data (ICES 2010b), and no obvious controlling factors have been identified to-date explaining general fluctuations in the abundances of small pelagic fish in the area. Besides, an ecological network analysis of the Bay of Biscay continental food web provided evidence that bottom-up processes play a significant role in the population dynamics of upper trophic levels and in the global structuring of this marine ecosystem (Lassalle et al. 2011).

In a previous study in the area, Chouvelon et al. (2014) examined the trophic ecology of adults of the two fish species by SIA during a single specific period (spring 2010). The authors highlighted a trophic segregation between species during the study period. This may support the hypothesis that fluctuations of both fish species' abundances could be, at least in part, trophodynamically mediated, if the food environment on the medium to long term would tend to favour one species or the other, as a function of their respective dietary preferences (Van der Lingen et al. 2006). However, no link could be made with food resource composition and availability in this previous study (Chouvelon et al. 2014), because only one period of sampling and a single tissue (muscle tissue, i.e. medium- to long-term integrator of the food assimilated) were considered. Demonstration of such a link could highlight a strong dependency of one or both fish species to resource composition and availability, and/or reveal a relative trophic plasticity in one or both species relative to food resource variability. This may finally help to understand to which extent fluctuations and/or alternations of both species may be strongly trophodynamically mediated or not in the area.

In this general context, the aim of this study was twofold: (1) investigating intra- (seasonal) and inter-annual variations in the trophic ecology of adult sardines and anchovies from the Bay of Biscay; and (2) linking potential temporal variation in the diet of both fish species with variations in the mesozooplankton resource, to depict potential differential feeding strategies in both fish species in relation to resource variability. Several studies have highlighted

that zooplankton (and notably copepods belonging to the mesozooplankton community) are by far the most important dietary component for sardines and anchovies compared with phytoplankton (e.g. Van der Lingen et al. 2006; Espinoza et al. 2009; Nikolioudakis et al. 2012). As such, we focused on mesozooplanktonic prey as the major food resource for both fish species in the present study. Three different periods of sampling with contrasting abiotic conditions were considered, with one of these periods referring to those investigated by Chauvelon et al. (2014). SIA was undertaken on identified mesozooplanktonic prey and predators and mixing models used to estimate consumption patterns. The results obtained provide some understanding as to what extent potential trophodynamic differences and/or dependence on food resource variability (composition and availability) can influence fluctuations and/or alternations of both fish species abundances in the highly productive Bay of Biscay area.

2. Materials and Methods

Mesozooplankton and fish samples were collected in the spring of 2010 and 2011 and autumn of 2011, during sea surveys conducted by the French Research Institute for the Exploitation of the Sea (IFREMER) on the continental shelf to the shelf-edge of the Bay of Biscay: PELGAS 2010 and PELGAS 2011 surveys (25 April–5 June 2010 and 26 April–4 June 2011, respectively) and EVHOE 2011 survey (18 October–30 November 2011). As noted above, isotope values of samples from the PELGAS 2010 survey were presented in a previous study in the area (Chauvelon et al. 2014), as well as the methodological aspects related to the study of trophic relationships between mesozooplankton and planktivorous fish through SIA. Isotope results of the spring 2010 survey are thus only used here for direct comparison with the two other periods examined (i.e. spring and autumn 2011) and further link with the variation in resource abundance between the three periods.

These seasons were selected for sampling for various reasons regarding the objectives of the study. First, it was hypothesised that food resource abundance and composition would greatly differ between spring and autumn, i.e. between seasons presenting different environmental conditions in temperate areas such as the Bay of Biscay (Villate et al. 1997; Valdés and Moral 1998; Zarauz et al. 2007). Moreover, survey data indicated that both springtime periods were different in terms of temperature and salinity patterns in particular, potentially leading to different food resource availability as well (i.e. warmer sea surface temperatures during the spring 2011 campaign, in comparison with the spring 2010 campaign; IFREMER survey data, see also www.previmer.org/observations). Finally, sampling seasons were chosen with regard to the main spawning period of both fish species, potentially driving different feeding strategies in the study fishes. Indeed, for the Bay of Biscay anchovy, the peak spawning period has been reported to be in spring (i.e. May–June; Motos 1996), and the onset of spawning is concurrent with the sharp seasonal increase in surface temperature (ICES 2010b). Even though feeding migrations would occur after spawning (i.e. in summer and autumn), with fat content increasing during these seasons (Dubreuil and Petitgas 2009), anchovy continue to feed during the spawning season (Plounevez and Champalbert 1999), with the duration of the spawning season depending on energy intake during this period (ICES 2010b). For the Atlanto-Iberian and Biscay sardine, the main spawning period is between October and June and thus partly overlaps with those of anchovy in the Bay of Biscay (ICES 2010b). As for anchovy, fat content peaks in early autumn (i.e. beginning of the spawning season), although sardines also feed throughout the year (ICES 2010b).

Mesozooplankton were collected by vertical trawls of 200- μ m mesh-size WP2 nets, from 100 m depth (or bottom depth for inshore stations) to the surface. 10–16 stations were selected depending on the survey (Fig. 1). During PELGAS (spring) surveys, the stations followed transects used for the hydroacoustic assessment of small pelagic fish biomass. They were thus

distributed from the north to the south of the Bay of Biscay and from the coastline (C) to the continental slope (Sl) including stations over the continental shelf (Sh) (Fig. 1a). During PELGAS 2011, one oceanic (O) station was also considered (Fig. 1b). During EVHOE 2011 survey, stations followed randomly distributed fishing trawls, although as in PELGAS the stations were selected in order to cover all the Bay of Biscay area (Fig. 1c). After collection, mesozooplankton samples were concentrated on a 200 μm mesh and preserved in 70 % ethanol for further taxonomic identification and stable isotope analysis.

Adult sardines and anchovies were collected by pelagic trawls during PELGAS surveys (76×70 trawl with vertical opening of ~ 25 m or 57×52 trawl with vertical opening 15–20 m) and by bottom trawls during EVHOE survey (large vertical opening (GOV) trawl 36/47). This is due to a difference in the main initial objectives of the surveys (i.e. assessing abundance and distribution of pelagic fish in the Bay of Biscay using acoustic method during PELGAS; and assessing abundance and distribution of demersal and benthic resources using bottom trawl during EVHOE). During each survey and for each fish species, individuals were collected in 7–8 trawls over the continental shelf (Fig. 1). In some trawls, both species occurred at the same time; however, this does not indicate that they come from the same shoal given the duration of each trawl (between 30 and 60 min). Fish were immediately frozen at -20 °C until further dissection and analyses back to the laboratory.

2.1 Taxonomic determination of mesozooplankton and preparation for analysis

Taxonomic identification of mesozooplankton was carried out at the laboratory with a Leica M3Z stereo microscope (mag. $\times 65$ to $\times 160$), to genus and to species level whenever possible. For each spring station, identified taxa contributing at least 5 % of the total abundance of the sample both in number (individuals m^{-3}) and in biomass (mg m^{-3}) (i.e. ‘dominant taxa’), and likely to be part of the diet of sardines and anchovies (i.e. species that may be found in

stomach contents of anchovies from the Bay of Biscay area as reported by Plounevez and Champalbert (1999)), were sorted for further SIA. For each autumn station, as the diversity was lower, only identified taxa contributing at least to 10 % of the total abundance of the sample both in number and in biomass were subsequently sorted for SIA. As such, one to four ‘dominant taxa’ were analysed for stable isotope ratios within each of the stations sampled over the three periods. Details for the calculation of the relative abundance of each identified taxa in number and in biomass can be found in Chouvelon et al. (2014).

Depending on their size, 20–350 individuals belonging to each of the ‘dominant taxa’ were taken out from ethanol and carefully washed with distilled water in order to completely remove the ethanol, detritus and phytoplankton. Sorted and washed organisms were finally frozen at $-80\text{ }^{\circ}\text{C}$ for 48 h to be freeze-dried (24 h). A pool of individuals for each species sorted by station was then packed into 2 tin capsules for stable isotope analysis (i.e. half of sorted organisms within each capsule), and the mean value of the two capsules was used in further data analyses (Chouvelon et al. 2014).

For each fish species and for each survey, 30 to 40 adult individuals of similar size classes (average total length \pm standard deviation (SD) of 18.1 ± 2.2 and 13.9 ± 1.6 cm for sardines and anchovies, respectively) were defrosted and dissected at the laboratory to obtain portions of dorsal white muscle as well as the liver (Pinnegar and Polunin 1999). Specifically, the average total length for sardines was of 17.3 ± 2.6 , 18.7 ± 0.7 and 18.4 ± 2.6 cm for individuals collected in spring 2010, spring 2011 and autumn 2011, respectively. The average total length for anchovies was of 14.6 ± 1.8 , 13.3 ± 1.1 and 13.7 ± 1.5 cm for individuals collected in spring 2010, spring 2011 and autumn 2011, respectively. Within each species and at each season, these sizes corresponded to mature individuals and allowed comparison of morphologically similar fishes (i.e. adult individuals) at the three seasons investigated. Also, sardines were larger than anchovies, because the size at maturity is higher for sardines (i.e.

about 14 cm length, 1- to 2-year-old individuals) than for anchovies (i.e. about 10 cm length, 1 year old) (ICES 2010b). Muscle and liver samples were individually stored frozen at $-20\text{ }^{\circ}\text{C}$ in plastic bags prior to a 72-h freeze-drying period. White muscle and liver samples were ground manually or with a planetary ball mill (Retsch PM 200) and were treated with cyclohexane in order to remove naturally ^{13}C -depleted lipids (De Niro and Epstein 1977). Lipid-free samples were finally dried in an oven at $45\text{ }^{\circ}\text{C}$ for 48 h and packed in tin capsules for SIA.

2.2 *Stable isotope analysis*

The natural abundance of carbon and nitrogen stable isotopes in plankton and fish was determined with a Thermo Scientific Delta V Advantage mass spectrometer coupled to a Thermo Scientific Flash EA1112 elemental analyser. Results are expressed as isotope ratios δX (‰) relative to international standards (Pee Dee Belemnite for carbon and atmospheric N_2 for nitrogen), according to the formula:

$$\delta X = [(R_{\text{sample}} / R_{\text{standard}}) - 1] \times 10^3$$

where $X = ^{13}\text{C}$ or ^{15}N and $R = ^{13}\text{C}/^{12}\text{C}$ or $^{15}\text{N}/^{14}\text{N}$ (Peterson and Fry, 1987). Replicate measurements of internal laboratory standards (acetanilide) indicated a precision of approximately 0.2‰ for both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values.

2.3 *Data treatment and statistical analyses*

Chouvelon et al. (2014) demonstrated a significant effect of preservation (ethanol 70 % vs. freezing at $-20\text{ }^{\circ}\text{C}$) and of lipid content on mesozooplankton $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values. In the present study, for consistency of the treatment applied to prey and predators both in terms of preservation and of lipid correction, we thus applied the same corrections as proposed by

Chouvelon et al. (2014) for further analysis of the diet of sardine and anchovy through SIA. Briefly, this consisted in correcting $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of all mesozooplanktonic organisms preserved in 70 % ethanol for the effect of ethanol, and only $\delta^{13}\text{C}$ values of mesozooplanktonic organisms were corrected for the effect of lipid content (Chouvelon et al. 2014). The corrected values were then used in further statistical analyses and mixing models. All statistical analyses were conducted with R (R Development Team 2011). Normality of all data was tested using Shapiro–Wilk’s tests, i.e. for further use of parametric or nonparametric statistics. A Student *t* test or a Mann–Whitney–Wilcoxon test was thus applied when comparing two series of samples, e.g. for testing significant difference between both species. Similarly, an ANOVA (followed by post hoc Tukey tests) or a Kruskal–Wallis test (followed by a multiple comparison test with Holm’s adjustment method) was applied when comparing more than two series of samples, e.g. for testing significant difference between periods.

In order to link potential variations in the trophic ecology of both fish species inferred from SIA with the variability of the mesozooplankton resource, data on mesozooplankton abundances presented in the present study mainly concern the taxa contributing to more than 5 % of the total abundance both in number and in biomass, in at least one station for one of the periods considered (‘dominant taxa’). These taxa were effectively those analysed for SIA and considered in mixing models (see following section). The representativeness of these ‘dominant taxa’ relative to the whole mesozooplankton community was previously checked by analysing the correlation between total mesozooplankton abundance and total abundance of these ‘dominant taxa’ through a Spearman correlation coefficient test.

2.4 *Isotopic mixing models*

To account for numerous potential prey items in the diets of sardines and anchovies, the wide variability in the $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of mesozooplankton and for the uncertainty of TEFs

(i.e. the difference (Δ) in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ between the predator's tissue analysed and its diet), Bayesian isotopic mixing models were used (available as an open source R package SIAR; Parnell et al. 2010). In mixing models that are mathematically underdetermined (with more unknowns than equations and no unique solution) where the number of sources exceeds $n + 1$ (Phillips and Gregg 2003), one possible approach to encompass this common problem and to simplify the analysis is to combine some sources (Phillips et al. 2005). In the present study, potential prey items, that is, all entities 'taxa-station' (e.g. '*Temora* sp.-C2', 'Medium undetermined Calanoid-Sh3'), analysed for isotopes were thus grouped before running SIAR. As in Chouvelon et al. (2014), this grouping was performed through a hierarchical cluster analysis (HCA) for each period considered. HCA was based on $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values, average size (total length) of organisms (see Table 1) and geographical coordinates of each entity 'taxa-station' analysed for isotope ratios. The groups defined by HCA were then used in mixing modelling (Table 2).

To the best of our knowledge, precise TEFs are still unknown for mesozooplankton feeders such as sardines and anchovies. Post (2002) suggested that TEFs of 0.4 ± 1.3 and 3.4 ± 1 ‰ for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, respectively, could be widely applicable within a food web. Nevertheless, there is increasing evidence in the literature that TEFs may be highly variable as a function of the consumer's taxa or as a function of the type and the quality of the consumer's food (e.g. Vanderklift and Ponsard 2003; Caut et al. 2009). Recent studies have also shown that even considering uncertainty around TEFs or discrimination factors, Bayesian models outputs may be very sensitive to the chosen TEFs (e.g. Bond and Diamond 2011). To apply sensitivity analyses on the results obtained, four mixing models by species and by tissue were thus run using different values of TEFs found in the literature, for both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ (Post 2002, for general values; Pinnegar and Polunin 1999; Trueman et al. 2005; and Sweeting et al. 2007a, b for fish muscle or liver in particular; see Table 4 for the detailed TEFs used). The variability

around $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of each source taken into account in the mixing models corresponded to the standard deviation around the mean of each source group (i.e. SD given in Table 2). For each period considered, for each tissue and for each species, an average value of the estimated contribution of each group of mesozooplanktonic prey was finally calculated from the four mixing models applied (Table 4).

3. Results

3.1 *General abundance and distribution patterns in the mesozooplankton community*

Over the three study periods and considering all the stations selected for taxonomical identification, total abundance of mesozooplankton (in number) was the highest in spring 2010 and varied between 541 and 7,417 ind. m^{-3} (mean \pm SD: $3,316 \pm 2,609$ ind. m^{-3} , CV = 79 % for the 13 stations covered at this period in the Bay of Biscay area). In spring 2011, total abundances were slightly lower on average but varied among a similar range of values, i.e. from 305 to 8,433 ind. m^{-3} ($1,935 \pm 2,108$ ind. m^{-3} , CV = 109 % for the 16 stations covered). Total abundances finally displayed the lowest values in autumn 2011, varying from 53 to 3,366 ind. m^{-3} ($758 \pm 1,042$ ind. m^{-3} , CV = 138 % for the 10 stations covered). Within the whole mesozooplankton community, the percentage of copepods relative to the total abundance of mesozooplanktonic organisms varied from 21 to 99 % in spring 2010 and from 49 to 96 % in spring 2011. The values were the highest in autumn 2011, varying from 72 to 97 % (Fig. 2).

The correlation between the total abundance of mesozooplankton (in number) and the abundance of taxa contributing to more than 5 % of the total abundance (i.e. ‘dominant taxa’) was highly significant ($r_{\text{Spearman}} = 0.984$, $p < 0.0001$, $n = 39$ stations—i.e. all stations covered during the three periods investigated). This indicated these ‘dominant taxa’ of the wider mesozooplankton community. In spring of 2010 and 2011, coastal stations were mainly characterised by small- to medium-sized organisms such as *Acartia* sp., *Temora* sp. or

Appendicularia (Fig. 3a). The large copepod *C. helgolandicus* (especially abundant in spring 2010) or the smaller *Oithona* sp. were more abundant in stations from the shelf and/or from the slope, or in the station O4 from the oceanic area sampled in spring 2011. In autumn 2011, the copepods *Oncaea* sp. and *Temora* sp. were the most abundant in stations located near the coast and/or on the shelf, while large decapod larvae were abundant in two out of the ten stations analysed. Total abundances in stations located on or near the slope were very low at this period (Fig. 3).

Finally, the proportion of small organisms (see Table 1 for size ranges) was relatively stable throughout the three periods considered, varying between 51 and 55 % relative to the whole mesozooplankton community (i.e. community now represented by the ‘dominant taxa’) (Fig. 4a). The proportion of medium-sized organisms was higher in both spring and autumn 2011 (44 and 43 %, respectively) than in spring 2010 (34 %), whereas the proportion of large organisms such as *C. helgolandicus* was the highest in spring 2010 (16 vs. 4 and 2 % in spring and autumn 2011, respectively) (Fig. 4a). Abundances of organisms were the highest in stations from the coast and from the shelf both in spring and autumn 2011 (Figs. 3, 4). However, in spring 2011, a non-negligible part of the total abundance of mesozooplankton also belonged to stations from the slope (i.e. 21 %), as well as in spring 2010 where high abundances of organisms were found in the more oceanic stations (i.e. 32 %) (Figs. 3, 4).

3.2 Definition of prey groups and variability of mesozooplankton $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values

The HCA defined eight, nine and six groups of prey for spring 2010, spring 2011 and autumn 2011, respectively (Table 2). As such, the groups respected a certain ecological significance for further interpretation of the results of isotopic models, both in terms of sizes of organisms and in terms of their sampling location. Isotope values of the different groups were relatively distinct from each other (Table 2). Average $\delta^{15}\text{N}$ values varied from 4.2 ± 0.6 (group 1) to 7.2 ± 0.9 ‰

(group 8) in spring 2010, from 4.6 ± 0.3 (group 1) to 8.9 ± 0.6 ‰ (group 6) in spring 2011 and from 2.4 ± 0.2 (group 1) to 7.0 ± 0.4 ‰ (group 4) in autumn 2011. Average $\delta^{13}\text{C}$ values varied from -22.2 ± 0.1 (group 6) to -19.4 ± 0.3 ‰ (group 2) in spring 2010, from -21.8 ± 0.4 (group 1) to -19.0 ± 0.6 ‰ (group 7) in spring 2011 and from -20.9 ± 0.0 (group 4) to -20.2 ± 0.2 ‰ (group 5) in autumn 2011 (Table 2). Groups with large-bodied organisms generally displayed higher $\delta^{15}\text{N}$ values than those containing small- to medium-sized organisms within a same area. Also, within a same range of sizes, organisms collected in coastal waters generally displayed higher $\delta^{15}\text{N}$ values than those collected in more oceanic waters (Table 2). For instance, in spring 2010, large organisms from the shelf to the slope in the northern part (group 5) showed an average $\delta^{15}\text{N}$ value of 7.1 ± 0.9 ‰. On the contrary, the average $\delta^{15}\text{N}$ value of small- to medium-sized organisms from the slope in the northern part (group 1) was of 4.2 ± 0.6 ‰, and in the same area, small- to medium-sized organisms from the coast to the shelf in the northern part (group 4) displayed an average $\delta^{15}\text{N}$ value of 7.0 ± 0.6 ‰. In spring 2011, the same pattern of differences could be observed between these three types of groups collected in the northern part (corresponding to group 3, groups 1 and 2 considered together and group 6, respectively). This was also the case of groups from the southern area. Large organisms from the shelf to the slope (group 7) showed an average $\delta^{15}\text{N}$ value of 7.6 ± 0.7 ‰, while those of small- to medium-sized organisms from shelf to the slope (group 4) was of 5.6 ± 0.5 ‰. Small- to medium-sized organisms from the coast to the shelf (group 8) displayed an average $\delta^{15}\text{N}$ value of 7.2 ± 0.3 ‰ (Table 2).

3.3 Fish muscle $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values and isotopic mixing models

Within each of the three periods considered, *S. pilchardus* and *E. encrasicolus* differed significantly for both muscle $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (all p values <0.05 ; Table 3). *E. encrasicolus* always had lower $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values on average than *S. pilchardus* (Table 3; Fig. 5). In *S.*

pilchardus, individuals sampled in autumn 2011 displayed significantly lower muscle $\delta^{13}\text{C}$ values than individuals sampled in both spring 2010 and 2011, while $\delta^{15}\text{N}$ values were not significantly different between periods (p values >0.05 , Table 3). In contrast to *E. encrasicolus*, muscle $\delta^{13}\text{C}$ values were not significantly different between individuals collected at the three periods, but individuals collected in autumn 2011 showed significantly higher $\delta^{15}\text{N}$ values than those sampled in springs 2010 and 2011 (Table 3; Fig. 5).

In spring 2010, three groups out of the eight previously defined mainly contributed to the diet of *S. pilchardus*, whatever the TEF used: group 8 corresponding to small- to medium-sized organisms from the coast to the shelf in the central to southern part (average mean contribution \pm SD = 43.7 ± 5.9 %), group 4 corresponding to small- to medium-sized organisms from the coast to the shelf in the northern part (28.9 ± 9.6 %) and in lower proportion group 5 corresponding to large organisms from the shelf to the slope in the northern part (14.7 ± 9.5 %; Table 4). The same three groups presented the highest estimated contribution in the diet of *E. encrasicolus* as well (22.3 ± 7.7 , 19.3 ± 7.7 and 17.6 ± 10.0 % for groups 8, 4 and 5, respectively). However, in the latter species, two other groups also contributed significantly to its diet (i.e. average contribution close to or ≥ 10 %), namely group 6 corresponding to large organisms from the slope in the central to southern part (13.1 ± 11.8 %) and group 2 containing medium-sized organisms from the coast to the shelf in the central to northern part (11.3 ± 10.8 %; Table 4).

In spring 2011, four groups out of the nine defined mainly contributed to the diet of *S. pilchardus* and *E. encrasicolus* (i.e. average contribution ≥ 10 % in both species): group 6 containing small- to medium-sized organisms from the coast in the northern part (40.8 ± 16.0 and 11.2 ± 8.1 % in *S. pilchardus* and *E. encrasicolus*, respectively), group 3 corresponding to large organisms from the shelf to the slope in the northern part (17.4 ± 13.8 and 29.6 ± 24.8 % in *S. pilchardus* and *E. encrasicolus*, respectively), group 8 corresponding to small- to medium-

sized organisms from the coast to the shelf in the southern part (12.4 ± 13.0 and 11.7 ± 14.7 % in *S. pilchardus* and *E. encrasicolus*, respectively) and finally group 7 including large organisms from the shelf to the slope in the southern part (12.1 ± 12.1 and 9.5 ± 9.8 % in *S. pilchardus* and *E. encrasicolus*, respectively). In total, these four groups (i.e. groups 3, 6, 7 and 8) contributed on average to 82.7 and 62.0 % to the diet of *S. pilchardus* and *E. encrasicolus*, respectively (Table 4). However, group 6 presented the highest contribution in *S. pilchardus* (40.8 ± 16.0 %) whatever the TEF used, the group 3 was the most significant group in the diet of *E. encrasicolus* (29.6 ± 24.8 %) in three out of the four models performed (Table 4).

Mixing models performed on $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values in the muscle of the fish sampled in autumn 2011 highlighted the major contribution of three of the six groups defined in the diet of both species. In total, group 4 (corresponding to small- to medium-sized organisms from the coast to the shelf in the northern part) and group 5 (containing small- to medium-sized organisms from the coast to the shelf in the central part) both contributed on average 76.5 and 69.7 % to the diet of *S. pilchardus* and *E. encrasicolus*, respectively (Table 4). Group 6 including small- to medium-sized organisms from the coast to the slope in the southern part was the third contributor to the diet of both species, with an average contribution of 12.6 ± 7.2 and 14.0 ± 6.8 % in *S. pilchardus* and *E. encrasicolus*, respectively (Table 4).

3.4 Fish liver $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values and isotopic mixing models

In both spring and autumn 2011, *S. pilchardus* and *E. encrasicolus* differed significantly in liver $\delta^{13}\text{C}$ values (both *p* values <0.05). *E. encrasicolus* always displayed lower $\delta^{13}\text{C}$ values on average than *S. pilchardus* (Table 3; Fig. 5). However, liver $\delta^{15}\text{N}$ values did not differ significantly between both species at both periods. In *S. pilchardus*, individuals sampled in autumn 2011 showed significantly lower $\delta^{13}\text{C}$ values and higher $\delta^{15}\text{N}$ values than those sampled in spring 2011. In *E. encrasicolus*, individuals collected in autumn 2011 had higher average

$\delta^{15}\text{N}$ values than those sampled in spring 2011, but $\delta^{13}\text{C}$ values did not differ between seasons (Table 3, Fig. 5).

Interestingly, in both species, mixing models performed on liver $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of the fish sampled in spring 2011 showed an average contribution of all the defined prey groups $\geq 5\%$ (Table 4). Four to five groups out of the nine defined presented an average contribution $\geq 10\%$ in both species, with group 6 (containing small- to medium-sized organisms from the coast in the northern part), group 3 (including large organisms from the shelf to the slope in the northern part) and group 9 (corresponding to small- to medium-sized organisms from the oceanic area) being common major groups (given here in the increasing order of contribution) for both fish species. Other major groups contributing to their short-term diet were group 4 (including small- to medium-sized organisms from the shelf to the slope in the central to southern part) and group 8 (corresponding to small- to medium-sized organisms from the coast to the shelf in the northern part) in *S. pilchardus*, and the group 1 in *E. encrasicolus* (containing small- to medium-sized organisms from the slope in the northern part) (Table 4).

In autumn 2011, the results of the mixing models based on liver tissues were quite similar to those obtained with models performed on muscle $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values. The same three groups out of the six defined contributed significantly to the diet of both species (i.e. groups 4, 5 and 6). Group 4 (corresponding to small- to medium-sized organisms from the coast to the shelf in the northern part) contributed more than 50% on average to the diet of both species (53.7 ± 20.6 and $53.0 \pm 28.3\%$ in *S. pilchardus* and *E. encrasicolus*, respectively; Table 4). Group 2 including small- to medium-sized organisms from the slope in the northern part also contributed $10.7 \pm 5.3\%$ on average to the short-term diet of *E. encrasicolus*.

4. Discussion

4.1 *Spatial, temporal and size-related variability of mesozooplankton abundances and isotope values over time*

With all stations taken into account within a given period, the average total abundances of mesozooplankton showed a general decreasing trend over the three periods considered with spring 2010 > spring 2011 > autumn 2011. In all cases, copepods dominated the mesozooplankton community, with the exception of some coastal stations (e.g. C4) that sometimes displayed a relatively high percentage of meroplankton or other taxa (e.g. Appendicularia, Cladocerans), especially in spring. These general patterns in the composition of the mesozooplankton community analysed here are consistent with the current knowledge on this compartment concerning European shelf seas (Williams et al. 1994) and more specifically concerning the Bay of Biscay area (Villate et al. 1997; Valdés and Moral 1998; Plounevez and Champalbert 1999; Albaina and Irigoien 2004). When focusing on abundances and distribution of the ‘dominant taxa’, which were well correlated with total mesozooplankton abundances, the abundances were generally higher in coastal stations and notably in autumn. This is quite common for neritic areas at this latitude; i.e. maximum densities are generally observed in late spring extending into summer, a secondary peak of high biomass occurs in autumn and values are minimum in winter. In contrast, oceanic areas generally present a single annual peak in spring, there is no autumn peak or it is very weak, and generally low summer values are observed (Valdés and Moral 1998). In the Bay of Biscay and especially in spring, Plounevez and Champalbert (1999) and Dupuy et al. (2011) effectively reported higher zooplankton biomass in neritic stations and notably those located in the water plume of the Gironde estuary, relative to more oceanic stations. However, in our study, abundances were also quite high in stations from the slope relative to coastal stations in spring 2010, with high densities of the copepod *C. helgolandicus* in particular when compared to spring 2011 (Fig. 3).

Spatio-temporal variation in mesozooplankton abundance and composition, especially inter-annual variations (i.e. between two consecutive springs), can be directly related to spatial and year-to-year variations in water temperature and salinity (Villate et al. 1997, Zarauz et al. 2007). Moreover, in the Bay of Biscay, the plumes of the Gironde and the Loire Rivers considerably influence the hydrological structure and the primary production on the continental shelf, all along the year (Planque et al. 2004; Puillat et al. 2004, 2006; Loyer et al. 2006; Dupuy et al. 2011). Slope currents occurring on the shelf break (Koutsikopoulos and Le Cann 1996) can also favour primary production in these waters due to nutrients inputs (e.g. Holligan and Groom 1986). For instance, Albaina and Irigoien (2004) related peaks of mesozooplankton abundance and distinct mesozooplankton assemblages with the plume of the Gironde River (i.e. nutrients discharge) and the frontal structure associated with the shelf break (i.e. internal wave generation) in the area. In our study, inter-annual variations in mesozooplankton abundances and composition between both springtime periods can be directly linked to temperature and salinity patterns observed during the sampling campaigns as well, and consequently to a temporal lag between both years in the ecological processes occurring in this area in spring (i.e. water stratification and planktonic blooms). Indeed, during the survey in spring 2010, sea surface temperatures were low, especially in the northern part of the area (from 12 to 14.5 °C), and river discharges were low too (IFREMER survey data; previsions for sea surface physico-chemical parameters by date in the Bay of Biscay may be also found at www.previmer.org/observations). Surface temperatures increased and stratification strengthened only during the second half of the sampling campaign in spring 2010. On the contrary, during the spring 2011 survey, sea surface temperatures over the Bay of Biscay area were high (above the average on the time series PELGAS) and relatively homogeneous over the whole Bay of Biscay area (from 15.5 to 17 °C on average). River discharges were as low as in 2010, but temperature depth profiles showed a strong stratification of the water column

(IFREMER survey data). Furthermore, there was evidence that a spring bloom had occurred before the survey in 2011. Between both surveys in springs 2010 and 2011, abiotic conditions were thus totally different. Furthermore, the Bay of Biscay is known to face late winter phytoplankton blooms, mainly constituted of diatoms, and this within both the Gironde and Loire Rivers plumes (Herbland et al. 1998; Labry et al. 2001; Gohin et al. 2003; Dupuy et al. 2011). This results in early phosphorus limitation in spring that subsequently favours the development of small autotrophic unicellular species on which microzooplankton feeds (Sautour et al. 2000; Dupuy et al. 2011). Interestingly, in spring 2010, while temperatures were particularly low and the spring bloom had not already occurred, large organisms such as the copepod *C. helgolandicus* were more abundant than in 2011, and notably in stations from the slope. Coastal zones effectively generally show a larger ratio of small organisms (Sourisseau and Carlotti 2006; Irigoien et al. 2009), and neritic species of copepods are generally smaller in body size than offshore species (Williams et al. 1994). Moreover, *C. helgolandicus* preferentially feeds on diatoms (Irigoien et al. 2000), such as those that can develop in late winter phytoplankton blooms. Differences in hydrological characteristics (e.g. temperature, salinity and water stratification) as well as associated ecological processes described in the literature for the Bay of Biscay area (e.g. different phytoplankton blooms between winter and spring) may thus explain the mesozooplankton variability especially found between both consecutive spring surveys studied here (i.e. late winter conditions in spring 2010 vs. advanced spring conditions in spring 2011).

Alternatively, even though mesozooplankton varied greatly over the three periods considered in terms of abundances and composition, patterns of isotopic values within this planktonic compartment were similar from one period to another. There was some inter-specific variability of isotope values linked to the size of organisms, as described previously in Chouvelon et al. (2014). Larger organisms displayed higher $\delta^{15}\text{N}$ values than smaller organisms

in a given area, reflecting an a priori higher trophic level of larger organisms in the planktonic food web. The only exception consisted in particularly low $\delta^{15}\text{N}$ values measured in large decapod larvae analysed as a whole in autumn 2011. In arthropods, crude exoskeleton chitin is effectively depleted in ^{15}N but not in ^{13}C (Schimmelmann and De Niro 1986). As described in Chouvelon et al. (2014), there was also an intra-taxa variability of isotope values linked to spatial patterns in the area, especially concerning $\delta^{15}\text{N}$ values that were more variable than $\delta^{13}\text{C}$ values between mesozooplanktonic groups of prey. The temporal variability of plankton isotopic signatures, which could have constrained the use of mixing models on liver and muscle data from planktonic prey sampled at only one period (those of the survey), was thus negligible, at least at the scale of the Bay of Biscay ecosystem. In fact, spatial differences in $\delta^{15}\text{N}$ values in particular are more likely linked to processes occurring at the dissolved inorganic nitrogen (DIN) level (for a complete review on this subject see Sherwood and Rose 2005; Montoya 2007; and references therein). Many processes can effectively lead to enriched ^{15}N values of the available DIN pool, and the following general conclusions can be drawn: (1) when DIN demand is higher than the supply of nutrients, primary producers may be faced with a ^{15}N -enriched nitrogen source (e.g. 'recycled' or ammonium-enriched, especially if it comes from higher trophic levels), which is then reflected in the local food chain. Alternatively, during upwelling events for instance (in areas subject to this), the physical supply of 'new' nutrients overwhelms the biological uptake rate and favours ^{15}N -depleted nitrogen sources (at least non-enriched) for producers of this environment. Moreover, high primary production (blooms) during spring on the continental shelf reduces nutrient quantities, thus favouring ^{15}N -enrichment of the available DIN. Even if short-lived, this effect may be lasting for benthic consumers in particular due to the sinking of particles to the bottom; (2) rivers may be a vector of ^{15}N -enriched organic matter into coastal waters as well (Fry 1988; McClelland et al. 1997; Vizzini and Mazzola 2006). All these processes can be involved in the Bay of Biscay; however,

the derived spatial patterns of $\delta^{15}\text{N}$ values from the base of the food chain (i.e. investigated at the mesozooplankton level here) were thus similar from one period to another.

4.2 Linking resource variability and feeding patterns of sardines and anchovies over time

During the three study periods, *S. pilchardus* and *E. encrasicolus* were well segregated by both their $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values as measured in the muscle of individuals. Moreover, mixing models applied on this tissue (medium-term integrator of the food consumed) emphasised different feeding strategies of the two fish species. In both spring periods surveyed (2010 and 2011), *E. encrasicolus* showed a greater trophic plasticity than *S. pilchardus*, both in terms of feeding areas and in terms of sizes of prey organisms among the mesozooplankton resource (i.e. zooplankton $>200\ \mu\text{m}$). Indeed, almost all the defined groups of mesozooplankton prey presented an average contribution $\geq 5\%$ in *E. encrasicolus*, while only some of the defined groups presented such a contribution to the diet of *S. pilchardus* in both spring periods. In terms of feeding areas, groups 8 and 6 (in Spring 2010 and Spring 2011, respectively) containing organisms from the coast to the slope effectively showed the highest contribution to the diet of sardines (i.e. 43.7 ± 5.9 and $40.8 \pm 16.0\%$, respectively). It suggests that sardines are more limited to coastal areas and the mesozooplanktonic species of these waters for feeding than anchovies. Besides, these groups showed the highest $\delta^{15}\text{N}$ values at both periods, which is in accordance with the highest $\delta^{15}\text{N}$ values measured in muscle tissue of *S. pilchardus* at the two periods and which also suggests that the feeding pattern of pelagic fish is constrained spatially. Indeed, in terms of sizes of prey, significantly lower $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values measured in the muscle of anchovies collected in both springs 2010 and 2011 could have been related, at first sight, to the consumption of lower trophic level organisms in anchovies. However, the spatial variability of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values from the base of the different food webs in the area (Chouvelon et al. 2012), and also shown here with isotope values of mesozooplanktonic species,

rather supports the hypothesis of more offshore feeding habits for anchovies than the hypothesis of a lower trophic level. Anchovies would effectively be able to capture larger particles than sardines (Louw et al. 1998; Van der Lingen et al. 2006), thanks to differences in gill raker morphology between both species and the existence of a larger branchial apparatus in anchovies (James and Findlay 1989). In several cases, anchovies have thus been found to feed at a slightly higher trophic level than sardines (e.g. Stergiou and Karpouzi 2002), and specifically in the Bay of Biscay (i.e. data from Ecopath modelling; Lassalle et al. 2011). Moreover, this morphological difference would lead anchovies to be opportunistic and efficient planktivores (James and Probyn 1989) on prey species from the mesozooplankton compartment at least and would confirm that *E. encrasicolus* is not specialist feeder in the Bay of Biscay area, as already reported for the North and Baltic Seas (Raab et al. 2011). Such particulate feeding in anchovies allows for a rapid and efficient intake of prey minimising metabolic costs and is thus the main feeding mode in this species (James and Probyn 1989; Van der Lingen 1994). In contrast, filter feeding on smaller zooplanktonic prey and/or phytoplankton would be the major feeding mode in sardines (Van der Lingen 1994; Garrido et al. 2007). However, most dietary carbon and/or nitrogen is obtained from zooplanktonic prey (and not phytoplankton) in adult sardines in general (Van der Lingen 1994; Bode et al. 2004; Nikolioudakis et al. 2011; Costalago et al. 2012), and the contribution of phytoplankton to sardine diet can vary greatly at small spatial scales and seasonally (Garrido et al. 2008).

Medium-term feeding preferences of sardines and anchovies differed within both spring periods studied here. Alternatively, their diets were relatively similar during the autumn period following our mixing model results, whereas average isotope values were significantly different (although associated standard deviations were large). This may be due to the fact that the isotopic mixing models used here consider individual fish values (i.e. consumers) and not mean values \pm SD as for prey (Parnell et al. 2010). As such, mixing models based on muscle tissues

highlighted a preference of both species for small- to medium-sized organisms from neritic waters (i.e. from the coast to the shelf) in central and northern parts of the Bay of Biscay, which notably corresponds to the autumn-/winter-feeding grounds described for anchovies in this area (ICES 2010b). In fact, it appeared that the more abundant and diversified the mesozooplankton resource is in terms of prey sizes available (i.e. with spring 2010 > spring 2011 > autumn 2011), and the more sardines are specialised on fewer prey groups compared with anchovies (Table 2). Indeed, 25 % of the groups of prey (i.e. three out of the eight defined) contributed on average to 87.3 % to the medium-term diet of *S. pilchardus* in spring 2010, while 45 % of the groups contributed to 82.4 % to its diet in spring 2011, and 50 % of the groups contributed to 89.1 % to its diet in autumn 2011. In autumn 2011, the same groups contributed to 83.7 % to the medium-term diet of *E. encrasicolus*. Thus, when the mesozooplankton resource is abundant and diversified (i.e. in both springs compared with the autumn period), and while potential competition could be high because of some spawning overlap between the two species (ICES 2010b), it is likely that the high degree of specialisation shown by sardines limits competition with anchovies (and with other small pelagic fish in general) in spring. On the contrary, trophic overlap could occur in autumn, when the resource is less abundant and diversified, leading to potential competition for food between both fish species. Moreover, during this period, it has been reported that the fat content of both species peaks (ICES 2010b), indicating a common period of need for reserve storages before the beginning of the spawning season (i.e. for sardine) or before winter (for anchovy). However, both species are able to feed throughout the year and notably during the spawning season, which may limit the competition for resource in autumn as well.

In spring 2010, major contributing groups of prey to the medium-term diet of both fish species were mostly constituted of small- to medium-sized organisms from neritic waters, despite a wider range of prey sizes and of feeding areas for *E. encrasicolus* as noticed above. In contrast,

in spring 2011, two out of the four major groups of prey for both species (i.e. contributing more than 10 % to the medium-term diet of both species) contained large organisms from the shelf to slope areas. Interestingly, this was not in accordance with the reported differences in abundance and diversity of mesozooplanktonic prey between the two consecutive springs, both in terms of sizes available (i.e. abundance of larger prey in spring 2010 > spring 2011) and in terms of mesozooplankton distribution in the area (i.e. abundant species were more fairly distributed between coastal and shelf to slope areas in spring 2010, whereas abundances were slightly higher in coastal areas in spring 2011). Furthermore, if the mesozooplankton community showed variation from one spring to another, this did not visibly impact the medium-term feeding strategies of both species, which remained the same (i.e. general segregation). Therefore, our results do not highlight any obvious link between variation observed in the mesozooplankton resource and the trophic ecology of both fish species depicted through SIA, at least concerning both spring periods studied. In autumn 2011, the spread of isotope values for anchovies was relatively large. Chouvelon et al. (2012) already reported such a wide range of $\delta^{15}\text{N}$ values in anchovies sampled in the autumns of 2009 and 2010 in the Bay of Biscay, in comparison with individuals sampled in springs 2009 and 2010 and in comparison with sardines sampled at the same periods. As a potential explanation, the authors argued for two different hypotheses. The first one is related to the high mobility of most small pelagic fish species (e.g. Nøttestad et al. 1999). Indeed, we cannot exclude here a potential mixing of individuals and/or part of the population that have fed in different areas presenting different baseline signatures in $\delta^{15}\text{N}$ in the Bay of Biscay, particularly in autumn when food supply is less abundant in neritic waters. The second hypothesis refers to a possible greater trophic plasticity of anchovies so as to avoid competition with sardines at this period of the year, as an adjustment on behalf of the species facing variations in the food supply (e.g. Lefebvre et al. 2009). In autumn, abundances of mesozooplankton may effectively stay at levels that anyway

sustain energetic needs of both species and other plankton feeders. For instance, Plounevez and Champalbert (1999) already suggested that feeding efficiency in *E. encrasicolus* would be more related to zooplankton specific composition than to zooplankton abundance, even if the results of our study cannot confirm or invalidate this hypothesis. Marquis et al. (2011) also reported that small pelagic fish only represent 30 % of the total predation on the mesozooplanktonic compartment in coastal stations in the Bay of Biscay (from spring data), and 60 and 65 % at the mid-shelf and the slope stations, respectively. These authors suggested that a large fraction of the mesozooplankton production would be then available for other planktivorous organisms such as suprabenthic zooplankton (euphausiids and mysids) or macrozooplankton (medusa or large tunicates) in the Bay of Biscay (Marquis et al. 2011). Finally, this could also explain why the variations observed in the mesozooplanktonic community in the present study do not fully correlate with the trophic ecology of adult anchovies and sardines, depicted here through SIA over the three periods investigated.

The lack of relationships between variations in the mesozooplankton resource and the trophic ecology of both species may be also due to the fact that until now, only the trophic ecology inferred from muscle isotope values (i.e. a medium-term integrator of the food assimilated) was considered because this was the tissue commonly sampled over the three periods. Indeed, as described above, variation in the plankton community a priori depends on short-term events such as phytoplankton blooms; so analysis of liver stable isotope values (a shorter-term integrative tissue) could be more relevant for comparison with resource variability. As such, in spring 2011, contrary to values measured in the muscle, $\delta^{15}\text{N}$ values in particular measured in the liver did not differ significantly between both species. Moreover, mixing models highlighted a common predominant group of prey (i.e. group 6), contributing to more than 20 % in both species and corresponding to small- to medium-sized organisms from the coast in the northern part. In the liver tissue of fish, carbon and nitrogen half-lives were shown to be considerably

lower than in the muscle (e.g. Buchheister and Latour 2010 for flatfish) and in fact, from hepatic results, it was likely that both sardines and anchovies appeared to be short-term opportunistic feeders in spring 2011 (i.e. all prey groups contribution $\geq 5\%$). Although this pattern of quite similar average contributions for most prey groups may be an indication that the model cannot reliably find a fit for the data, this could be also related, in terms of ecological interpretation, to a temporary opportunistic behaviour of both species that are facing short-term variation in food availability. This would be also quite consistent with the fact that both species may feed during spawning season, with the spawning season potentially overlapping between the two species during this period (spring). However, the main contributing prey groups revealed by mixing models based on liver isotope values did not fully correspond to the most abundant prey items available in the Bay of Biscay at the period of sampling. So, results of mixing models performed on the liver tissue did not reveal any clear relationships between either the food available or that assimilated by the two fish species. Nonetheless, in autumn 2011, results obtained in the livers corroborated those obtained in the muscles, with an apparent sharing of the mesozooplankton resource at this period. Finally, the lack of precise TEFs for planktivorous fish may be also responsible of potentially imprecise results, highlighting the recurrent crucial needs for more experimental studies in isotopic ecology (Martínez del Rio et al. 2009). This is particularly true for isotope values measured in fish liver, as many dedicated studies focus on the muscle tissue as the reference tissue for the study of trophic interactions (Pinnegar and Polunin 1999).

4.3 Concluding remarks and further work for understanding small pelagic fish fluctuations

SIA represents an alternative and/or complementary method for determining the diets and feeding strategies of small sympatric pelagic fish species (e.g. Costalago et al. 2012). The

results of the present study highlighted that it also provides useful information on potential trophic overlap between species in the very general context of understanding forage fish alternations and/or co-occurrence in a given area. In the Bay of Biscay, it effectively appeared that adults of sardines and anchovies do not compete strongly for the mesozooplankton resource in spring, where the spawning season of both species overlap and during which their energetic needs may be increased. In autumn, potential competition for the mesozooplankton resource may occur, although this may be compensated by the fact that both species feed throughout the year (ICES 2010b) and notably in spring when the food resource is abundant. Alternatively, in the present study, no clear relationships were revealed between the trophic ecology of adult sardines and anchovies depicted through SIA, and variations in the mesozooplankton resource in the Bay of Biscay area over the three different periods were investigated. Other food resources than mesozooplankton (i.e. microplankton) may also contribute to their diet, and the lack of consideration of this compartment here may contribute to explain the lack of relationships (in addition to the other elements described above such as imprecise TEFs for plankton-feeding fish, for instance). However, in the Bay of Biscay, the microplankton fraction (i.e. 50–200 μm) appears in fact to be mainly constituted by phytoplankton (unpublished data). Moreover, several studies demonstrated that zooplankton, and notably copepods belonging to the mesozooplankton community, are by far the most important dietary component for both fish species compared with phytoplankton (e.g. Van der Lingen et al. 2006; Espinoza et al. 2009; Nikolioudakis et al. 2012). Furthermore, this is not the first time that a lack of relationship between food concentration and food ingestion in such small plankton-feeding fish is found in the Bay of Biscay (e.g. Plounevez and Champalbert 1999; Bachiller et al. 2012). Interestingly, in other systems, some authors have however already shown that feeding mode and food consumption in adult sardines, for instance, can be highly dependent on food density (Garrido et al. 2007), notably in the Mediterranean Sea (Nikolioudakis et al. 2011; Costalago et al. 2012).

Differences in the general function of the different systems may induce such differences in the feeding strategies of small pelagic fish between systems. Indeed, in upwelling systems for instance, alternative abundance fluctuations of sardines and anchovies have been demonstrated and partly explained by both climatic (e.g. Lluch-Belda et al. 1989; Schwartzlose et al. 1999) and/or biological factors (e.g. trophodynamic mediation suggested by Louw et al. 1998; Van der Lingen et al. 2006). When two predator species show clear trophodynamic differences, as demonstrated for sardines and anchovies in various ecosystems and notably in upwelling systems in terms of size of prey, there is effectively a high potential for trophodynamically mediated fluctuations of both species abundances if a peculiar food environment (dominated by either small or large particles) persists either spatially or temporally under specific abiotic conditions. Indeed, it may favour the occurrence/maintenance of one of the predator species relative to the other in the area, a phenomena that would be enhanced by concurrent better reproductive success of this predator (Van der Lingen et al. 2006). In the Bay of Biscay case study, sardines and anchovies are generally segregated in terms of trophic ecology, highlighting a potential for trophodynamically fluctuations of both species' abundances in the area at first sight. However, they both showed at the same time a certain trophic plasticity relative to the composition of the mesozooplankton resource available, although this trophic plasticity appeared to be higher in anchovy than in sardine. As such here, while anchovies were shown to efficiently remove large particles in various systems (see Van der Lingen et al. 2006 for a review, and the present study for the Bay of Biscay area), large organisms did not necessarily dominate the diet of anchovies when the mesozooplankton resource contained a higher proportion of large organisms (such as in spring 2010). Conversely, while sardines were shown to efficiently remove or favour smaller particles in various systems (see Van der Lingen et al. 2006 for a general review, and the present study for the Bay of Biscay area), large organisms

could also contribute to their diets when the mesozooplankton resource was largely dominated by small- to medium-sized organisms (such as in spring 2011).

In the Bay of Biscay ecosystem, no clear patterns of abundances of both fish species and no potential explanation for fluctuations of their stocks have been reported yet. The present study therefore emphasised that fluctuations in sardines and anchovies from the Bay of Biscay cannot also be totally explained by the trophic ecology of adults of both species. Indeed, adult sardines and anchovies do not compete strongly for food resource in the Bay of Biscay area. Furthermore, species segregate diets, and although this can represent a potential for trophodynamically mediated fluctuations under specific abiotic conditions, no clear link was made between food resource availability and fish diets (i.e. no strict dependency of both species relative to the composition and availability of the mesozooplankton resource). In this sense, our results seem to corroborate those of Irigoien et al. (2009) who found a negative correlation between anchovy recruitment and zooplankton biomass in the Bay of Biscay, suggesting then that the 2002–2006 failures in anchovy recruitment in the area were not due to a decrease in mesozooplankton biomass.

Through the results of the present study, we provide further evidence that alternations of species should be considered in conjunction with spawning success and year class formation (Van der Lingen et al. 2006). Besides, a focus on the trophic ecology of larvae of both species may also constitute a next step. This should be then coupled to an analysis of long-term fluctuations in mesozooplankton and microplankton (may be preyed on by larvae as well) composition and abundance, with consideration of abiotic factors too. Changes in the plankton community, in relation to environmental parameters, have effectively been shown to directly affect survival of larvae and consequently fish recruitment (e.g. Beaugrand et al. 2003). From a more theoretical ecological point of view, investigating what maintains the trophic segregation between adults

of both species, despite variations in abundance and composition of the mesozooplankton community, should be also of interest.

Acknowledgements:

This work was supported by the European project REPRODUCE (EratNet-Marifish, FP7). Authors are very grateful to J. Massé, P. Petitgas, and M. Doray from IFREMER for facilitating the sampling during PELGAS surveys. Many thanks to M. Huret and P. Bourriau (IFREMER) too for their help during plankton sample collection, and P. Lespagnol (IFREMER) for fish sampling. Authors also thank G. Guillou and P. Richard (UMR LIENSs) for assistance in stable isotope analysis and finally the anonymous reviewers of the earlier version of the manuscript for facilitating its improvement.

Table 1: Average size and size-class classification used for mesozooplanktonic organisms identified and analysed in this study.

Size-class classification used in this study	Taxa	Average size (mm) ^a
Small organisms	Copepod nauplii	0.1
	<i>Euterpina</i> sp.	0.6
	<i>Oithona</i> sp.	0.7
	<i>Oncaea</i> sp.	0.7
	<i>Coryceus</i> sp.	0.9
	Appendicularia	0.9
	<i>Evadne</i> / <i>Podon</i> sp.	0.9
	<i>Acartia</i> sp.	1.0
	Small undetermined Calanoids including copepodites	1.1
Medium-sized organisms	<i>Temora</i> sp.	1.4
	<i>Centropages</i> sp.	1.5
	Medium undetermined Calanoids	1.9
Large organisms	<i>Calanus helgolandicus</i>	2.9
	Decapod larvae	3.5

^a Average size corresponds to an average value of sizes reported for species included in the taxa (i.e., mostly genus) that may be found in the Bay of Biscay area and/or in the North-East Atlantic. Main references for the reported species: Cabal et al., 2008; Isla et al., 2004; Plounevez and Champalbert, 1999; Valdés et al., 2007. Main reference for the size of species: Rose, 1933.

Table 2: $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (Mean \pm Standard Deviation in ‰) of the mesozooplanktonic prey groups defined by hierarchical cluster analysis and used in mixing models for the 3 periods studied (Spring 2010, Spring 2011 and Autumn 2011). The values presented here are corrected for the effects of preservation and/or delipidation, for consistency of treatment between prey and predators (see text). As groups are not strictly identical between the three periods investigated, they are numbered and presented in the default order for each hierarchical classification performed.

Group	Average range of sizes (mm)	Species forming the group and associated stations	$\delta^{13}\text{C}$ Mean \pm SD	$\delta^{15}\text{N}$ Mean \pm SD
<i>Spring 2010</i>				
1. Small- to medium-sized organisms from the slope, north	0.7–1.9	<i>Oithona</i> sp. (S11)	-20.3 ± 0.4	4.2 ± 0.6

Table 3: Results of statistical tests for significant differences between periods or between species for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values measured in muscle and/or liver of fishes. For the muscle tissue, within a species and for one element at time (i.e. carbon or nitrogen), vertical bars (|) indicate means that do not differ significantly following post hoc Tukey's tests in the case of ANOVA or multiple comparison test with Holm's adjustment method in the case of Kruskal–Wallis (test chosen according to satisfying conditions for parametric statistics or not). For the liver tissue, analysed at two periods only, vertical bars (|) indicate means that do not differ significantly following the Student t tests or Mann–Whitney–Wilcoxon tests applied (according to satisfying conditions for parametric statistics or not). To assess significant between-species differences, Student t tests or Mann–Whitney–Wilcoxon tests were also performed, and p values are indicated for each period and for each tissue considered. N = number of individuals. $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (Mean \pm SD in ‰) for each group of fish are specifically represented in Fig. 5.

Tissue	Period	$\delta^{13}\text{C}$					$\delta^{15}\text{N}$

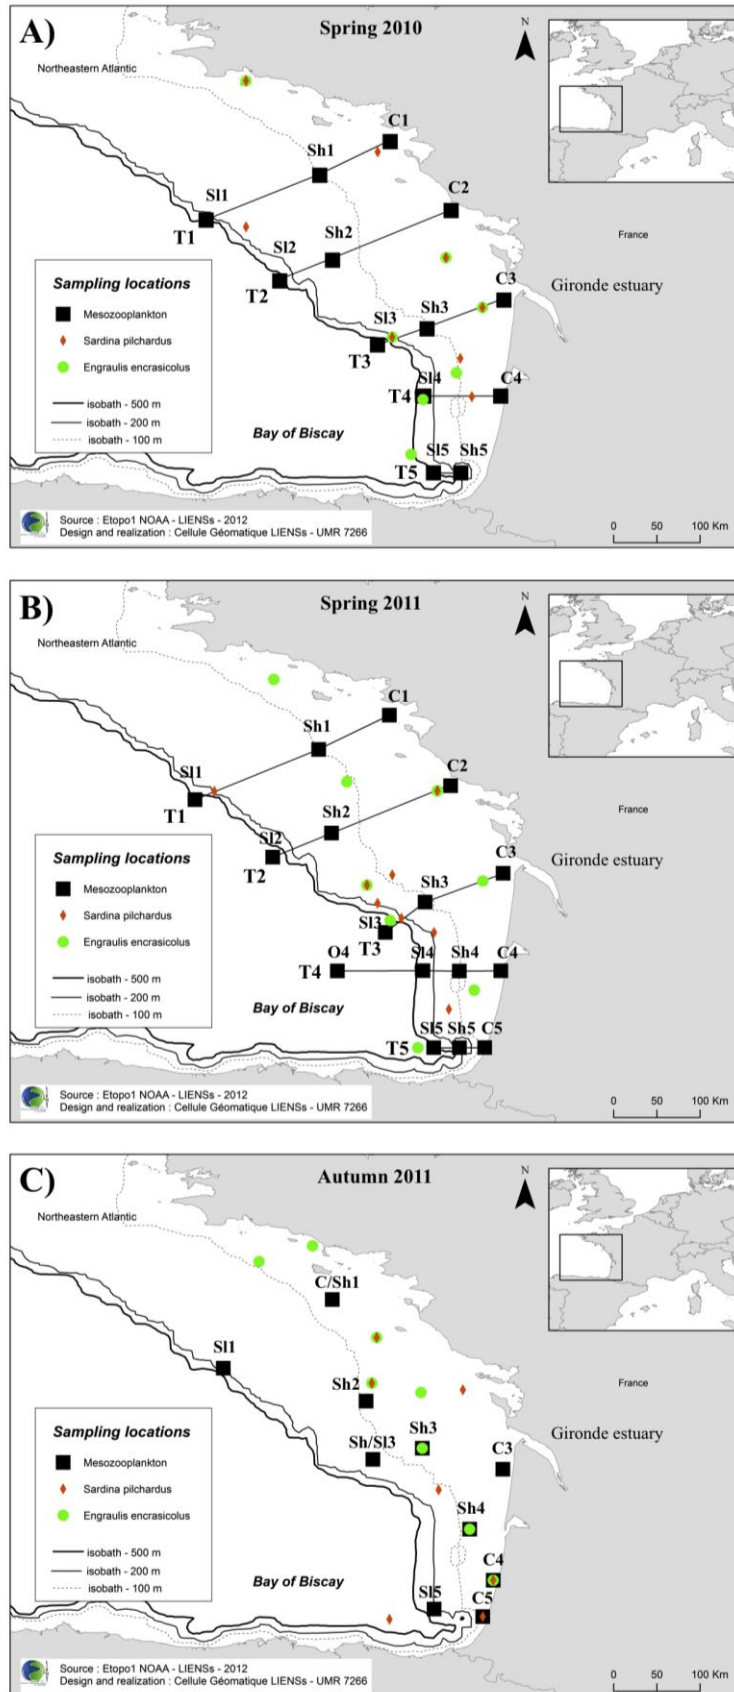

Figure 1. Maps of the study area (Bay of Biscay), with transects realised from the coastline to the slope and stations selected for plankton sampling for each of the 3 periods considered in this study: A) Spring 2010, B) Spring 2011 and C) Autumn 2011. Trawls of fish sampling are also indicated. T = Transect; C = Coast; Sh = Shelf; Sl = Slope; O = Oceanic.

Figure 2. Percentage of copepods relative to the total abundance of mesozooplanktonic organisms (in number of individuals / m³) for each station selected and considered for taxonomic identification in spring 2010, spring 2011 and autumn 2011.

Figure 3. Results of the taxonomic identification performed on mesozooplankton samples collected in a spring 2010, b spring 2011 and c autumn 2011. The number above a pie corresponds to the total abundance of organisms within a station (in number of individuals m^{-3}), and the size of pies is proportional to the total abundance. Among the ‘dominant taxa’ (see text), small organisms are represented in *shades of red to yellow*, medium-sized organisms in *shades of green* and large organisms in *shades of blue* (see Table 1). Within each station, the proportion of taxa in minor proportion (i.e. with an abundance $<5\%$ when taken individually, and therefore not analysed for stable isotope ratios—see text) is indicated in *black*. The study area represented (*outlines of the box*) extends from 0° to $8^{\circ}W$ and from $43^{\circ}N$ to $48^{\circ}N$ (*Source*: Etopo1 NOAA—LIENSs—2013. Design and realisation: Cellule Géomatique LIENSs—UMR 7266)

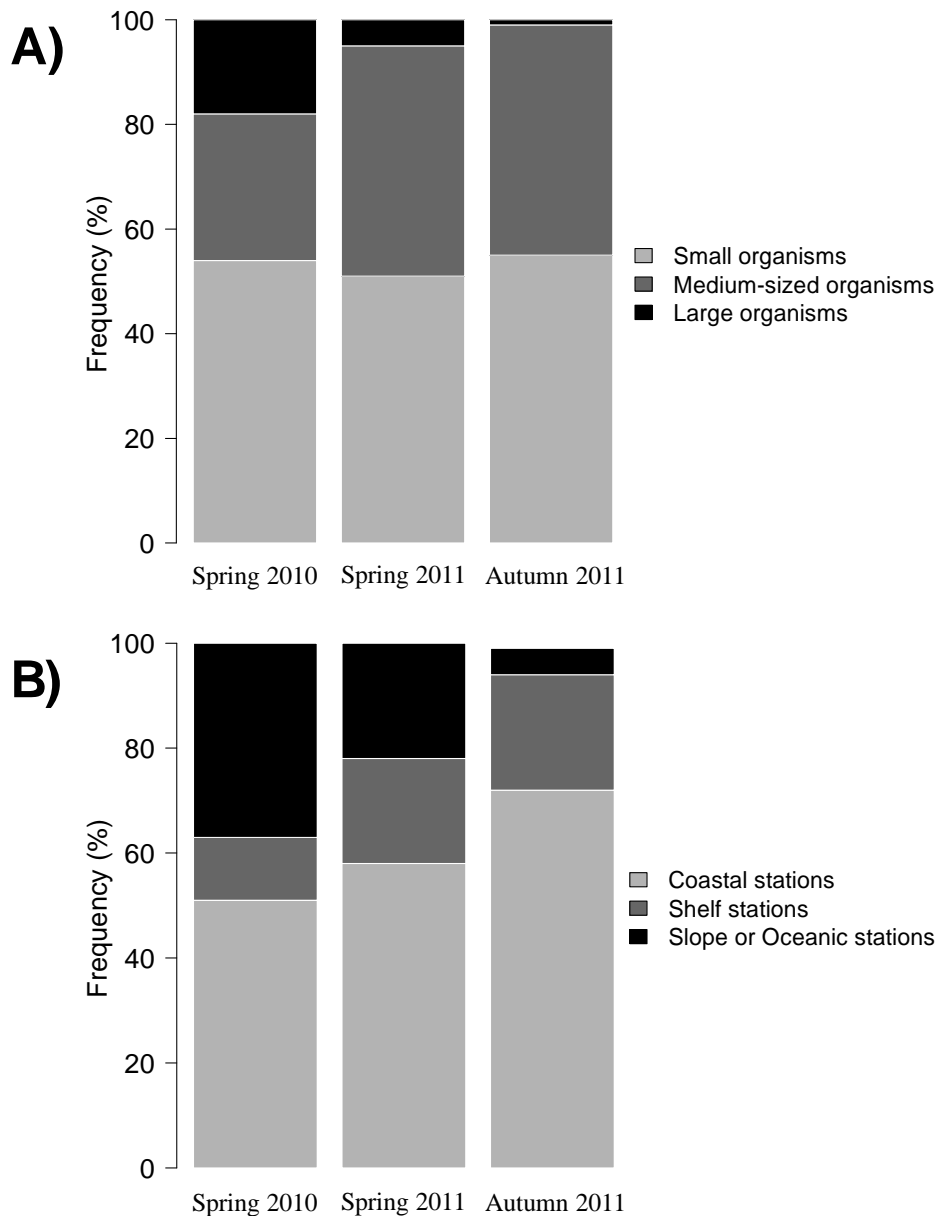

Figure 4. Stacked bar charts presenting a the frequency of identified organisms belonging to small, medium-sized or large organisms within each of the three periods considered in this study, all stations considered together over the Bay of Biscay; b the frequency of organisms identified in coastal stations, stations from the shelf or stations from the slope and oceanic stations within each of the three periods considered in this study, all sizes considered together. Only organisms belonging to ‘dominant taxa’ were taken into account for both histograms (see text).

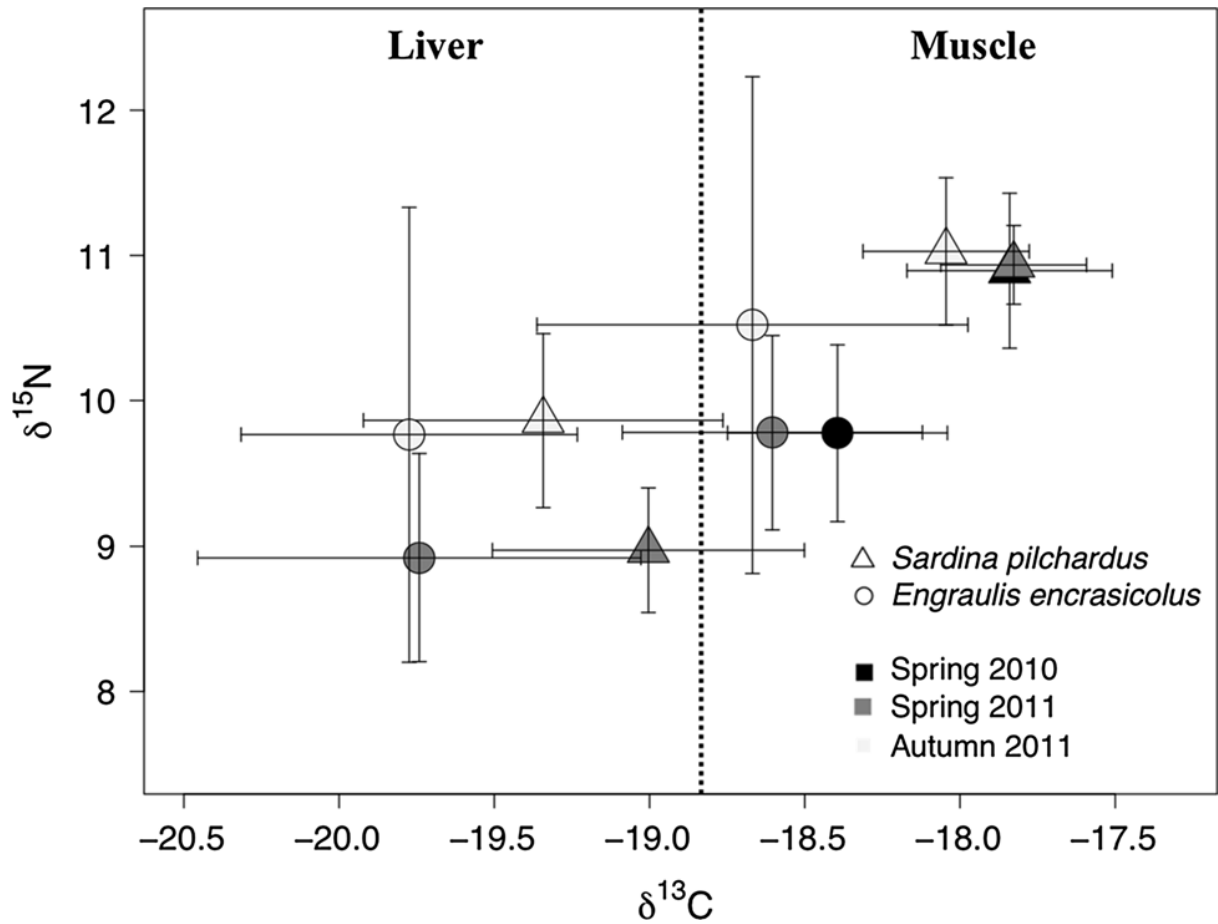

Figure 5. $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values (mean \pm SD, in ‰) for European sardine *Sardina pilchardus* and European anchovy *Engraulis encrasicolus*, depending on the period considered and on the tissue analysed. Detailed results of statistical tests for significant difference between species or between periods for a given tissue or for a given element are presented in Table 3. The *dotted line* is only drawn as a guide to visually distinguish muscle and liver tissue values that are presented here on the same figure
