Abstract

Thread milling is a machining technique which is becoming widely used in specific contexts such as large diameter threading. Furthermore, compared to tapping, it is fully adapted to produce internal threads in difficult-to-cut materials, because the tool can be easily removed if a breakage occurs. For thread milling, as well as for form milling, groove and worm machining, geometrical considerations are critical aspects to succeed surface machining with the required accuracy. Interference phenomena may appear and appropriate cutter profiles and tool trajectories have to be defined to generate the desired shape. The proposed study is focusing on the threading of non-symmetric profile. A geometrical model computing the envelope profiles and using full parametrical definitions of the tool and thread is proposed. Its exploitation allows an analysis to explain and to quantify the influencing parameters on overcut. Then, an iterative method based on a direct approach, is proposed to define the tool design allowing to machine non-symmetric threads with good accuracy.

Keywords: Modelling; Milling; Thread, Interefence

1. Introduction

Thread milling allows producing both internal and external threads and is more and more used instead of tapping for high cost parts manufacturing. Thread milling induces a lower torque, a constant cutting speed, and the tool can be easily removed when breakage occurs. As a consequence, this technique is well adapted for low machinability materials.

Thread milling is a complex technique, due to the cutting tool geometry [1] and the milling trajectory. Thus, several studies focus on geometrical and mechanical aspects [2], cutting geometry effects [3, 4], penetration strategies [4, 5], cutting force modeling [6, 7] and dynamical stability [7].

Furthermore, there is a drawback linked to the thread milling technique, interferences appear and affect the thread accuracy. This geometrical phenomenon implies more, or less respectively, material is removed, i.e. overcut, undercut respectively. The reason is that the tool shape does not fit everywhere along its profile or for any tool position, with the desired surface which is intended to machine. This is quite common in machining with form tools, as in 5-axis flank milling [8-9], during helical groove [10-14], thread [15,16] and worm [17,18] grinding or milling with disc-type tools. From a global approach, interference can be compensated by adapting the tool profile, its trajectory, or both. Finally there are two main problems linked to the interference [10,17]. The first is to compute the geometrical error from the tool shape and its trajectory; it is named the direct problem. The second is to determine the tool profile from the desired surface geometry; it is named the inverse problem. Few studies are focused on the second approach [10,11,19], most of them only deal with the computation of geometrical errors [13,14,16,18], and someone may implement an iterative algorithm to the direct model to establish the tool profile for thread grinding [15] or for thread milling [20].

In internal thread milling, the configuration is different from groove, worm or thread machining with disc type tools, because the tool axis is parallel to the thread one, which is a less favorable situation from the interference point of view. Moreover, it is proven that the tool penetration can induce a
significant overcut of the nominal thread, and the penetration has to respect different constraints to avoid it [5]. With symmetric thread profiles, the interference can be compensated during the full thread machining by changing the radius of the helical trajectory [20], which is not possible with non-symmetric thread profiles.

The present study deals with the interference compensation during the internal thread milling of non-symmetric thread profiles, such as buttress threads (S, GS & KS threads defined by DIN 513-1, DIN 55525, DIN 6063-1 standards). The used approach is based on a direct model of geometrical errors, and associated to an iterative algorithm for computing the tool profile correction and fitting the generated thread profile with the nominal one.

Nomenclature

Nominal thread characteristics:
- \( \alpha_i \): \( i \)th thread flank angle
- \( D \): major/nominal diameter (mm)
- \( D_1 \): minor diameter (mm)
- \( D_2 \): pitch diameter (mm)
- \( L_c \): crest length (mm)
- \( L_g \): groove length (mm)
- \( P \): pitch (mm)
- \( P_{ti} \): \( i \)th characteristic point of the nominal thread profile
- \( R \): major radius of the thread (mm)
- \( R_1 \): minor radius of the thread (mm)
- \( R_2 \): thread pitch radius (mm)

Mill cutter characteristics:
- \( D_m \): major diameter (mm)
- \( D_{2m} \): pitch diameter (mm)
- \( L_{cefe} \): length of the front cutting edge
- \( P_{mi} \): \( i \)th characteristic point of the mill profile
- \( P_{min} \): \( i \)th characteristic point of the new mill profile
- \( R_m \): major radius of the thread (mm)
- \( R_{1m} \): minor radius of the thread (mm)
- \( R_{2m} \): thread pitch radius (mm)

Computed parameters:
- \( E_r \): radial error between nominal and generated thread (\( P_m \))
- \( E_a \): axial error between nominal and generated thread (\( P_m \))
- \( R_{mc} \): helix radius of the mill center trajectory (mm)
- \( D_{mgt} \): maximum diameter of the generated thread flank

Geometrical objects:
- \( \text{FTP}(z) \): fundamental thread profile in \((O,E_1E_3)\) frame
- \( \text{MP}(z) \): mill profile in \((O,e_1e_3)\) frame
- \( \text{NTP}(z) \): nominal thread profile in \((O,E_1E_3)\) frame
- \( \text{EMET}(z) \): envelope of the mill envelope trace in the \((O,E_1E_3)\) plane
- \( \text{GTP}(z) \): generated thread profile in \((O,E_1E_3)\) frame

2. Thread milling parameterization

The parameterization of the thread milling operation is presented in Fig. 1. The nominal thread profile (\( \text{NTP} \)) is composed of 5 lines as shown in Fig. 2 and the mathematical formulation is the one used in [20]. Equations (1) give a full analytical definition of this profile and its 6 characteristic points in \((O,E_1E_3)\) reference system. They depend on the following parameters: thread radius \((R, R_1, R_2)\), flanks angles \((\alpha_1, \alpha_2)\) and groove and crest lengths \((L_g, L_c)\) from which result the thread pitch \((P)\).

For the initial start of the simulation, the mill profile (\( \text{MP} \)) corresponds to the nominal thread one, i.e. same groove and crest lengths, same flank angles, but with considering lower diameters so the tool can enter into the hole.
In order to focus on well-defined thread applications, further down, the following relations (2) are considered, which match with buttress thread profile according to DIN 513-1 standard.

\[
\begin{align*}
D_1 &= D - 1.5P \\
D_2 &= D - 0.75P \\
P &= 2L_c = 2L_s
\end{align*}
\] (2)

3. Interference modelling

An interference model aims at the computation of geometrical errors. The steps of the algorithm are presented in Fig. 3. The used model is the one fully detailed in [20] and which is experimentally validated and confirmed by a different mathematical approach in [5]. The principle is as followed. The radius of the mill center trajectory \( R_{mc} \) is computed, as explained in Fig. 2. For each point of the mill profile, defined by its altitude \( z_{ce} \) in mill referential, the mill envelope trace \( (O, E_3) \) plane, is calculated. Then, the generated thread profile \( (GTP) \) is resulting from the envelope of every mill envelope traces \( (EMET) \). Finally the radial error \( E_r \) and the axial error \( E_a \) are obtained by calculating the distances from the \( GTP \) profile to the fundamental thread profile \( (FTP) \), as shown in equations (3) and Fig. 4.

\[
\begin{align*}
E_r(z_{ce}) &= \|EMET(z_{ce}) - FTP(EMET(z_{ce}))E_i\| \\
E_a(z_{ce}) &= \|EMET(z_{ce}) - FTP(z_{ce})E_i\| \\
FTP(z_{ce})E_i &= EMET(z_{ce})E_i \\
EMET(P_{nig})E_i &= R_i, \quad i \in (3, 4) \\
D_{nig} &= 2\text{Min}(EMET(P_{nig})E_i, EMET(P_{nig})E_i)
\end{align*}
\] (3)

4. Parametric study

The overcut is resulting both from thread dimensions and tool ones. Table 1 is showing 8 configurations with constant flank angles and gives the maximal radial error \( E_{r\text{ max}} \) for each flank. It has to be noticed that the error may vary from a 1000 factor, and up to 1 mm. Consequently, errors linked to interference have to be corrected to produce thread within a given tolerance.

The higher the \( P/D \) ratio is, the higher the radial error is. This ratio is in relation with the thread helix angle. From a geometrical point of view, when the thread helix angle is higher, the nominal thread surface crosses much more the tool envelope which has no helix angle, because it is a revolution surface. The error sensitivity to this ratio error is very high. Nevertheless, this parameter cannot be changed from the manufacturer position, and it is only linked to thread dimensions.

The higher the \( D_m/D \) ratio is, the higher the radial error is. Thus, it is constrained, because from a mechanical point of view a bigger mill diameter makes the tool stronger and limits
its deflection. Nonetheless, this ratio sensitivity on error is lower than the one of the previous ratio.

These observations are also established in [5,20]. Furthermore, the effect of the flank angle is studied, and Fig. 5 shows simulation results for a flank angles changing from 45° to 80°.

For a given flank angle, it is observed that the error on flank slightly increases, which means the generated flank has a different angle than the nominal one.

When the flank angle moves from 70° to 80°, the maximum radial error on the flank increases from 180 μm to 800 μm. Thus, the sensitivity to the flank angle is very high, but like with the P/D ratio, it is a fixed constraint. Moreover, it appears that the flank becomes shorter when the flank angle increases (as observed on Fig. 4.). Consequently, in addition to the radial error, it is also needed to produce threads with a lower flanks prohibit the overcut, i.e. \(P_m2\) and \(P_m3\) for the lower flank, and \(P_m4\) and \(P_m5\) for the upper flank are modified. Nonetheless, there are constraints relatively to the thread geometry and several cases may appear.

First of all, the 1st test concerns the flank length. It is a condition expressed by equation (5), and the length of the front cutting edge (same condition than for the 3rd test). On the one hand, the flank has to be long enough, but on the other hand the front cutting edge length cannot be reduced over a too low value which makes the tool too brittle. At the simulation start, a low length of the front cutting edge (fce) may result directly from nominal thread geometry.

The main idea is to shift extreme points of the mill profile flanks to prohibit the overcut, i.e. \(P_m2\) and \(P_m3\) for the lower flank, and \(P_m4\) and \(P_m5\) for the upper flank are modified. The strategy for the interference compensation is mainly based on modification of the mill profile (MP). An iterative approach and the direct model for the error computation are used. Fig. 6 presents the correction algorithm which is integrated as a loop in the simulation detailed in Fig. 3. Fig. 7 shows the geometrical construction for the mill profile correction.

Fig. 5. Radial error along flanks and roots for different thread flank angles (case B: D = 16 mm; P = 3 mm; Dm = 10 mm).

5. Interference compensation

5.1. Simulation algorithm

During the 1st step, if it is necessary to increase the flank length and if it can be, \(P_m3\) and \(P_m4\) are translated in r & z directions as defined by equations (6). If not, it is most of the time after the 1st correction loop, when the MP height has been adjusted, these 2 points are only shifted in the axial direction from the axial error (equations (7)) in order to get the new points (noted with a “n” exponent).

\[
D_{\text{req}} < D
\]  

(5)
and from the new mill profile (MPn) of these two points to the right side. Depending on the 2nd test, length.

fr respecting equations (12), in order not to have too short a fundamental thread profile (Pm2g).

Then, if it is necessary, the 4th step shifts one point in r & z directions with different vectors. Then, the 4th step shifts the Pm3 point to the right side to align vertically these two points, then it results the lower flank length is longer than needed.

Thus, another threading technique like cut tapping, or form tapping for a greater precision [21], has to be chosen.

5.2. Applications of the computerized simulation

It is considered the thread milling case G, cf. Table 1. The initial maximum radial error is near 390 µm on the upper flank and 36 µm on the lower one. Fig. 8 presents the error along the flanks after each correction loop.

The maximal error after the 1st loop is drastically reduced to 6 µm. The upper flank reaches the R radius. Because αt flank angle is higher than the one on the lower flank, the error is more important on it. Thus, the correction algorithm translates further the Pm4 point in r & z directions than the Pm3 point (1st step). The 4th step shifts the Pm3 point to the right side to align vertically these two points, then it results the lower flank length is longer than needed.

During the 2nd correction loop, 1th step is applied, the points are only vertically shifted, and the flank length is not affected. The resulting radial error becomes insignificant on both flanks. This error can be considered to be null on the flanks extreme points, which is the principle of the correction algorithm. Then, the goal is reached, additional loops are useless, and this case was solved with only two iterations.
Moreover, the error being null at the extreme flank points and having a parabolic form between these points, it can be deduced that the exact solution to fit the nominal thread profile along the entire flank, is not a straight line. Nevertheless, the error being already so small, and also other phenomena that cause interference appear (tool bending, machine error), it is really considered that the simulation is sufficient enough to improve the thread accuracy.

The case B is presented on Fig. 9. The initial and maximal radial error is around 800 μm on the upper flank. Here three correction loops are needed to obtain no error on the extreme upper flank points. The residual radial error reaches 9 μm. A better profile cannot be obtained with a mill profile composed of straight lines, however it is considered to be sufficient enough. Furthermore, the main point in this application is concerning the upper flank length which does not match the R nominal thread radius. The root length of the nominal thread is initially low vs the overcut to correct, and the algorithm enforces a minimum front cutting edge length which equals to \( L_{f \epsilon} = 0.2 \text{ mm} \). Then, in this case the new mill profile is modified by the 5th step of the algorithm at each loop. Consequently, the profile cannot be higher because of the fε length constraint, and then no more flank can be generated.

In this case, the mill diameter being already low, it might not be reduced anymore. Nonetheless, the accuracy may be sufficient; it depends on the required precision. Furthermore, it also has to be considered that the root is tangent to the flank and this curve smoothly evolves. Then, for a given interval tolerance, the flank which contributes effectivity to the assembly with the screw, may be partially the root of the generated thread.

- and a global approach about the possibility to machine accurate threads with using thread milling, which would be experimentally validated with considering other aspects (tool bending …).

Furthermore, about the understanding of interference in thread milling, it is also established that the perfect solution for the mill flank profile, is not exactly a straight line, but it can be approximated very precisely by it.

The proposed simulation is only available for thread milling of profiles composed of straight lines. Further works would consider curved thread profiles, such as Rd round thread. Thus, the approach would consider the inverse problem, i.e. build the mill profile directly from the thread one, and not an iterative method.
