ABSTRACT

More and more users are watching online videos produced by non-professional sources (*e.g.*, gamers, teachers of online courses, witnesses of public events) by using an increasingly diverse set of devices to access the videos (*e.g.*, smartphones, tablets, HDTV). *Live streaming service providers* can combine adaptive streaming technologies and cloud computing to satisfy this demand. In this paper, we study the problem of preparing live video streams for delivery using cloud computing infrastructure, *e.g.*, how many representations to use and the corresponding parameters (resolution and bit-rate). We present an integer linear program (ILP) to maximize the average user quality of experience (QoE) and a heuristic algorithm that can scale to large number of videos and users. We also introduce two new datasets: one characterizing a popular live streaming provider (Twitch) and another characterizing the computing resources needed to transcode a video. They are used to set up realistic test scenarios. We compare the performance of the optimal ILP solution with current industry standards, showing that the latter are sub-optimal. The solution of the ILP also shows the importance of the type of video on the optimal streaming preparation. By taking advantage of this, the proposed heuristic can efficiently satisfy a time varying demand with an almost constant amount of computing resources.

1. INTRODUCTION

The management of live video services is a complex task due to the demand for specialized resources and to real-time constraints. To guarantee the quality of experience (QoE) for end-users, *live streaming service providers* (*e.g.*, TV operators and multimedia broadcasters) have traditionally relied on private data-centers (with dedicated hardware) and private networks. The widespread availability of *cloud computing platforms*, with ever decreasing prices, has changed the landscape [17]. Significant economies of scale can be obtained by using standard hardware, Virtual Machine (VM), and shared resources in large data-centers. As illustrated in Figure 1, live streaming providers use these services in combination with widely available content delivery network (CDN) to build an elastic and scalable platform that can adapt itself to the dynamics of viewer demand. The only condition is to be able to use the standardized cloud computing platforms to prepare the video for delivery.

The emergence of cloud computing platforms has enabled some new trends, including: (i) the adoption of adaptive bit-rate (ABR) streaming technologies to address the heterogeneity of end-users. ABR streaming requires encoding multiple video representations, and thus increases the demand for hardware resources. Modern cloud computing platforms can meet this demand. And (ii) the growing diversity of live video streams to deliver. The popularity of services like Twitch [1] illustrates the emergence of new forms of live streaming services, where the video stream to be delivered comes from non-professional sources (*e.g.*, gamers, teachers of online

Figure 1: Live streaming in the cloud

courses, witnesses of public events). Instead of a few high-quality well-defined video streams, live streaming providers have now to deal with many low-quality unreliable video streams.

In comparison to the significance of the shift, relatively few academic studies have been published. The scientific literature contains papers related to ABR streaming into CDN (*e.g.*, [2,14]). However, to the best of our knowledge, the *preparation* of the streams into data-centers has not been addressed by the scientific community. The preparation of a given video channel includes deciding the number of representations to encode, setting the encoder parameters, allocating the transcoding jobs to machines, and transcoding each raw video stream into multiple video representations.

Existing works address some of these problems individually. For instance, some papers [7,9,11–13] present algorithms to schedule transcoding jobs on a group of computers, typically in order to maximize CPU utilization [7,11] or to minimize the finishing time [12,13]. Other researchers have analyzed the performance of video encoding and the relationship between power, rate and distortion [8,21,25] using analytical models and empirical studies. In each case the encoding parameters (*i.e.*, resolution and rate) are input parameters of these algorithms, and are assumed to be known. Yet, they can have a significant impact on the QoE and on the total bandwidth used, as discussed in [22].

Even though solutions have already been proposed for these subproblems, it is non-trivial to combine them to form a single solution and there is no guarantee that a combination of optimal solutions of each subproblem is an optimal and feasible solution of the global problem. For example, selecting the available representations (resolution and bit-rate) without considering the available computing resources is likely to lead to unfeasible solutions.

In this paper we are interested in maximizing the average user QoE by selecting the optimal encoding parameters under given computing and CDN capacity constraints. More specifically, we make three contributions:

1. We provide three datasets to help the community study the problem of preparing ABR video in data-centers. The first dataset is based on a measurement campaign we have conducted on Twitch between January and April 2014. The second dataset, based on [4], gives bandwidth measurements on real clients downloading ABR streams. The third dataset is the result of a large number of transcoding operations that we have done on a standard server, which is typical of commoditized data-center hardware. Thanks to this dataset, it is possible to determine the computing resources needed to transcode a video and the QoE of the output video.
2. We formulate an optimization problem for the management of a data-center dealing with a large number of live video streams to prepare for delivery (section 5). Our goal is to maximize the QoE for the end-users subject to the number of available machines in the data-center. With this problem, we highlight the complex interplay between the popularity of channels, the required computing resources for video transcoding, and the QoE of

end-users. We formulate this problem as an integer linear program (ILP). We then use a generic solver to compare the performances of standard stream preparation strategies (where all the channels use the same encoding parameters for the transcoding operation) to the optimal. Our results highlight the gap between the standard preparation strategies and the optimal solution.

3. We propose a heuristic algorithm for the preparation of live ABR video streams (section 6). This algorithm can decide on-the-fly the encoding parameters. Our results (section 6) show that our proposal significantly improves the QoE of the end-users while using almost constant computing resources even in the presence of a time varying demand.

2. RELATED WORKS

Cloud-based transcoding has been the subject of several papers. Most of these works [7,9,11–13] take advantage of the fact that some modern video compression techniques divide the video stream into non-overlapping Group of Pictures (GOPs) that can be treated independently of each other. The encoding time of each GOP depends on its duration and on the complexity of the corresponding scene. The algorithms exploit this fact to increase the utilization of each computing node at the expense of an increased complexity, including the time and resources needed to split the input video into appropriately sized GOP.

One downside of these solutions is that they need to know the transcoding time of each GOP in order to assign it to the most suitable computing node. Some authors [7,11] propose fairly complicated systems to estimate the encoding time of each GOP based on real-time measurements, while others [9,12,13] assume that this information is directly available, for instance [9] by profiling the encoding of a few representative videos of different types, similarly to what we have done (see section 3.2). Another downside of a GOP-based solution is that the encoding of each GOP can be completed out of order and then need to be reordered before being delivered to the users. This out-of-order problem is especially important when dealing with live content that requires real-time constraints. Only Huang et al. [9] explicitly consider real-time constraints in a GOP-based system.

Lao et al. [12] and Lin et al. [13] deal only with batches of videos to transcode and present different scheduling algorithms to minimize the overall encoding time.

Zhi et al. [23] propose to leverage underused CDN computing resources to jointly transcode and deliver videos by having CDN servers transcode and store the most popular video segments. Such a solution can offer significant gains, especially for non-live popular streams, but it requires the cooperation of the CDN, which is not always owned and operated by the cloud provider.

Cheng et al. [6] present a framework for real-time cloud-based video transcoding in the context of mobile video conferencing. Depending on the number of participants and their locations, every video conference corresponds to one or more transcoding jobs, each one located in a potentially different data center. They use a simple linear model to estimate the resources needed by each transcoding job; if the currently running VMs have

enough spare capacity to handle the new job, they use them, otherwise they start new VMs, without a constraint on the total number of VMs used. They assume a *linear* relationship between the video encoding rate and CPU usage, based on some measurements, for which no details are given. As shown in section 3.2, this is not consistent with our experiments using `ffmpeg` to `encode` H.264 videos.

The literature on video encoding is vast. A few papers have studied the relationship between power consumption, rate and distortion (often abbreviated as P-R-D). The first paper to investigate the P-R-D model by He et al. [8] contains a detailed analysis and corresponding model of the video encoding process. The authors use this model to define an algorithm that, given rate and power constraints, minimizes the distortion of the compressed video. Su et al. [21] use a different definition for the distortion and propose a different algorithm to solve the same optimization problem. These works deal with a *single video flow* and take the rate as an input parameter, they do not address how to choose its value.

Yang et al. [25] present the results of an empirical study based on the H.264 Scalable Video Coding (SVC) reference software JSVM-9.19 [18]. While non-SVC H.264 can be considered as a special case consisting of only one layer, the authors emphasize the results related to the SVC part. Since the raw data is not publicly available, and since the figures in the paper do not correspond to the inputs we need, we run similar experiments leading to the dataset presented in section 3.2.

3. PROBLEM DEFINITION BY DATASETS

In this Section, we present the three datasets used throughout the paper. They will help us to introduce the parameters influencing the stream preparation. The three datasets cover the chain of involved (directly or indirectly) actors: broadcasters, live service provider, and viewers.

3.1 The Broadcasters

We will interchangeably use the terms *channel* and *broadcaster* to indicate the people using the live streaming system to deliver a video. At any given time, a channel can be either *online*, when the broadcaster emits the video stream, or *offline* when the broadcaster is disconnected. Each online period is called a *session*. During a session, a broadcaster captures a video, encodes it, and uploads it to the service provider. We say that this video stream is the *source* or the *raw video stream*. The service provider is then in charge of transcoding this video into one or multiple video representations, and of delivering these representations to the *viewers*, or *end-users*. The number of viewers watching a session can change over time. Figure 2 shows the evolution of the popularity of a given channel over time, this channel containing two sessions.

Today’s channels in cloud-based live streaming services are mostly “non-professional.” We focus here on the thousands of broadcasters who use live streaming services such as `ustream`,¹ `livestream`,² `twitch`,³ and `dailymotion`⁴ to broadcast live an event that they are capturing from

Figure 2: A life in a channel

their connected video device (*e.g.*, camera, smartphone, and game console). As opposed to the traditional TV providers and the content owners from the entertainment industry, these broadcasters usually do *not* emit ultra-HD video streams (2160p also known as *4k*) and they tolerate a short lag in the delivery. However, these broadcasters are less reliable. First, a channel can switch from offline to online and vice versa at any time. Second, the emitted streams have various bit-rates and resolutions, as well as various encoding parameters. Third, the broadcasters do not give much information about their video streams.

In this paper, we use a dataset based on Twitch, a popular live streaming systems. Twitch provides an Application Programming Interface (API) that allows anybody to fetch information. We used a set of synchronized computers to obtain a global state every five minutes (in compliance with API restrictions) between January, 6th and April, 6th 2014. We fetched information about the total number of viewers, the total number of concurrent online channels, the number of viewers per session, and some channel metadata. We then filtered the broadcasters having abnormal behavior (no viewer or online for less than five minutes during the last three months). The dataset is publicly available.⁵ We summarize the main statistics in Table 1.

Data Statistics	
total nb. of channels	1,536,492
total nb. of sessions	6,242,609
“online less than 5 min. overall” channels	25%
“no viewer” channels	11%
filtered nb. of channels	1,068,138 (69%)
filtered nb. of sessions	5,221,208 (83%)

Table 1: The Twitch dataset

Figure 3 shows the average number of concurrent online channels, which is a useful metric to estimate the computing power needed and thus the data-center dimensions. Between 4,000 and 8,000 concurrent sessions always require data-center processing.

To illustrate the diversity of the raw videos, Figure 4 shows the cumulative density function (CDF) of the bit-rates of sessions for the three most popular resolutions. The key observation is the wide range of the bit-rates, even for a given resolution. For example, the bit-rates of 360p sources range from 200 kbps to more than 3 Mbps.

3.2 The Live Streaming Service Provider

One of the missions of the live streaming service is to transform the raw video into a multimedia object that can be delivered to a large number of users. We call *preparation* this phase. In this paper, we focus on the task of *transcoding* the raw video stream into a set of ABR video streams for delivery, and we neglect other tasks such as content sanity check and the implementation of the digital right management policy. For each session, our goal is twofold: (i) to define the set of video representations to be transcoded, which supposes to decide the number of representations, and, for each representation, the bit-rate and the resolution; and, (ii) to assign the transcoding *jobs* to the data-center machines.

A key information for our study is the amount of central processing unit (CPU) cycles that are required to transcode one raw video into a video stream in a different format. This quantity depends on various parameters, but mostly on (i) the bit-rate and the resolution of the source, (ii) the type of the source, and (iii) the bit-rate and the resolution of the target video stream. To obtain a realistic estimate, we have performed a set of transcoding operations from multiple types of sources encoded at different resolutions and rates to a wide range of target resolutions and rates. For each one of the transcoding operations, we have estimated the QoE of the transcoded video, and measured the CPU cycles required to perform it. This dataset as well is publicly available.⁶

Source Types. We consider four types of video content, corresponding to four test sequences available at [24]. Each of these four test sequences corresponds to a representative video type as given in Table 2.

Video Type	Video Name
Documentary	Aspen, Snow Mountain
Sport	Touchdown Pass, Rush Field Cuts
Cartoon	Big Buck Bunny, Sintel Trailer
Video	Old Town Cross

Table 2: Test videos and corresponding type.

Source Encoding. In current live streaming systems, the encoding of the source is done at the broadcaster side. As shown in Figure 4, the raw video that is emitted by the broadcaster can be encoded with different parameters. Based on our analysis of the Twitch dataset, we consider only four resolutions, from 224p to 1080p, and we let the analysis of 4k raw videos for future works. We also restrict the video bit-rates to be in ranges covering 90% of the sources that we observe in the Twitch dataset. See Table 6 in the Appendix for more details.

Target Videos. The format of the target videos depends on the source video. For each input video we consider all the resolutions that are smaller than or equal to the input video and for each resolution we consider all the rates that are smaller or equal to the rate of the input video (see Table 6 in the Appendix for more details).

Transcoding. We perform the transcoding on a standard server, similar to what can be found in most public data-centers. The debate about whether graphics processing unit (GPU) can be used in a public cloud is still acute today. Those who do not believe in a wide availability of GPU in the cloud emphasize the poor performance of standard virtualization tools on GPU [19] and the preferences of the main cloud providers for low-end servers (the so-called *wimpy* servers) in data-centers [3]. On the other hand, new middleware have been developed to improve GPU sharing and VM-GPU matching in data-centers [16], so it may be possible to envision a wider deployment of GPU in a near future. Nevertheless, in this paper, we stick to a conservative position, which is the one adopted by today’s live streaming service providers, and we consider only the availability of CPU in the servers.

As for the physical aspect of the CPU cycles measurements, we consider that the virtualization has no impact on the performances, *i.e.* a transcoder running in a VM on a shared physical machine is as fast as if it ran directly on the physical machine. The server that we used is an Intel Xeon CPU E5640 at 2.67GHz with 24 GB of RAM using Linux 3.2 with Ubuntu 12.04.

Figure 5 shows the experimental results for all the target videos generated from a source of type “movie,” 1080p resolution and encoded at 2,750 kbps. The empirical CPU cycles measurements are depicted as marks. Section A.2 in the Appendix, gives more details on how these curves have been generated. Overall, 588 curves similar to these ones were prepared to cover the 12,168 transcoding operations. For the sake of brevity, we show only these four. The interested reader can consult the full set of curves in the publicly available dataset, as mentioned above.

Estimating QoE. We evaluate the QoE by means of the Peak Signal to Noise Ratio (PSNR) score [20], which is a full-reference metric commonly used due to its simplicity. We

⁶<http://dash.ipv6.enstb.fr/dataset/transcoding/>

apply the PSNR filter⁷ provided by `ffmpeg` in two different cases illustrated in Figure 7.

The first case, depicted on top of Figure 7, corresponds to the scenario where a target (transcoded) video at a given spatial resolution is watched on a display of the same size. The PSNR filter compares the target video against a reference video. The reference is the source encoded at the same resolution as the target but with the largest encoding bit-rate considered in this study (3,000 kbps). We repeat this measurement as many times as target videos, *i.e.*, 12,168 times. As in the case of the live-transcoding CPU curves, we only depict in Figure 6 the PSNR curves corresponding to one example. We provide the remaining set of curves in the public site hosting the dataset.

The second scenario, shown on bottom of the Figure 7, refers to the situation when a target (transcoded) video at a given resolution need to be upscaled to be watched on a display with a higher size. This up-scaling introduces a penalty on the final QoE for the viewer. To estimate these penalties, we carry out a new battery of transcoding operations, using the same `ffmpeg` command as before, but the input and output video are the target and the upscaled video, respectively. The upscaled video is compared against a reference with an encoding rate of 3,000 kbps but with the *same resolution as the upscaled target*. The penalty, using the example of up-scaling from 360p to 720p in Figure 7, can simply be computed by subtracting from the PSNR measure on top of the Figure the PSNR measurement on the bottom. In Figure 8, we depict the up-scaling penalties for a 224p source of type movie.

Figure 5: Transcoding CPU curves. Source: 1080p, 2,750 kbps, type *movie*. Target resolutions in the legend.

Figure 7: Estimating the QoE for a target video. On top, a video at 360p and 1.6 Mbps. On the bottom, the same video upscaled to be watched on a 720p display.

Figure 8: Up-scaling penalties curves. Sources: rate in x-axis, 224p, type *movie*. Target resolutions in the legend. Target rates equal to source rates

3.3 The Viewers

Finally, we need a dataset that captures the characteristics of a real population of viewers, and in particular its heterogeneity.

This dataset comes from [4]. Since the Twitch API does not provide any information about the viewers (neither their geographic positions, nor the devices and the network connections), we need real data to set the download rates for the population of viewers. The dataset presented in [4] gives multiple measurements over a large number of 30s-long DASH sessions from thousands of geographically distributed IP addresses. From their measurements, we infer the download rate of each IP address for every chunk of the session and thus obtain 500,000 samples of realistic download rates. After filtering this set to remove outliers, we randomly associate one download rate to one of the viewers watching a channel from the Twitch dataset snapshot.

4. CURRENT INDUSTRIAL STRATEGIES

Today's live service provider have to implement a strategy for stream preparation. To the best of our knowledge, no provider has yet implemented an optimal strategy. Typically one of the following two options is implemented. In the first one, used by Twitch, ABR streaming is only offered to some premium broadcasters. That is, only a small subset of channels is transcoded into multiple representations. For the other broadcasters, the raw video is forwarded to the viewers without transcoding. The problem of this solution is that many viewers of standard broadcasters cannot watch the stream because their downloading rate is too low. This problem has been recently discussed in [15].

⁷<https://www.ffmpeg.org/ffmpeg-filters.html#psnr>

The second option consists in delivering all channels with ABR streaming. This is the option we study in the paper. To the best of our knowledge, the live streaming providers apply the same transcoder settings for all channels although it has been shown in [22] that such a strategy is sub-optimal. In this paper, we consider two possible strategies.

Full-Cover Strategy. This corresponds to a strategy with one representation for each resolution smaller than or equal to the source resolution. The bit-rate is chosen such as to be the lowest possible for the former resolution (100 kbps for low resolutions and 1000 kbps for the high ones). With this strategy, viewers with low bandwidth connections and display sizes smaller than or equal to the source resolution are guaranteed to find one representation. Moreover, since the CPU requirements are low for low bit-rates, this strategy is the least CPU-hungry possible strategy (among the strategies with at least one representation per resolution).

Zencoder Strategy. We follow here the recommendations of one of the main cloud transcoding providers, namely Zencoder. The recommendations are given on their public website.⁸ We give in Table 3 the characteristics of the set of representations. Again, only representations with a bit-rate and a resolution smaller than or equal to the video source are produced.

Video Resolution	Bit-rates (in kbps)
224p	200, 400, 600
360p	1000, 1500
720p	2000
1080p	2750

Table 3: Zencoder encoding recommendations for live streaming (adapted to our bit-rate ranges).

5. OPTIMIZING STREAM PREPARATION

We first address the problem of live video stream preparation with an optimization approach. As previously said, the preparation includes both the decision about the encoding parameters of the video representations and the assignment of transcoding jobs to the machines. Our goal is to maximize the QoE of viewers subject to the availability of hardware resources. In the following we first provide a formal formulation of the problem, and then we present the ILP model that we use to solve the optimization problem. Finally, we compare the performance of the industry-standard strategies with the optimal.

5.1 Notations

Let \mathcal{I} be the set of raw video streams encoded at the broadcaster side. Each video stream $i \in \mathcal{I}$ is characterized by a type of video content $v_i \in \mathcal{V}$, an encoding bit-rate $r_i \in \mathcal{R}$ and a spatial resolution $s_i \in \mathcal{S}$, where \mathcal{V} , \mathcal{R} and \mathcal{S} are the sets of video types, the set of encoding bit-rates (in kbps) and the set of spatial resolutions, respectively. We have shown in Section 3.1 the diversity of raw videos.

Let \mathcal{O} be the set of the possible video representations that are generated from the source by transcoding jobs. Each

⁸<http://zencoder.com/en/hls-guide>

Name	Description
$f_{iou} \in \mathbb{R}^+$	QoE level for representation o transcoded from stream i watched on a display of size s_u
$f_{io} \in \mathbb{R}^+$	QoE level for representation o transcoded from stream i if display size s_u matches resolution s_o
$q_{ou} \in \mathbb{R}^+$	Penalty due to up-scaling from resolution s_o to display size s_u
$d_{iu} \in \mathbb{Z}^+$	Number of viewers of type u watching a stream i
$r_o \in \mathbb{R}^+$	Value in <i>kbps</i> of the bit-rate of the representation o
$c_u \in \mathbb{R}^+$	Connection capacity in <i>kbps</i> of viewer type u
$v_u \in \mathcal{V}$	Video stream requested by viewer type u
$s_u \in \mathcal{S}$	Display size (spatial resolution) of viewer type u
$N \in \mathbb{Z}^+$	Overall number of viewers
$R \in [0, 1]$	Minimum fraction of viewers that must be served
$p_{io} \in \mathbb{R}^+$	CPU requirement to perform the live transcoding from stream i to representation o in <i>GHz</i>
$P_m \in \mathbb{R}^+$	CPU capacity of a machine m in <i>GHz</i>

Table 4: ILP notation.

representation $o \in \mathcal{O}$ corresponds to a triple (v_o, r_o, s_o) , that is, to a video representation of type of content $v_o \in \mathcal{V}$ encoded at the resolution $s_o \in \mathcal{S}$ and at the bit-rate $r_o \in \mathcal{R}$.

Let \mathcal{M} be the set of physical machines where the transcoding tasks should be performed. Each machine $m \in \mathcal{M}$ can accommodate transcoding jobs up to a maximum CPU load of P_m GHz.

To reduce the size of the problem, and make it more tractable, we introduce the notion of *viewer type*. Let \mathcal{U} be the set of viewers types. All viewers in a given viewer type $u \in \mathcal{U}$ have the same display resolution (i.e., the spatial resolution at which the video is displayed on the device) $s_u \in \mathcal{S}$, request the same video type $v_u \in \mathcal{V}$, and use an Internet connection with the same bandwidth of c_u kbps. However, viewers of the same type u watch different channels. We denote by d_{iu} the number of viewers of type u watching a given channel i . Note that a viewer of a given type u can play segments encoded at resolutions lower than its display size s_u by performing spatial up-sampling before rendering.

A viewer from viewer type u watching a video representation o transcoded from a stream i experiences a QoE level of f_{iou} , which is an increasing function of the bit-rate r_o . Based on the dataset presented in Section 3.2, we know that the QoE function depends on the video content type v_o , the resolution s_o and the original raw video stream i . As previously said, the QoE level f_{iou} also depends on whether the video should be up-scaled or not, since up-scaling introduces a penalty on the final QoE value. We incorporate this up-scaling penalty into the QoE computation by the following definition of f_{iou} :

$$f_{iou} = \begin{cases} f_{io}, & \text{if } s_o = s_u \\ f_{io} - q_{ou}, & \text{if } s_o < s_u \end{cases} \quad i \in \mathcal{I}, o \in \mathcal{O}, u \in \mathcal{U} \quad (1)$$

where f_{io} is the QoE level when the display resolution and the target video resolution match, and q_{ou} is the penalty of the up-scaling process from resolution s_o to the viewer display size s_u . Table 4 summarizes the notation used throughout the paper.

Integer Linear Programming formulation

$$\max_{\{\alpha, \beta\}} \sum_{i \in \mathcal{I}} \sum_{o \in \mathcal{O}} \sum_{u \in \mathcal{U}} f_{iou} \cdot \alpha_{iou} \quad (2a)$$

$$\text{s.t. } \alpha_{iou} \leq N \cdot \sum_{m \in \mathcal{M}} \beta_{iom}, \quad i \in \mathcal{I}, o \in \mathcal{O}, u \in \mathcal{U} \quad (2b)$$

$$\sum_{m \in \mathcal{M}} \beta_{iom} \leq \sum_{u \in \mathcal{U}} \alpha_{iou}, \quad i \in \mathcal{I}, o \in \mathcal{O} \quad (2c)$$

$$\alpha_{iou} \leq \begin{cases} N, & \text{if } s_u \geq s_o \\ 0, & \text{otherwise} \end{cases} \quad i \in \mathcal{I}, o \in \mathcal{O}, u \in \mathcal{U} \quad (2d)$$

$$\sum_{o \in \mathcal{O}} \alpha_{iou} \leq d_{iu}, \quad i \in \mathcal{I}, u \in \mathcal{U} \quad (2e)$$

$$\sum_{i \in \mathcal{I}} \sum_{o \in \mathcal{O}} (r_o - c_u) \cdot \alpha_{iou} \leq 0, \quad u \in \mathcal{U} \quad (2f)$$

$$\sum_{i \in \mathcal{I}} \sum_{o \in \mathcal{O}} \sum_{u \in \mathcal{U}} \alpha_{iou} \geq R \cdot N, \quad (2g)$$

$$\beta_{iom} \leq \begin{cases} 1, & \text{if } (v_i = v_o \ \& \\ & s_i = s_o \ \& \\ & b_i > b_o) \ \parallel \\ & (v_i = v_o \ \& \\ & s_i > s_o \ \& \\ & b_i \geq b_o) \\ 0, & \text{otherwise} \end{cases} \quad i \in \mathcal{I}, o \in \mathcal{O}, m \in \mathcal{M} \quad (2h)$$

$$\sum_{m \in \mathcal{M}} \beta_{iom} \leq 1, \quad i \in \mathcal{I}, o \in \mathcal{O} \quad (2i)$$

$$\sum_{i \in \mathcal{I}} \sum_{o \in \mathcal{O}} p_{io} \cdot \beta_{iom} \leq P_m, \quad m \in \mathcal{M} \quad (2j)$$

$$\alpha_{iou} \in [0, N], \quad i \in \mathcal{I}, o \in \mathcal{O}, u \in \mathcal{U} \quad (2k)$$

$$\beta_{iom} \in \{0, 1\}, \quad i \in \mathcal{I}, o \in \mathcal{O}, m \in \mathcal{M} \quad (2l)$$

5.2 ILP Model

We now describe the ILP. The decision variables in the model are:

$\alpha_{iou} \in \mathbb{Z}_{\geq 0}$: Number of viewers of type u watching a representation o transcoded from a stream i .

$$\beta_{iom} = \begin{cases} 1, & \text{if machine } m \text{ transcodes stream } i \text{ into} \\ & \text{representation } o \\ 0, & \text{otherwise.} \end{cases}$$

With these definitions, the optimization problem can be formulated as shown in (2).

The objective function (2a) maximizes the average viewer QoE. The constraints (2b) and (2c) set up a consistent relation between the decision variables α and β . The constraint (2d) establishes that a viewer of type u can play only the transcoded representations o with spatial resolutions equal or smaller than the viewer display size s_u , that is, those susceptible to experience an up-sampling operations at the rendering. The constraints (2e) ensures that the sum of all the viewers of type u watching any representation o transcoded from a given stream i does not exceed the number of viewers of type u originally watching the stream i . The constraint (2f) limits the viewer link capacity. The constraint (2g) force us to serve at least a certain fraction R of viewers. The constraint (2h) forces that only transcoding operations defined over the same video content type are allowed and it forbids senseless transcoding operations, like transcoding to higher bit-rates

or higher resolutions or transcoding to the same rate-resolution pair. The constraint (2i) guarantees that a given transcoding task (i, o) is performed in one unique machine m . Finally, (2j) sets the CPU capacity of each machine m .

5.3 Settings for Performance Evaluation

To find the exact solution of the optimal problem, we use the generic solver IBM ILOG CPLEX [10] on a set of instances. Unfortunately, this approach does not allow solving instances as large as the ones that live service providers face today. Thus, we have built problem instances based on the datasets introduced in Section 3 but of a smaller size.

Incoming Videos from Broadcasters. We restrict the size of the set of sources by picking only the 50 most popular channels from the Twitch dataset (see Section 3.1). More precisely, we take 66 snapshots from the dataset, corresponding to those ones extracted every 4 hours along 11 days since April, 10th 2014 at 00:00. For each snapshot, we use the channel information (bit-rate and resolution), which we modify slightly to match the spatial resolutions and bit-rates from Table 6. Each channel is randomly assigned to one of the four video types given in Table 2.

QoE for Target Videos. We use the dataset presented in Section 3.2 to obtain the QoE (estimated as a PSNR score) f_{io} of a target video o obtained from transcoding a source i . The up-scaling penalties q_{ou} are fixed using PSNR measures from the situation shown on bottom of the Figure 7 (target resolution lower than display one).

CPU for the Transcoding Tasks. Still to reduce the size of the instances, and thus the complexity of the problem, we fit an exponential function to the set of CPU measurements:

$$p = a \cdot r^b \quad (3)$$

where p is the number of GHz required to transcode a source into a target, a and b are the parameters used in the curve fitting and the parameter r is the bit-rate in Mbps of the target video. The values of the parameters a and b depend on (i) the source video (content type, bit-rate and resolution), and (ii) the resolution of the target video. The fitting curves are identified by continuous lines in Figure 5. Table 5 gives the parameters a and b used in the curves shown in Figure 5.

Target Resol	a	b
224p	0.673091	0.024642
360p	0.827912	0.033306
720p	1.341512	0.060222
1080p	1.547002	0.080571

Table 5: Parameters of the fitting model of the transcoding CPU curves. Source stream: 1080p, 2,750 kbps, movie

Viewers. The viewers set \mathcal{U} is based on the dataset [4] presented in Section 3.3. However, the number of viewers is too large and we implement the concept of user type. To build the types, we divide the range of bandwidth into *bins*, whose limits are selected so that each bin contains an equal number of viewers. A viewer type corresponds to a bin, with a display spatial resolution set according to the lower bandwidth in the bin, and the downloading rate of

the viewer type is equal to the lower bandwidth in the bin. The number of viewers d_{iu} watching a raw video i is proportionally set up according to the popularity of the channel in the Twitch dataset.

5.4 Numerical Results

We now show the results of our analysis. We use the previous settings and we also fix the CPU capacity P_m of all the machines to 2.8 GHz, the speed clock of the physical processors used by the amazon cloud computing C3 instances⁹. Our motivation is to determine how far from the optimal are current industry-standard strategies. In Figure 9, we represent the average QoE, expressed as the PSNR in dB, as a function of the number of machines. The line represents the results obtained from solving the optimization problem with CPLEX. We show with grey pins the results for both industry-standard strategies. The results are the average over all the snapshots we took from the Twitch datasets.

We first emphasize that the amount of hardware resources in the data-center has a significant impact on the QoE for the viewers. The difference of PSNR reaches 4 dB between 10 and 100 machines. This remark matters because it highlights the need of being able to reserve the right amount of resources in the data-center. However, the ability to forecast the load and to reserve the resources is not trivial for elastic live streaming services such as Twitch.

Our second main observation is that, on our datasets, the Full-Cover strategy is more efficient than the Zencoder one in terms of trade-off QoE-CPU. The Full-Cover strategy is close to the optimal, and thus represents an efficient implementation with respect to its simplicity. Note however that Full-Cover needs 48 machines, while there exists a solution with the same QoE but with only 35 machines. Therefore, a significant reduction of resources to reserve can be obtained. The Zencoder strategy is outperformed by the Full-cover one, as it consumes nearly twice the CPU cycles for a tiny increase of the QoE. For a similar amount of CPU, the QoE gap between the Zencoder strategy and the optimal is more than 0.9 dB, which is significant.

Figure 9: Optimal average QoE for the viewers vs. the number of machines that are used in the data-centers. The 50 most popular channels from several snapshots of the Twitch datasets are transcoded.

To complete this study, we provide another view of the choices to be taken in Figure 10. Here, we show the ratio of served users and the amount of delivery bandwidth required to serve the users. In our ILP, we optimize the average QoE so the solutions found by CPLEX are not optimal on other aspects. In Figure 10b, we see that the delivery bandwidth of the optimal solution is significantly higher than the Full-Cover, which may annihilate the gains obtained by using fewer machines. Please note that both parameters of Figure 10 can also be the objective of the ILP. In the same vein, the ILP can also be re-written so that the parameter to be optimized is the amount of CPU needed, subject to a given QoE value.

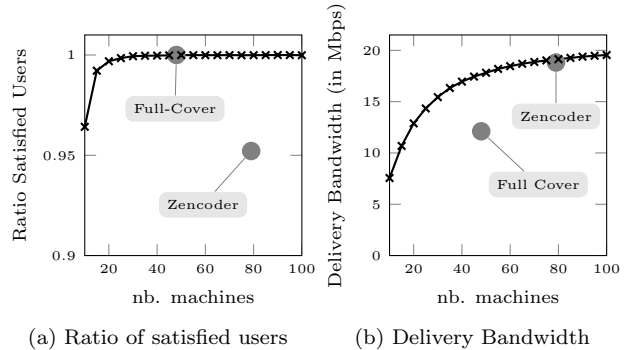

Figure 10: Other views on the optimal solution of Figure 9

6. A HEURISTIC ALGORITHM

We now present and evaluate an algorithm for massive live streaming preparation. Our goal is to design a fast, light, adaptive algorithm, which can be implemented in production environments. This algorithm should in particular be able to *absorb* the variations of the streaming service demand while using a fixed data-center infrastructure.

6.1 Algorithm Description

The purpose of the algorithm is to update the set of transcoded representations with respect to the characteristics and the popularity of the incoming raw videos. The algorithm is executed on a regular basis (for example every five minutes to stick to the Twitch API) by the live streaming service provider in charge of the data-center. You can find in Appendix B the pseudo-code of the algorithms and some additional details.

Algorithm in a Nutshell. We process each channel iteratively in a decreasing order of their popularity. For a given channel, the algorithm has two phases: First, we decide a CPU budget for this channel. Second, we determine a set of representations with respect to the CPU budget computed during the first phase.

Set a CPU Budget Per Channel. We base our algorithm on the observations of the optimal solutions found by CPLEX. Four main observations are illustrated in Figure 14 in the Appendix: (i) the ratio of the overall CPU budget of a given channel is roughly proportional to the ratio of viewers watching this channel; (ii) the CPU budget per channel is less than 10 GHz; (iii) some video types

⁹<http://aws.amazon.com/ec2/instance-types/>

(e.g., sport) require more CPU budget than others (e.g., cartoon); and (iv) the higher is the resolution of the source, the bigger the CPU budget.

We derive from these four observations the algorithm shown in Algorithm 1. We start with the most popular channel. We first set a *nominal* CPU budget according to the ratio of viewers and the maximal allowable budget. Then we adjust this nominal budget based on a *video type weight* and a *resolution weight* (interested readers can find in the Appendix details about the values we chose for these weights, based on observations from the optimal solutions). We obtain a CPU budget for this channel.

Decide the Representations for a Given CPU Budget. The pseudo-code is detailed in Algorithm 2. This algorithm builds the set of representations by iteratively adding the best representation. At each step, the needed CPU budget to transcode the chosen representation should not exhaust the remaining channel budget. To decide among the possible representations, we need to estimate the QoE gain that every possible representation can provide if it is chosen. To do so, we estimate the assignment between the representations and the viewers in Algorithm 3. In short, this algorithm requires a basic knowledge on the distribution of downloading rates in the population of viewers, which is usually the case for service providers. (In this work, we study the worst case scenario where service providers do not have this information and they assume a uniform distribution in the range between 100 kbps and 3,000 kbps). The idea is then to assign subsets of the population to representations and to evaluate the overall QoE. Details are given in the Appendix.

6.2 Simulation Settings

Our simulator is based on the datasets presented in Section 3 and the extra settings given in Section 5.3. However, in contrast to the ILP, our heuristic is expected to scale. Therefore we evaluate the heuristic and the aforementioned industry-standard strategies on the complete dataset containing all online broadcasters at each snapshot. Regarding the viewers, we consider now each viewer, to which we randomly assign a bandwidth value as presented in Section 3.3 and a display resolution accordingly. We use the actual number of viewers watching channels according to the Twitch dataset.

Please note also that we focus here on the decision about the representations (number of representations and transcoding parameters), and we neglect the assignment of transcoding jobs to machines. This does not impact the evaluation since all tested strategies (our heuristic and both industry-standard strategies) can be evaluated without regard to this assignment. We let for future works the integration of the VM assignment policy into middleware such as OpenStack.¹⁰

6.3 Performance Evaluations

In the following, we present the same set of results from two different perspectives; first, we show how the performances evolve throughout the eleven days we consider. Then, we present the results in order to highlight the main features of the algorithms.

In Figure 11 we show the three main metrics during our 11-days dataset. The combination of the three figures reveals the main characteristics of the strategies. The main point we would like to highlight is that our heuristic keeps a relatively constant, low CPU consumption without regard to the traffic load in input. Our heuristic also succeeds in maintaining a high QoE. To achieve this excellent trade-off, our heuristic adjusts with the ratio of served viewers. Yet, this ratio maintains a high value since it is always greater than 95%. Our heuristic thus demonstrates the benefits from having different representation sets for the different channels according to their popularity. The industry-standard strategies are less capable of absorbing the changing demand. In particular, the CPU needs of the Zencoder strategy ranges from 1,000 GHz to 18,000 GHz while the average QoE is always lower than for our heuristic.

To highlight the relationship between CPU needs and QoE for the population, we represent in Figure 12 a cloud of points for each snapshot. The Full-Cover has most points in the southwest area of the Figure, which corresponds to a low CPU utilization but also a low QoE. We also note that the distance between two points can be high, which emphasizes an inability to absorb load variations. This inability is even stronger for the Zencoder strategy, for which the points are far from each other, covering all areas of the Figure. On the contrary, our heuristic absorbs well elastic services, with points that are concentrated in the northwest part of the Figure, which means low CPU and high QoE.

7. CONCLUSIONS

This paper studies the management of new live adaptive streaming services in the cloud from the point of view of *streaming providers* using *cloud computing platforms*. All the simulations conducted in the paper make use of real data from three datasets covering all the actors in the system. The study is focused on the interactions between the optimal video encoding parameters, the available CPU resources and the QoE perceived by the end-viewers. We use an ILP to model this system and we compare its optimal solution to current industry-standard solutions, highlighting the gap between the two. Due to the ILP computational limitations, we propose a practical algorithm to solve problems of real size, thanks to key insights gathered from the optimal solution. This algorithm finds representations beating the industry-standard approaches in terms of the trade-off between viewers QoE and CPU resources needed. Furthermore, it uses an almost-constant amount of computing resources even in the presence of a time varying demand.

APPENDIX

A. TRANSCODING CPU USAGE

In this Appendix we give more details about the experiments that we have used to estimate the CPU usage of different transcoding operations.

A.1 Input and Output Rates

As discussed in Section 3.2, we consider only the rates covering 90% of the sources that we observe in the Twitch dataset, as detailed in Table 6. For low resolutions (224p and 360p), the set of bit-rates ranges from 100 kbps up to 3000 kbps with steps of 100 kbps, while for high resolutions (720p and 1080p), the set of bit-rates ranges from 1000 kbps up to 3000 kbps with steps of 250 kbps. Thus, each video sequence from Table 2 can be encoded into 78 different combinations of rates and resolutions. To obtain these 78 sources, we took the original full-quality decoded videos from Table 2 and we encoded them into each of the 78 videos that we consider as possible raw videos.

Resol.	Width × Height	Min–Max Rates	Rate Steps
224p	400 × 224	100–3000 kbps	100 kbps
360p	640 × 360	100–3000 kbps	100 kbps
720p	1280 × 720	1000–3000 kbps	250 kbps
1080p	1920 × 1080	1000–3000 kbps	250 kbps

Table 6: Resolutions and ranges of rates for the raw videos.

A.2 Transcoding

The transcoding operation that we have performed is summarized in Figure 13. This operation has been done 12,168 times in total. This corresponds to 4 (the number of video types) multiplied by 78 (the number of possible sources) multiplied by 39 (the average number of possible target videos). Recall that, for each input video, we produced only videos with resolutions and bit-rates lower than or equal to those of the input. That is, only a subset

of the 78 possible representations are created from a given raw video.

We have used `ffmpeg` for the transcoding with the same parameters as in [5], which is a study conducted by the leading developers of the popular GPAC video encoder. The command is

```
ffmpeg -i source_name -vcodec libx264 -preset
ultrafast -tune zerolatency
-s target_resolution -r 30 -b target_rate -an
target_name
```

Figure 13: Measuring the CPU cycles for the transcoding of any source to any target video. Here an example with a source at 720p and 2.25 Mbps and a target video at 360p and 1.6 Mbps.

Measuring CPU cycles. As discussed above and in Section 3.2, we have run many transcoding operations using an Intel Xeon CPU E5640 at 2.67GHz with 24 GB of RAM using Linux 3.2 with Ubuntu 12.04. To measure the number of used CPU cycles, we use the `perf` tool¹¹, a profiler for Linux 2.6+ based systems, with the next command:

```
perf stat -x -e CYCLES
```

This command provides access to the counter collecting the number of CPU cycles at the Performance Monitoring Unit (PMU) of the processor. Then, this number is divided by the duration in *s* of the video sequences to obtain the frequency of CPU (in GHz) required to perform the transcoding during a running time equal to the play time of the video, that is, the frequency of CPU required to do a live transcoding.

B. HEURISTIC

B.1 Settings

CPU Budget Per Channel. The values we used for both *video type weight* and *resolution weight* are given in Tables 7. These values correspond the average of the curves plotted in Figure 14, which we obtain from the optimal solutions computed by CPLEX on the 50 most popular channels and 100 machines. The *x*-axis is the rank of the channels according to their popularity. On the top we show the average distribution of CPU budget per channel. On the bottom, we show the average difference between the average CPU budget when a channel from a given type (respectively resolution) is at a given rank and the average CPU budget for channels at this rank. This difference allows us to compute the adjustment of CPU budget according to the video type and the resolution.

¹¹<https://perf.wiki.kernel.org>

Video Type	Weight	Resolution	Weight
Cartoon	-0.176	224p	-0.917
Documentary	0.072	360p	-0.657
Sport	0.190	720p	-0.108
Video	-0.076	1080p	0.432

Table 7: Video type and resolution weights

Figure 14: CPU information for a given channel popularity rank. Data comes from the average optimal solution with 100 machines. From the average total CPU % according to the rank (top figure), we derive the difference between distinct video types (middle figure) and between distinct channel input resolutions (bottom figure).

Estimation Viewers QoE. To estimate the QoE gain when choosing one representation, we need to consider all the assignments representations-viewers. In Algorithm 3, we evaluate the representations in the set in descending order of their bit-rates. At each iteration, we identify the fraction of viewers whose bandwidth is between the rate of the considered representation and the closest representation with superior bit-rate. Then, we also have to take into account the display sizes of the viewers (it also depends on the knowledge of the service provider; we again considered it a minimal knowledge of the population). Therefore, this fraction of viewers is again split into one or more sub-fractions corresponding to their display resolutions. A different value of PSNR is then computed for each sub-fraction. This value is multiplied by the ratio of viewers belonging to the sub-fraction. When all the representations have been assessed, the sum of the PSNR contributions of all the sub-fractions of viewers is returned as the estimated QoE of the set.

B.2 Algorithms in Pseudo-code

This section includes the pseudo-codes of the heuristic described in Section 6.

Algorithm 1: Main routine

Data: **channelsSet:** Channels metadata (e.g. number of viewers, id) sorted by decreasing channel popularity.
Data: **totalCPU:** total CPU Budget in GHz.

```

1 representations ← emptySet()
2 foreach channel ∈ channelsSet do
3   cpu ← channel.viewersRatio * totalCPU
4   cpu ← min(cpu, MAX_CPU)
5   w_video ← getVideoTypeWeight(channel.video)
6   w_resol ← getResolutionWeight(channel.resolution)
7   cpu ← max(cpu * (1 + w_video + w_resol), 0)
8   representations.append(findReps(channel, cpu))
9 return representations

```

Algorithm 2: findReps Find the channels representations set meeting a budget

Data: **channel:** Channel metadata (e.g. number of viewers, id).
Data: **CPU:** calculated channel CPU Budget in GHz.

```

1 representations ← emptySet()
2 freeCPU ← CPU
3 repeat
4   newRep ← false
5   foreach
6     resolution ≤ channel.resolution ∈ resolutionsSet do
7       foreach bitRate ∈ bitRatesSet[resolution] do
8         thisRep ← (resolution, bitRate)
9         if bitRate ≤ channel.bitRate and
10        thisRep ∉ representations then
11          thisRep.cpu ← getCPU(thisRep, channel)
12          if thisRep.cpu ≤ freeCPU then
13            reps ← representations + thisRep
14            thisRep.qoe ← getQoE(reps, channel)
15            if not newRep or
16              newRep.qoe < thisRep.qoe then
17              newRep ← thisRep
18 if newRep then
19   representations.append(newRep)
20   freeCPU − = newRep.cpu
21 until not newRep
22 return representations

```

Algorithm 3: getQoE Obtain an estimation of PSNR for a given representation set of one channel

Data: **channel:** Channel metadata (e.g. number of viewers, id).
Data: **repSet:** Set of representations for a given channel.

```

1 totalPSNR ← 0
2 foreach rep ∈ repSet do
3   ranges ← getResolutionsRanges(rep)
4   foreach viewersRange ∈ ranges do
5     v_ratio ← getViewersRatio(viewersRange)
6     v_resol ← getViewersResolution(viewersRange)
7     partialPSNR ← calcPSNR(rep, channel, v_resol)
8     totalPSNR+ = v_ratio * partialPSNR
9 return totalPSNR

```
