Abstract. Meat quality includes intrinsic qualities (the characteristics of the product itself) and extrinsic qualities (e.g. animal health and welfare, environmental impacts, price). There is still a high level of variability in beef palatability, which induces consumer dissatisfaction. We also observe a general trend towards an increasing importance of healthiness and safety (intrinsic) and environmental issues and animal welfare (extrinsic). Most grading systems describe carcasses using only animal traits (e.g. weight, conformation, fatness, animal age and sex). In North American and Asian countries, emphasis has been put on maturity and marbling. The European system is mainly based on yield estimation. The Meat Standards Australia grading scheme, which predicts beef palatability for each cut, proved to be effective in predicting beef palatability in many other countries. Some genetic markers are available to improve beef quality. In addition, gene and protein expression profiling of the bovine muscle revealed that the expression level of many genes and the abundance of many proteins may be potential indicators of muscle mass, tenderness, flavour or marbling of meat. The integration of all these parameters is likely to predict better beef palatability. The integration of extrinsic qualities in the prediction model increases the difficulty of achieving a global evaluation of overall meat quality. For instance, with respect to environmental issues, each feeding system has its own advantages and disadvantages. Despite this, win–win strategies have been identified. For example, animals that were less stressed at slaughter also produced more tender meat, and in some studies the most economically efficient farms had the lowest environmental impact. In other cases, there are trade-offs among and between intrinsic and extrinsic qualities. In any case, the combination of the different integrative approaches appears promising to improve the prediction of overall beef quality. A relevant combination of indicators related to sensory and nutritional quality, social and environmental considerations (such as e.g. carbon footprint, animal welfare, grassland biodiversity, rural development) and economic efficiency (income of farmers and of other stakeholders of the supply chain, etc.) will allow the prediction of the overall quality of beef mainly for consumers but also for any stakeholder in the supply chain.

Additional keywords: data combination, palatability, prediction model, social expectations.

Received 12 March 2014, accepted 18 June 2014, published online 19 August 2014

Introduction

Despite a great deal of research and effort by the industry to control beef quality, its variability remains high. The inability of the supply chain to guarantee consistent good-quality beef to the consumer is one reason for dissatisfaction. Consumers' beef purchase intentions depend mainly on beef eating quality attributes, which are a combination of consumers' taste, tenderness and juiciness assessments (reviewed by Hocquette *et al.* 2014). Consumers generally welcome the idea of a beef eating-quality guarantee, but, to do so, we need the tools to deliver a reliable outcome in a commercial setting (Verbeke *et al.* 2010).

Consumers also have increasing concerns for traceability, safety and healthiness due to different safety crises (bovine spongiform encephalopathy, foot and mouth disease, etc.). Statements from the medical profession that beef meat may be a risk for the development of various diseases in humans, despite existing strategies to enhance nutritional value of beef such as increasing omega-3 fatty acids, add to these concerns (reviewed by Doreau *et al.* 2011). All these factors have induced a decrease in beef consumption in most developed countries, and this trend was amplified by media campaigns (illicit trading and use of hormones, safety crisis, emphasis on environmental degradation

by livestock, etc.). Consumers' dissatisfaction was further amplified by economic and societal evolutions (industrialisation, intensification of agriculture and urbanisation), which have delivered cheaper meat alternatives (chicken, pork) (reviewed by Pethick *et al.* 2011) and also induced a disconnection between citizens and consumers on one hand, and farmers and farm animals on the other hand. As a consequence, urban citizens and consumers have more and more concerns related to animal welfare and environmental issues relative to beef production.

The problems mentioned above are resolvable. For example, Scollan *et al.* (2011) indicated that there were numerous synergies and win-win strategies to improve simultaneously beef quality, safety and carbon footprint as well as animal welfare. Science and innovation have a major role to play in helping the industry respond to societal and consumer concerns and expectations, and can contribute substantially to finding solutions for major challenges facing the beef industry. Unfortunately, transfer of knowledge and innovation from science to the industry is weak in the meat sector and needs to be strengthened to maintain its competitiveness (Troy and Kerry 2010).

In the first section of this review, recent progress to predict beef palatability (one major intrinsic quality criterion of beef) will be described based on the recent evolution of grading systems and more long-term research (in muscle biochemistry and genomics). The second section will deal with win-win strategies or trade-offs for extrinsic quality traits of beef (welfare, environmental, societal or economic issues) and intrinsic ones. In this section, examples of win-win strategies to enhance sensory traits (tenderness) while maximising animal welfare, farm efficiency and low environmental impacts will be described. The last section will suggest research priorities based on multicriteria analyses to develop integrative approaches aiming to respond to a range of demands of consumers and citizens while producing beef with enhanced palatability.

Recent progress to predict beef quality

Grading systems: towards a global appraisal of beef palatability

Grading has been developed to provide a common basis for the description of carcasses for pricing purposes and for use in trade for the transaction between livestock producers and meat processors. There are many carcass-based grading systems in the World depending on the country (reviewed by Polkinghorne and Thompson 2010). There is also a trend to move away from visual classification towards automated, non-destructive, non-invasive, objective, cost-effective, and accurate methods to assess carcass characteristics in the abattoir at line speed (reviewed by Craigie *et al.* 2012). Current carcass grading systems include several characteristics, such as carcass weight, and according to the system, sex, age or maturity of the animal, fatness, fat colour, and carcass conformation. The EUROP grid of carcass classification was developed in the common EU market (Council Regulation 1234/2007). It is based on visually assessed scores for conformation and fat classes, which are combined to form a categorical description of the carcass. The EUROP grid is mainly based on yield estimation to pay producers, but it does not predict eating quality at the consumer level (Bonny *et al.* 2013).

In countries from Asia, America and Oceania, the carcass grading systems also include marbling and lean colour. USDA Quality Grades are used to predict the palatability of meat from a beef carcass, using carcass physiological maturity and marbling. USDA 'Prime' is the top grade of beef available on the market. 'Prime' has the most amount of marbling, which is supposed to guarantee taste, tenderness and juiciness. 'Choice' is typically lower in cost and quality, but still provides good beef. USDA 'Select beef' is the lowest grade of beef. It is much leaner than 'Prime' or 'Choice'.

In reality, most of the current carcass grading and classification schemes are indicators of cattle finishing or fatness and/or meat yield rather than indicators of the real beef palatability at the consumer level (reviewed by Polkinghorne and Thompson 2010). Therefore, consumer grading schemes were set up to predict more or less accurately consumer satisfaction with ready-to-use products. Depending on perception of consumers' expectations, different strategies were developed based on tradition, image, geographical origin or palatability. In Europe, consumers have to make a choice between official labels and non-official ones. The former identify a superior quality based on image and palatability (e.g. 'Label Rouge' in France), on environmental quality (e.g. organic farming), on tradition (e.g. 'TSG' meaning traditional speciality guaranteed) or associated to origin (e.g. 'PDO' for protected designation of origin and PGI for protected geographical indication). Non-official labels include certified products differentiated from standard products by some specific characteristics or products highlighting a specific feature (such as meat produced from grass-fed animals or 'on-farm processed' or 'mountain produced'). There are in fact many beef schemes related to areas of geographical origin, brands, and/or breeds (for example, specialist Hereford or Aberdeen Angus beef and beef products). Generally, consumers have a positive perception of products with official labels, but they express a degree of misunderstanding on the real guarantees offered by the numerous labels (official or non-official) that exist in the market. The development of such schemes is based on the assumption that consumers attach great importance to taste, to the pleasure of eating, to pre-existing know-how, to typical geographical areas where production takes place, to traditional gastronomy, and/or to sustainable development of agriculture. However, a high price for labelled products does not favour final purchase. This explains the relative success of non-official labels (or certified products), which are cheaper but with fewer guarantees compared with official labels (reviewed by Hocquette *et al.* 2012b). At least in France (Normand *et al.* 2009), no clear relationship was found between the price of beef at the market level and its real tenderness assessed by consumers. This means that consumers can find good beef at a low price or can be disappointed by expensive beef, which is not good for the development of the beef market.

In addition, consumers do not eat carcasses but portions of meat derived from muscles or cuts. Therefore, we can simply argue that any carcass-grading scheme will not be able to accurately predict palatability of cooked beef at the plate level. Highlighting this view is that muscle type and cooking method have a great impact on palatability (Thompson 2002) and that *post-mortem* factors (especially ageing) are very important for

beef palatability compared with *pre-mortem* factors (Juárez *et al.* 2012). The development in Australia of the Meat Standards Australia (MSA) grading scheme to predict beef quality for consumers has been based on these principles. It predicts a palatability score (on a 0–100 scale) for each cut × cooking method combination and according to different factors including ageing time (reviewed by Thompson 2002). The MSA success has been based on standardisation of the consumer evaluation protocols and on accumulation of large amounts of data over time that have been treated by rigorous statistical analyses in order to identify the main factors affecting beef palatability (reviewed by Polkinghorne and Thompson 2010). In this approach, assessment of quality (tenderness, flavour liking, juiciness, overall liking) is done by untrained consumers, and not by trained panellists, as in many global studies. The MSA approach has been tested successfully in many countries including South Korea, the USA, Japan, South Africa, New Zealand, Northern Ireland, the Irish Republic, Poland (for review, see Hocquette *et al.* 2014) and France (Legrand *et al.* 2013) (Fig. 1). Despite some minor differences that need to be taken into account in the prediction, consumers provide similar responses for the assessment of beef quality in all studied countries.

Recent advances in biochemistry and genomics

All the previous grading systems have been developed to satisfy consumers based on the intrinsic quality (e.g. palatability for the MSA approach) or the extrinsic quality (e.g. image, origin,

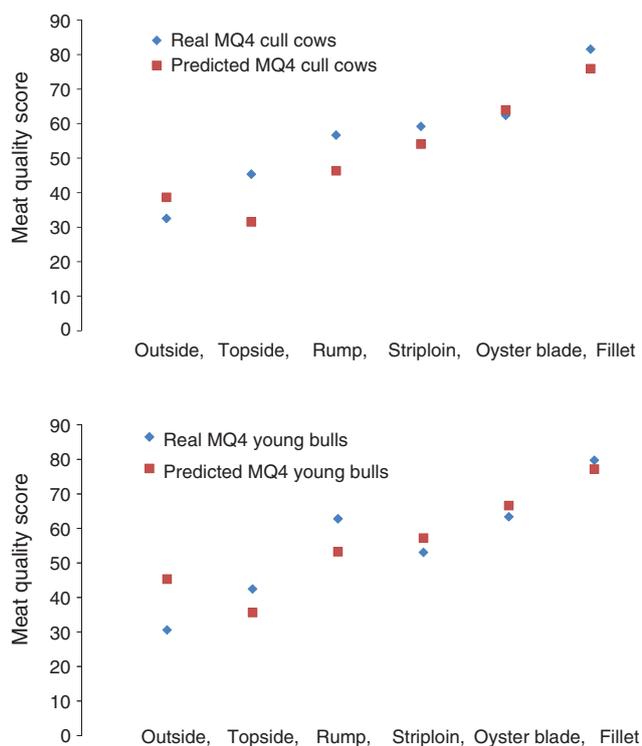

Fig. 1. Prediction of beef quality in France for cull cows and young bulls using the Meat Standards Australia (MSA) system. Meat quality score (MQ4) is indicated on a 0–100 scale. Real MQ4 from consumer tests and predicted MQ4 from the MSA model are both indicated for each muscle (adapted from Legrand *et al.* 2013).

tradition) of the products for consumers. However, prediction models can also be developed for other key players (i.e. other than consumers) who may be geneticists, producers or retailers (reviewed by Hocquette *et al.* 2014) to improve breeding strategy or adapt farming practices depending on animals' capacities. In that case, emphasis for modelling has been put on muscle biochemical characteristics and on the genes and proteins that determine these characteristics.

For several years, various functional genomic programs were conducted at national and international level to search for biomarkers of beef qualities. Some studies focussed on muscle and adipose tissue development, others on muscle hypertrophy, flavour or marbling (for reviews, see Cassar-Malek *et al.* 2008; Picard *et al.* 2011), but the most numerous studies concerned beef tenderness (Picard *et al.* 2012).

A major challenge for meat scientists around the world is to understand the variability in tenderness which is at the origin of a dissatisfaction of the beef consumers. For beef producers, it is of interest for breeding or finishing purposes to predict the ability of live animals to produce good meat, with specific attention towards tenderness. Today tenderness can be estimated only after slaughter, by sensory analysis tests and/or mechanical measurements. Thus, the Beef sector is looking for biological or molecular indicators that would identify live animals with desirable quality attributes, in order to direct them towards the most appropriate production system. Meat tenderness is a multifactorial trait that has been extensively studied worldwide. However, although some biochemical factors are well known and several Quantitative Trait Loci (QTLs) for tenderness were detected, the control of tenderness variability remains a major challenge.

Several studies report QTL detection of tenderness sensorial score or Warner–Bratzler shear force (for a review, see Hocquette *et al.* 2008). For example, single-nucleotide polymorphisms in the CAPN1 and CAST genes were identified and significantly associated with shear force. Markers in the CAPN1 and CAST genes are currently integrated into marketed genetic tests. Several validation studies confirmed that polymorphisms in both genes were associated with differences in tenderness but with relatively modest substitution effects ranging from 0.1 to 0.4 phenotypic standard deviation (for review, see Picard *et al.* 2012). Allais *et al.* (2011) demonstrated that single-nucleotide polymorphisms in these two genes were not consistently associated with tenderness in the three main French beef breeds (Limousin, Charolais, Blonde d'Aquitaine). Besides these two genes, several studies revealed associations between tenderness and other candidate genes: *HGD*, *CAPN3*, *POMC*, *CEBPA*, *GHR*, and *PPARG*. However, none appeared markedly significant. The strategy based on the search for a limited number of candidate genes that would explain most of the variability of meat quality has to date been unsuccessful.

Therefore, genomic analyses have been conducted to better understand processes underlying tenderness or to provide biological markers predicting tenderness (Cassar-Malek *et al.* 2008; Picard *et al.* 2012). Comparative transcriptomic and proteomic analyses, conducted on bovine muscles with low or high tenderness scores estimated by sensory analysis and/or mechanical measurements, bring up a list of potential biological markers that may be used as phenotypic biomarkers

to predict the ‘tenderness potential’ of an animal or a carcass (for review, see Hocquette *et al.* 2008). The main results obtained in the *Longissimus thoracis* (LT) from French beef breeds have demonstrated that in more tender LT, the slow oxidative-type proteins were more abundant. These proteins include, for example, α Enolase, an isoform of troponin T slow, slow isoforms of myosin-light chains, the creatine kinase M, and the mitochondrial protein NADH-ubiquinone oxidoreductase. Other experiments of the literature led to similar conclusions about the relationship between oxidative metabolism and tenderness in LT muscle (Picard *et al.* 2011, 2012). Consistent with this view, proteins related to glycolytic metabolism (such as phosphoglucosmutase (PGM), lactate dehydrogenase B (LDH B), triphosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), the fast troponin T (TnTf) isoforms and the β enolase) were less abundant in the more tender LT. Several proteins involved in calcium metabolism were also identified as positive markers for tenderness. For example, the amount of Parvalbumin peptides is considerably increased in tender muscle (Picard *et al.* 2012). The calcium cycle proteins seem strongly involved in meat tenderness, in connection with the important role of calcium in meat ageing. Accordingly, Bjarnadottir *et al.* (2012) recently found a relationship between Annexin 6, involved in release of calcium, and tenderness. A set of proteins of the family of heat shock proteins (Hsp) was revealed as markers of tenderness at the transcript or protein level in different experiments. For

example, it was shown that gene expression *DNAJ1* protein (Hsp40) was an appropriate indicator of meat toughness of Charolais young bulls (for a review, see Cassar-Malek *et al.* 2008). According to the hypothesis of Ouali *et al.* (2013), the antiapoptosis *DNAJ1* could slow down the process of cell death during the early stages of transformation of muscle into meat, and therefore induce more toughness. Other family members (Hsp27, Hsp20, α B-crystallin, Hsp70) were also identified as markers of tenderness in several programs (Ouali *et al.* 2013). Other results revealed also a role in tenderness of proteins involved in oxidative stress such as super-oxide dismutase and Peroxiredoxin 6 (for a review, see Picard *et al.* 2012).

From this list of protein markers of beef tenderness, a bioinformatic analysis was conducted in order to have a better understanding of the biological functions involved in tenderness and the interactions between all these proteins (Guillemin *et al.* 2011). This work highlighted cellular pathways strongly involved in tenderisation processes: apoptosis, HSP functions and oxidative stress resistance.

In order to analyse biomarkers on a large number of samples simultaneously, new molecular tools were developed (Fig. 2). A DNA chip with specific genes involved in muscle biology or beef quality was developed to study simultaneously the expression of ~3000 genes (Hocquette *et al.* 2012a). At the protein level, a dot-blot tool was developed for the measure of relative abundance of proteins (Picard *et al.* 2011). This

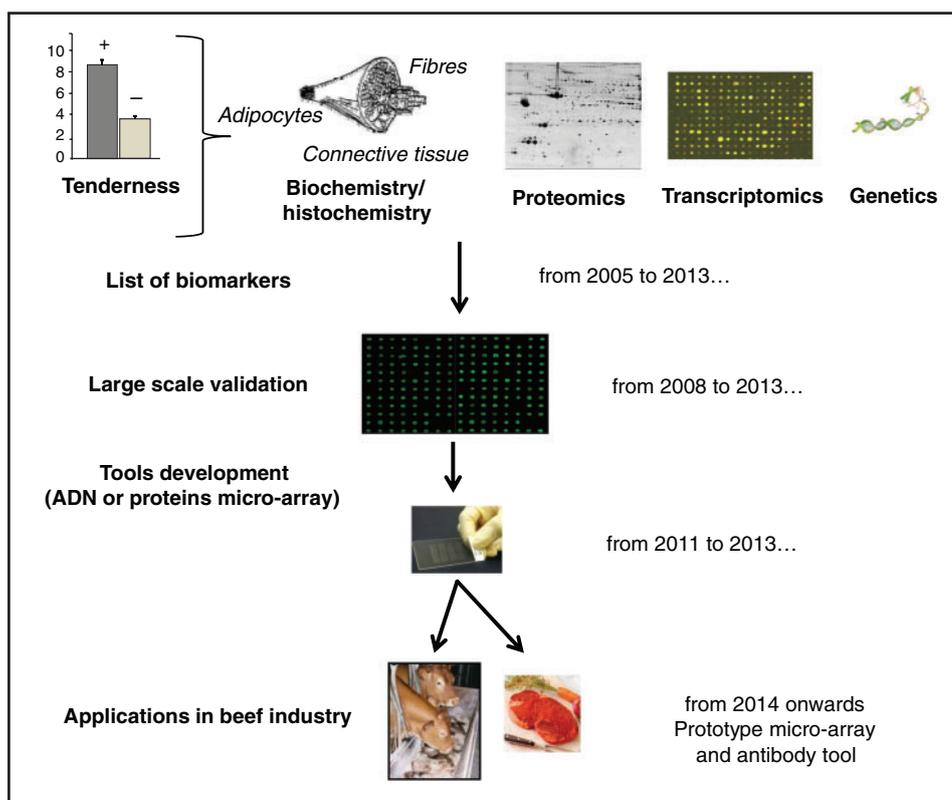

Fig. 2. Overall strategy of genomics research to improve the prediction of beef quality including tenderness, flavour and marbling.

immunological tool allows measuring the relative abundances of many proteins for several muscle samples simultaneously. These tools are currently used in several experiments with different breeds and muscles in order to establish predictive equations of beef tenderness from the relative abundance of a list of 24 proteins. The preliminary results showed that regression equations predicting tenderness were specific for breed (Picard *et al.* 2012) or animal groups that differ by husbandry factors (Hocquette *et al.* 2012a).

This strategy of research of biomarkers of quality is developing worldwide for several qualities and for the study of the effect of animal type and management factors on the expression of the biomarkers (for a review, see Picard *et al.* 2011). However, the general observation is that the ability of gene markers, gene expression or protein levels to predict tenderness is generally breed-specific, muscle-specific or specific of animal groups, making it difficult to develop generic equations for the prediction of tenderness across a broad population of beef cattle in a commercial context. This is in line with biochemical studies that demonstrated that the prediction of beef tenderness from muscle characteristics (collagen amount and solubility, size, type and metabolism of muscle fibres) depends on muscle and animal type (young bulls, cows, etc) (Chriki *et al.* 2013). However, marbling or intramuscular fat level have a phenotypic and genotypic association with tenderness, which make them simple and relevant markers for tenderness although the underlying mechanisms are not completely understood. It is thought to be associated with lowering connective tissue toughness in both sheep and cattle (Reverter *et al.* 2003; Mortimer *et al.* 2014). Unfortunately, as for biomarkers of tenderness, none of the known biomarkers to predict the ability of livestock to produce marbled beef are omnipotent.

From a genetic point of view, this may not be such a problem with the advent of genomic selection, which is based on markers that cover the whole genome. Therefore, the whole genetic variance is potentially explained by all these markers which can be analysed simultaneously at a relatively low cost using commercially available DNA chips for genotyping. This new strategy is changing the agendas and organisation of private companies, as genomic selection is redesigning animal breeding programs. However, genomic selection requires accurate recording of phenotypes on large reference populations. Therefore, phenotyping is becoming the next challenge in animal science (for a review, see Hocquette *et al.* 2012c), and especially in meat science. This is the reason why ontology programs have been designed. Similarly, standardised methods have been set up to analyse, in a repetitive manner, sensory traits of beef (for a review, see Polkinghorne and Thompson 2010).

Win-win strategies or trade-offs for extrinsic and intrinsic quality traits of beef

Win-win strategies for sensory quality and welfare issues

Consumers demand beef of good quality while animal welfare is becoming increasingly important for citizens. Therefore, beef palatability and animal welfare issues during rearing and at slaughter need to be simultaneously addressed.

It has long been known that slaughter conditions may have a significant impact on meat quality. For example, earlier studies found that in bulls, aggressive behaviour caused an increase in Dark, Firm, Dry (DFD) meat. The underlying mechanisms are well described: following slaughter, muscle glycogen is degraded, but in the absence of oxygen and blood circulation, protons and lactate accumulate locally in the muscle, causing a pH decline. This decline is initially fast, then slows and stabilises at a value called ultimate pH, reached ~24 h *post mortem*. The extent of pH decline depends principally on muscular glycogen reserves before slaughter. Increased activity and associated psychological stress during the hours preceding slaughter reduces muscle glycogen reserves and may result in high ultimate pH which is the cause of DFD meat. DFD meat has adverse qualities in terms of colour, microbiological development and shelf life, water-holding capacity and meat touch (sticky touch), taste and juiciness. Consequently, much effort was undertaken to improve slaughter conditions in order to limit production of meats with these quality defects. Animal stress should thus be reduced from the farm to the slaughter house including loading in trucks, transportation, unloading, and waiting in individual boxes before slaughtering. Some guidelines are now available (for instance, the French standard NF V46001 of December 1996).

While the phenomenon of high ultimate pH was well known in cattle, for many years little attention was paid to possible variations between cattle in early *post-mortem* pH decline. The initial rate of pH decline depends on the metabolic activity of the muscle during the early *post-mortem* period. Variations in pH decline were noticed nearly 20 years ago in calf carcasses and may represent an important explanatory factor of colour variation, sometimes more important than muscle haem iron contents (mainly linked to feeding) in some specific muscles (e.g. *psaos major*: Guignot *et al.* 1992). Only recently it was established that this phenomenon can also be observed in older cattle. Increased stress levels in Normand cows or bulls of different breeds, indicated by faster heart rates only a few minutes before slaughter, are accompanied by a faster pH decline, explaining 36–50% of the variability in the rate of pH decline between individuals (Bourguet *et al.* 2010; Terlouw *et al.* 2012). Stress before slaughter not only influences early pH decline, but also sensory beef quality. Warner *et al.* (2007) found that the use of electric prodders was associated with lower sensory ratings, including tenderness, by consumers. Gruber *et al.* (2010) also showed a relationship between elevated blood lactate concentration (at bleeding) and reduced tenderness, suggesting that acute stress just before slaughter can negatively influence tenderness. In another experiment, cows slaughtered with minimal stress (7 min transport) produced significantly more tender meat than cows slaughtered after a stress treatment (48 min transport combined with a physical and emotional stress treatment: Bourguet *et al.* 2010). These effects of stress on tenderness were not directly related to rate of pH decline or ultimate pH (Terlouw *et al.* 2012). The biochemical mechanisms underlying beef tenderness appear to depend on the slaughter conditions. When slaughtered with minimal stress, cows that had relatively low heart rates on the farm just before being loaded onto the lorry produced meat with relatively high tenderness (Fig. 3). When slaughtered after the stress treatment, meat

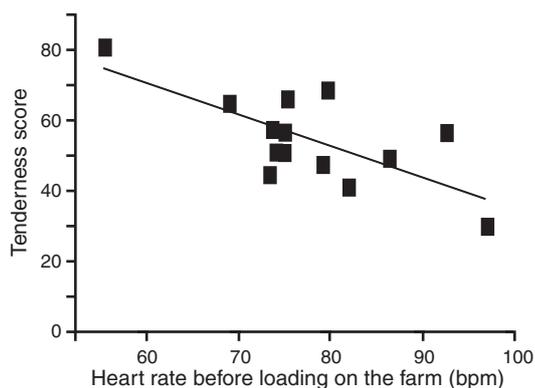

Fig. 3. Tenderness score (values from 0–100, higher scores indicating increased tenderness) rate was negatively correlated ($r = -0.71$, $P = 0.004$) with heart rates (beats per minute, bpm) just before loading the cows ($n = 14$) in the lorry.

was toughest in cows having relatively low levels of oxidative metabolism in the muscle immediately after slaughter (Terlouw *et al.* 2012).

Stress at slaughter depends not only on the slaughter conditions, but also on the stress reactivity of the animals. When subjected to several reactivity tests during rearing, it was possible to identify cows that were more likely to be reactive to the slaughter procedure, in terms of reduced tenderness (Terlouw *et al.* 2012).

Overall, results indicate that stress reactivity measured during rearing may predict stress reactions of cattle during the slaughter period. Stress reactions at slaughter have a potentially strong impact on technical and sensory meat quality indicators, including pH decline, ultimate pH, colour, water-holding capacity, shelf-life, juiciness, taste and probably tenderness. The above results show that although the underlying mechanisms are sometimes not yet entirely known, meat quality may be significantly improved if at slaughter stress levels of the animals are kept low. Today, efforts continue to improve slaughter procedures. The selection of animals with a very low reactivity to stress is sometimes suggested and may contribute to reduce stress at slaughter but has its limits. The reason is that some stress reactivity is necessary for survival as it allows adaptation to a changing environment. For example, a very placid animal would not attempt to escape from danger and would also be very difficult to be driven forwards by humans. In addition, certain physical characteristics considered advantageous for breeding purposes may be genetically linked to stress reactivity.

In conclusion, limiting stress at slaughter, particularly by improving slaughter procedures, would be beneficial for animal welfare and for meat quality and therefore represents a win–win strategy.

Win–win strategies and trade-offs between environmental value and other beef quality traits

There are very few examples of direct interaction between intrinsic beef quality and environmental value. Palatability depends for a great part on non-nutritional factors, although good nutrition prior to slaughter is important, whereas

environmental value is mostly related to animal feeding and farming systems. In Australia, it was shown that a high continuous growth rate from birth improves meat palatability (reviewed by Thompson 2002) and may simultaneously improve environmental/feed efficiency outcomes due to a reduction in the proportion of food used in maintenance. Nutritional quality of beef from a human health perspective also depends on animal feeding and could thus be related to environmental value. This has been shown for the enrichment of the animal diet with omega-3 fatty acids. Supplementation of finishing diets with linseed results not only in a higher content of omega-3 fatty acids in meat (Doreau *et al.* 2011) but also a decrease in methane emission per kilogram of liveweight gain (Eugène *et al.* 2011). However the positive effect on the environment is of lower extent when the whole beef system is considered, owing to a partial compensation by an increase in other greenhouse gases than methane, and because the finishing period represents only 10% of the total greenhouse gas emissions (Nguyen *et al.* 2012).

Grass feeding is considered to provide beef of good quality because it is rich in omega-3 fatty acids and produced in a natural way. Even if the relationship between grass feeding and good palatability is not demonstrated, this mode of production is treated as such by many European consumers, leading to quality labels associated with origin, or to specific types of production such as organic farming. The positive externalities of grass feeding mainly concern natural grasslands in mountain areas or other non-arable areas. Contrary to farming in arable areas using temporary grasslands, interspersed with broadacre cropping, natural grasslands and associate structures (hedges, banks, ditches) allow the maintenance or the increase of plant biodiversity (Dumont and Tallowin 2011). In addition, plant biodiversity can have a positive effect on animal health (Farruggia *et al.* 2008). Moreover, in most cases, carbon sequestration in soils under natural grassland compensates in part for the greenhouse gas emissions (Soussana *et al.* 2010). Beef production based on grass in mountains or other areas with a limited production potential leads to a better quality of water due to a limited use of fertilisers and pesticides, and contributes to the vitality of rural territories because other agricultural production is not possible or less profitable (Peyraud 2011). Such ecosystem services are seldom taken into account in environmental evaluations of beef farming because a unique methodology is not shared by the scientific community (e.g. case of biodiversity or territorial management) or because reliable data are not available (e.g. case of carbon sequestration, of which the extent is extremely variable). It is sometimes argued that the use of natural grasslands for beef production requires large soil area per kilogram of meat in a world where land occupation is a major issue, but these areas generally do not compete with crops for human food or for other animal products. In countries such as Australia, South Africa and the western USA there is a huge area of land that cannot be cropped and where grassland is the only possible production base. Ruminants alone can convert large quantities of poor-quality herbage unsuitable for humans into a highly nutritious energy- and protein-dense human food.

When considering extrinsic qualities of beef, it is mandatory to be very careful regarding trade-offs between criteria, as shown by Doreau *et al.* (2013) when considering all aspects of livestock

sustainability. For example, in the case of environmental impacts, a comparison between a feedlot-type high-concentrate diet and diets based on maize silage or hay in finishing bulls, which differed in liveweight gain, resulted in a much lower emission of methane for the high-concentrate diet, but a lower difference between diets when all greenhouse gases are considered (Table 1); energy use is lowest with the maize silage diet whereas eutrophication and acidification potential are lowest with the hay diet. The concentrate diet was more risky for animal health while the maize silage diet produced the highest gross margin for the farmer (Mialon *et al.* 2013). For the criterion of human nutritional quality, such as fatty acid composition of muscle, this study shows that the hay diet led to more beneficial fatty acids compared with the concentrate diet. So, in conclusion, there are examples of win-win strategies existing between the extrinsic qualities, but none on all the issues simultaneously.

A recent analysis of beef farms in French grassland areas with a limited production potential (Veysset *et al.* 2014, and unpubl. data) was done to conduct a joint environmental impact assessment and economic results of meat cattle production systems from commercial farms. It was considered here that greenhouse gas (GHG) emissions and fuel consumption of non-renewable energy were environmental indicators (among others). For each farm belonging to a known breeding network

(i.e. for which data structure, technical and economic results were available), GHG emissions and consumption of non-renewable energy have been calculated using a methodology adapted to French farming systems (Bochu 2002).

The 59 farms (169 ha on average) were specialised beef cattle and/or mixed farming–beef cattle enterprises located in the Charolais basin (central France), highly specialised with large low-intensity operations. The main forage area occupies, on average, 84% of the Utilised Agricultural Area (UAA); 16% of the UAA was devoted to cash crops that were largely self-consumed by the herd. With, on average, 171 livestock units (LU), the stocking rate was 1.21 LU/ha of forage area. These farms produce mainly lean animals. Over 60% of the young males (9–13 months) were sold to specialised feeders in Italy for the Italian market. According to grassland orientation and relatively low stocking rate, mineral nitrogen fertilisation was quite low. The average gross GHG emissions are 12.8 kg CO₂ eq/pound of live meat (kg live weight, lw). The major contributors to GHG was CH₄ (66% of emissions), followed by CO₂ (19%) and N₂O (15%). Enteric fermentation accounted for 82% CH₄ and 54% of total emissions. Manure management (storage building, spreading) represented 16% of CH₄ and 40% of N₂O. Excreta (faeces and urine) at grazing and fertiliser application accounted for 39% and 20% of N₂O emissions, respectively.

Table 1. Performances, nutritional quality, welfare, environment and economic indicators for three contrasted systems of bull fattening, based on hay (H), maize silage (MS) and concentrate (C)

Data are from Mialon *et al.* (2013), four primary publications cited in this latter paper, and unpublished data. Values followed by different letters are significantly different from each other at $P = 0.05$

Indicator	Experimental diet		
	H ^A	MS ^A	C ^A
<i>Performances</i>			
BW gain (kg/day)	1.49b	1.71ab	1.86a
Feed efficiency (kg BW gain/MJ NE _f ^B intake)	84.8	90.4	87.4
Carcass fat (kg/bull)	36b	48a	41ab
<i>Meat nutritional quality</i>			
Saturated FA (% total FA)	40.1b	44.1a	39.1b
n-6 FA : n-3 FA ratio	7.28c	8.27b	13.91a
<i>Animal welfare</i>			
Rumen average pH as index of digestive discomfort	5.8a	6.1a	5.5b
<i>Environment^C</i>			
Greenhouse gases emission ^D (kg CO ₂ eq/kg BW gain)	4.56	4.74	3.65
of which enteric methane (kg CO ₂ eq/kg BW gain)	3.33a	3.81a	1.56b
Eutrophication potential (g PO ₄ eq/kg BW gain)	16.5	19.0	21.5
Acidification potential (g SO ₂ eq/kg BW gain)	31.3	38.1	29.4
Energy consumption (MJ/kg BW gain)	18.7	13.0	19.7
Land use (m ² .year/kg BW gain)	11.7	4.5	4.6
of which arable land (m ² .year/kg BW gain)	3.4	4.5	4.6
<i>Economy^C</i>			
Economic margin ^E (€/bull)	231	305	261

^AH: 44% permanent grassland hay and 56% concentrates; MS: 58% maize silage and 42% concentrates; C: 92% concentrates and 8% straw.

^BNet energy for fattening, calculated using French feeding systems.

^CNo statistics can be performed on results of life cycle assessment and on economical results.

^DIncluding carbon sequestration by grasslands.

^ESale of carcasses minus calf purchase minus feed cost.

Overall, the animals were responsible for 78% of total emissions (rumination, manure), inputs for 15% (CO₂ from the energy needed to manufacture and transport inputs, and N₂O related to fertiliser application) and direct energy use (fuel, lubricants, electricity) on the farm is responsible for only 5% of gross GHG emissions.

These gross GHGs are offset up to 21% by storing carbon from the dynamic storage/retrieval in grasslands and croplands (Soussana *et al.* 2010), which represents 38% of enteric methane. The net GHG emissions then averaged 10.06 kg CO₂ eq/kg lw.

These averages mask considerable variability of economic and environmental outcomes. Gross GHG emissions range from 9.5 to 21.1 kg CO₂ eq/kg lw; that is, a difference of 122% between the extremes. Fifty percent of farms are between 11.6 and 13.6 kg CO₂ eq with 17% difference between the first and third quartiles. Net emissions vary from 7 to 15 kg CO₂ eq/kg lw. There was a negative correlation between net GHG emissions and productivity based on weight of beef produced per hectare ($r = -0.54$), but less than that observed between gross emissions and productivity. Gross GHG emissions were independent of the stocking rate while net emissions were positively correlated ($r = 0.32$) due to carbon sequestration, partly compensating for emissions. We also observe that the net GHG emissions by kg lw are positively correlated with the size of the farm: $r = 0.32$ and $r = 0.37$ respectively with the number of LU and the number of hectares of UAA. Specialisation of the operation also affects GHG emissions, with specialist beef production farms emitting less net GHG/kg lw ($r = -0.27$).

Gross bovine margin also varies from 150 €/LU to 550 €/LU and, importantly, varied showing a significant negative correlation with net emissions (Fig. 4). That is, the most productive efficient systems, i.e. maximising meat production by minimising the use of inputs, combined with strong economic performance (product with more controlled charges), had the lowest net emissions per unit of output – a clear win-win. However, this is not always the case: for instance, for a gross margin of 350 €/LU, net GHG emissions range from 9 to 13.6 kg CO₂ eq/kg lw, and for a net GHG emission of 12 kg CO₂ eq/kg lw, gross margin ranges from 200 €/LU to 480 €/LU.

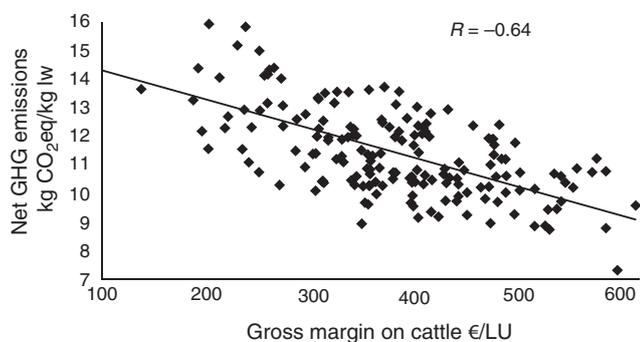

Fig. 4. Gross margin on cattle expressed in euros per livestock unit (LU) and net GHG emissions in kg CO₂ eq/kg liveweight produced.

Future research priorities

On the basis of the previous examples, more and more authors have suggested extending the concept of beef quality not only to cover all characteristics of the product itself (e.g. in terms of tenderness, palatability, nutritional value, safety) but also to cover all extrinsic qualities more or less associated with beef (such as e.g. livestock practices, animal welfare, carbon footprint, price for consumers, income for producers) (for review, see Hocquette *et al.* 2012b). A special focus has to be made on environmental issues due to the negative perception of beef production associated with GHG emissions. Therefore, Scollan *et al.* (2011) have suggested establishing an environmental index to combine carbon footprint, water and energy use for beef production. Soil acidification, plant biodiversity in pasture, and other environmental criteria can be added in this potential environmental index. Once established, this environmental index has to be combined with a beef palatability index (similar to the quality score provided by the MSA system), a nutritional value index (e.g. combining, for instance, iron content, fatty acid profile), an economic index (combining, for instance, a good price for consumers, reasonable incomes for producers and reasonable margins for distributors), and any other issues important for consumers and supply chain participants (Fig. 5).

Improving beef sustainability by enhancing the different components of extrinsic quality, and especially the environmental friendliness, is a major challenge. At first it is necessary to take the right indicators and numbers. A well known example is that of water use. It is frequently stated that 1 kg beef requires 15 000 L water for its production, but this value corresponds for almost 95% to 'green' water, i.e. water that is necessary for crop or herbage growing, and which should be 'used' even if land is free of animals. There is no correspondence between this calculation and water scarcity, which can be calculated from effective water withdrawals from rivers or aquifers (Doreau *et al.* 2012), and so effective water consumption for beef production is not a major source of water scarcity. However, GHG emissions per kilogram of meat are higher for beef than for pork and chicken (de Vries and de Boer 2010). Mitigation techniques have been extensively explored (Hristov *et al.* 2013), but they are not easy to implement for beef production because most emissions come from the cow-calf herd before fattening, as stated above, and because the major part comes from methane, which roughly depends on total feed intake required for producing meat (Veysset *et al.* 2010). Explorations of various improvements of the feeding and management of beef production have been made for Canadian and French systems (Beauchemin *et al.* 2011; Nguyen *et al.* 2013). These studies draw similar conclusions: a significant reduction of emissions is possible only when several techniques are used simultaneously. When these techniques require fewer areas for the same production, the released land can be used for additional production, or for carbon storage (for example, as forests). In theory, producing beef from the dairy herd may decrease GHG emissions, because emissions of the dairy herd are shared between milk and beef production. However, this possibility is limited by the reduction of the dairy herd due to more efficient dairy cows that produce more milk per cow but

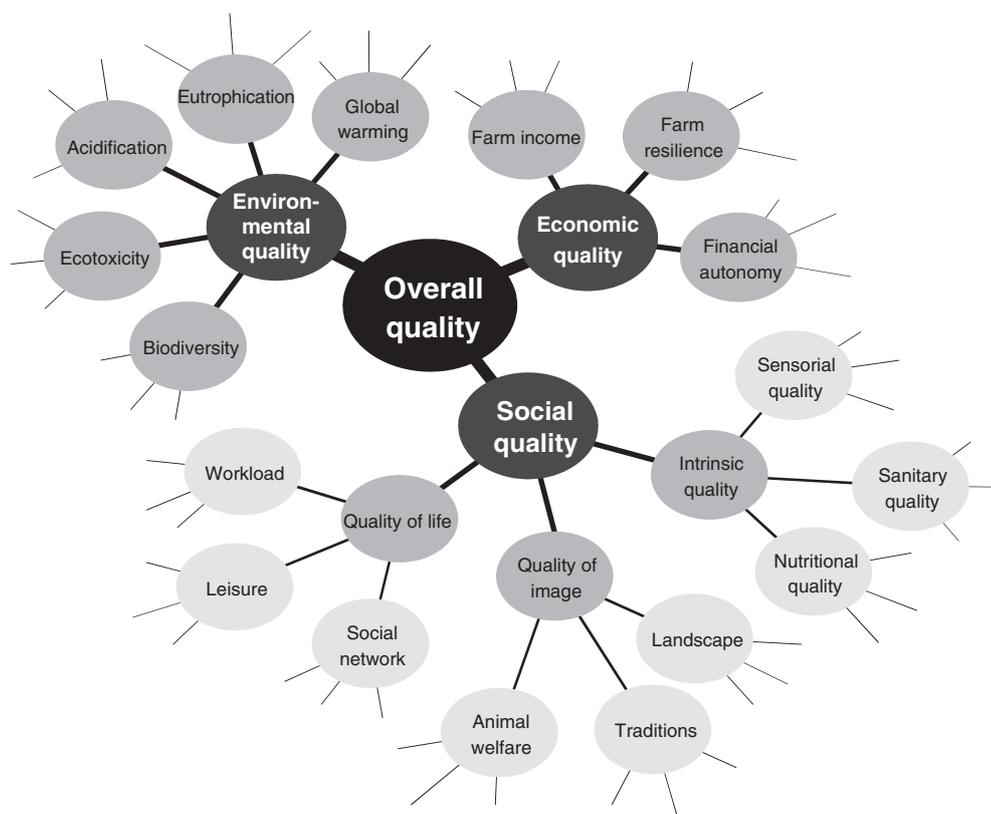

Fig. 5. Combination of intrinsic and extrinsic quality traits of beef for better sustainability of the whole beef supply chain.

not more beef. In the end, it is a trade-off worth having. For example, as discussed before, converting cellulose into meat from semimarginal lands may be considered as a tolerable GHG emission.

In northern Europe, a Sustainability Index was developed as a dynamic prototype. It is based on indicators for the evaluation of sustainability. Data from farms in Denmark and Sweden were collected and registered online in an existing tool 'AnalysePlatformen' (www.analyseplatformen.dk). The choice of indicators is crucial. A good indicator must be (1) based on generally accepted biological relations, (2) understandable and acceptable for stakeholders, and (3) reflect the actions of the farmer. The indicators that are registered in this prototype are related to animal welfare, climate change, use of resources, animal impact, biodiversity, social responsibility, and economy (Munk *et al.* 2013). In addition to the issue of indicator selection, the question of the aggregation of these indicators up to an overall assessment is also crucial: how can we combine pears and apples? This leads to issues on relative importance to be assigned to the different indicators and on compensations (should they be forbidden, limited, or even fully authorised as done when using a weighted sum?).

More generally, different authors or research groups have speculated about what future research priorities should be for the beef sector in order to satisfy the increasing number of wishes of consumers and citizens, which means a very broad concept of quality including all these wishes. Many experts

observe that, in fact, there is likely to be a trend for intensification in many parts of the World beef supply chain for reasons associated with economic efficiency and the need to produce more animal protein to feed a hungry world. This trend is in tension with other more traditional, more ecological or more sustainable views.

According to Dumont *et al.* (2013), to better protect the environment in the future, animal production systems must take into account the principles of agroecological thinking based either on agroecology (which is based on stimulating natural processes to reduce inputs) or on industrial ecology (which is based on reducing demand for raw materials, lowering pollution, and saving on waste treatment). These principles include adopting new management practices aiming to improve animal health, decrease inputs for production, decrease pollution, increase diversity and resilience within animal production systems and preserve biological diversity. The question is how these principles could be combined to generate sustainable animal production systems that include environmental, social and economic performances together. This looks feasible since economy of inputs and reduction of pollution are present in most ecology-based animal production systems (reviewed by Dumont *et al.* 2013).

From a broader perspective, the 'Animal Task Force' group (which is made up of the major research providers and industry-representative bodies in Europe) have identified four areas for research and innovation contributing to a 'better society' and

'competitive industries' in animal production. The first priority is resource efficiency with two main objectives: the efficiency of the use of resources by farm animals must increase (this means more efficient animals and farming systems) and the way we produce resources should be more efficient as well. This will induce both lower environmental footprints and satisfaction of the increasing demand for animal products. The second priority is healthy farm animals to ensure healthy consumers of meat and dairy products. The third priority is to develop animal production systems that simultaneously meet societal expectations for environmental control, human health and animal welfare. The fourth priority is knowledge exchange towards innovation (Animal Task Force 2013). Clearly, in this view, the 'Animal Task Force' group recommends to take into account the full range of livestock production systems (including multifunctional approaches, or more sustainable intensification of food production) and to develop multicriteria approaches in order to reach these priorities and to promote responsible livestock farming systems.

Herrero and Thornton (2013) mostly agreed with this view even if they presented it in a different way, but insisted on the fact that the livestock sector cannot be studied in isolation. This is especially true for the beef sector, which cannot be studied alone while ignoring the dairy sector or ignoring other meat sectors (pork and poultry production, for instance). More generally, the livestock sector has to be studied in connection with the whole food sector due to its social, environmental or economic connectedness with other food systems (Herrero and Thornton 2013).

In conclusion, we have speculated in this review for the need to combine indicators or predictors of both intrinsic qualities (the characteristics of the product itself, mainly tenderness and palatability, which are very important at the consumer level) and extrinsic qualities (such as e.g. animal health and welfare, carbon footprint, price) of beef, which are becoming more and more important for consumers. The Meat Standards Australia grading scheme combined with knowledge in muscle biochemistry and genomics are on the way to better predict sensory quality for the consumer. Extending aggregation of traits related to extrinsic quality or of their indicators is also a good starting point to reach a whole assessment of beef sustainability. This research strategy will help considerably in identifying win-win strategies that optimise different quality traits, some examples having been illustrated in this review. In this respect, most attention has been focussed on the environmental impacts of the beef sector. In all these analyses, using the correct metrics is essential. In this strategy, it is also important to better know interactions of the beef sector with other food sectors and other human activities. A further step of integration is thus the assessment of interconnections of the beef sector with other relevant sectors, and this also requires a multicriteria approach.
