## Abstract

Magnetic resonance techniques (Electron Paramagnetic Resonance – EPR and Nuclear Magnetic Resonance - NMR) are used for tracking the multi-stage process of fabrication of fluorescent nanodiamonds (NDs) produced by high-energy electron irradiation, annealing and subsequent nano-milling. Pristine commercial high temperature high pressure microdiamonds (MDs) with mean size 150  $\mu\text{m}$  contain  $\sim 5 \times 10^{18}$  spins/g of singlet ( $S = 1/2$ ) substitutional nitrogen defects P1 as well as  $sp^3$  C-C dangling bonds in the crystalline lattice. Half-field X-band EPR clearly shows (by appearance of intense “forbidden”  $g = 4.26$  line) that high-energy electron irradiation and annealing of MDs induce a large amount ( $\sim 5 \times 10^{17}$  spins/g) of triplet ( $S = 1$ ) magnetic centers identified as negatively charged nitrogen vacancy defects ( $\text{NV}^-$ ). It is supported by EPR observations of “allowed” transitions between Zeeman sublevels of the triplet state. After progressive milling of the fluorescent MDs down to ultrasubmicron scale ( $\leq 100$  nm), the relative abundance of EPR active  $\text{NV}^-$  defects in the resulting fluorescent NDs (FND) substantially decreases and, vice versa, the content of C-inherited singlet defects correlatively increases. In the fraction of the finest FNDs (mean particle size  $< 20$  nm), contained in the dried supernatant of ultracentrifuged aqueous dispersion of FNDs, the  $\text{NV}^-$  content is found to be reduced by one order of magnitude whereas the singlet defects content increases up to  $\sim 2 \times 10^{19}$  spins/g. In addition, another triplet-type defect, characterized by  $g = 4.00$  “forbidden” line, appears. On reduction of the particle size below 20 nm limit, the “allowed” EPR lines become practically unobservable, whereas “forbidden” lines remain the reliable fingerprint of the presence of  $\text{NV}^-$  centers in small ND systems. The same size reduction causes disappearance of characteristic hyperfine satellites in spectra of P1 centers. We discuss the mechanisms causing both the strong reduction of the peak intensity of the “allowed” lines in EPR spectra of triplet defects and the transformation of P1 spectra.

## I. Introduction

Fluorescent nanodiamonds (NDs) containing  $NV^-$  defects are novel objects gaining a number of innovative applications in magnetic sensing [1 – 3], cell microbiology [4 – 6], optical quantum telecommunications [7] and quantum information processing [8]. The large variety of these applications is based on unique properties of the negatively charged  $NV^-$  color centers in diamond with triplet spin properties.

$NV^-$  centers can be created in bulk synthetic diamond obtained by high pressure ( $\geq 5$  GPa) high temperature ( $T \geq 1300$  °C) technique from the graphite charge in the presence of a metal catalyst (HPHT diamonds). Nitrogen thus enters the diamond lattice as a substitutional impurity (usually  $\leq 200$  ppm) originating from air adsorbed on the reagents and the HPHT cell components. Irradiation of diamond microcrystals by a beam of high-energy ( $\leq 20$  MeV) particles creates a large number of vacancies. Subsequent annealing of the irradiated diamond at  $T \geq 850$  °C causes thermal diffusion of vacancies and the appearance of  $NV^-$  complexes consisting of vacancies stabilized in crystalline positions adjacent to the substitutional nitrogens [9].  $NV^-$  has a characteristic luminescence with a zero-phonon line (ZPL) at a wavelength of 638 nm and a broad (100 nm width) emission sideband due to strong phonon coupling.

One technique for obtaining fluorescent nanodiamonds is the milling of fluorescent micron size (average crystallite sizes 150 – 200  $\mu\text{m}$ ) diamond powders (MDs) to fine fractions characterized by average particle size below 100 nm. A good description of procedures for manufacturing of fluorescent NDs with the use of two-stage coarse and fine grinding of MDs is given in patent applications [10,11] and articles [12,13]. This method was found to be a more efficient and technologically justified one [14] in comparison with methods applying the aforementioned irradiation/annealing treatment to nano-sized fractions

1  
2  
3 of previously crushed initial synthetic HTHP diamonds. However, for using the first more  
4 efficient technique one has to pay a certain price. Upon grinding, the effective specific  
5 surface of the diamond material increases by 4–5 orders of magnitude. As a result, the  
6 fraction of  $NV^-$  centers falling into the near-surface (1 – 2 nm deep) zone of mechanically and  
7 chemically disturbed diamond lattice increases in comparison with the one of bulk  $NV^-$   
8 centers. Near-surface  $NV^-$  centers have been reported to be sensitive to surface functions [15  
9 – 17] and charge fluctuations [18], and may easily be converted into the  $S = 1/2$  neutral form  
10  $NV^0$ . Size estimation of the fluorescent ND containing at least one  $NV^-$  center may be found  
11 in the Supplemental Material [19], and it is about 9 – 10 nm.

16  
17  
18  
19  
20  
21  
22  
23  
24

25 Moreover it is well known from the 1960s, that mechanical grinding of  
26 semiconducting crystals of Group IV (Ge, Si, diamond) leads to the formation of surface  
27 paramagnetic centers - unpaired dangling orbitals originating from broken covalent bonds  
28 [20-22]. The dangling bonds have  $S = 1/2$  and their characteristic electron paramagnetic  
29 resonance (EPR) signature appears together with the signature of isolated substitutional  
30 nitrogen defect P1 which is the dominant intrinsic paramagnetic impurity in HPHT diamond.  
31 Dangling bonds interact with triplet  $NV^-$  centers being at distances less than 2 nm from them  
32 by both dipole-dipole and exchange pathways. Since their number can significantly exceeds  
33 the one of  $NV^-$  (in NDs there are dozens of  $S = 1/2$  centers per single  $NV^-$ -like defect [23])  
34 the basic parameters of  $NV^-$  centers may be substantially affected. It is expected that the  
35 effect of  $S = 1/2$  centers is more pronounced for small size (< 20 nm) NDs, and one of the  
36 goals of the present work is to verify this hypothesis. The last but not the least objective of  
37 the study reported here is to elucidate the evolution of “allowed” and “forbidden” EPR line  
38 characteristics (intensity and width) at the various stages of the fluorescent NDs fabrication  
39 process.

It was recently shown that magnetic  $NV^-$  centers in fine diamond powders may be

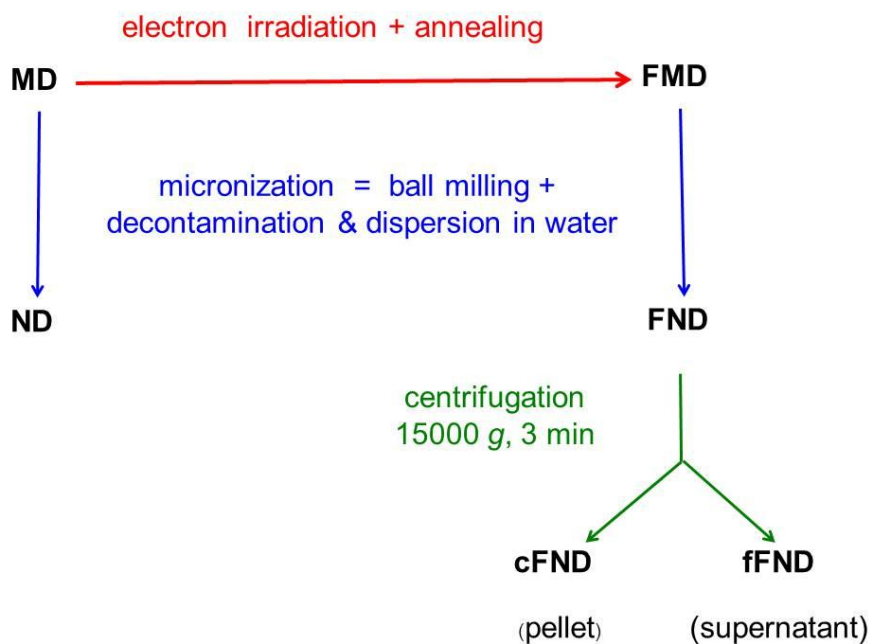

1  
2  
3 reliably detected by EPR technique using unique specific signature in half-field region  
4  
5 (characterized by  $g = 4.26$ ) [24]. This signature was ascribed to so-called “forbidden”  $\Delta M_S =$   
6  
7  
8 2 transition between electron sublevels of the triplet ( $S = 1$ ) ground state of  $NV^-$  centers in  
9  
10 diamond. In the present report we use the aforementioned EPR signature as well as the  
11  
12 accompanying “allowed”  $\Delta M_S = 1$  signals for estimation and quantification of the  
13  
14 concentration of EPR active  $NV^-$  centers in all diamond samples from the initial  
15  
16 microdiamond samples to the fluorescent nanodiamonds at all stages of processing (high  
17  
18 energy electron beam irradiation/annealing, micronization/crushing, nano-milling). This  
19  
20 technique is promising for the rapid characterization of the manufactured fluorescent  
21  
22 nanodiamond powders in terms of content of  $NV^-$  centers, even in some experimental  
23  
24 configurations where these centers are hard to detect by fluorescence techniques [25].

## 32 **II. Experimental**

33  
34  
35  
36  
37 Fluorescent MDs (sample FMD) were manufactured from the commercial non-  
38  
39 fluorescent MDs PDA999 (“Element Six Ltd/Ireland”, mean particle size  $\sim 150 \mu\text{m}$ , moderate  
40  
41 substitutional nitrogen content  $\sim 150 \text{ ppm}$ ) by high-energy ( $\sim 10 \text{ MeV}$ ) electron irradiation and  
42  
43 subsequent annealing in secondary vacuum. Fluorescent NDs (sample FND, mean particle  
44  
45 sizes  $< 100 \text{ nm}$ ) were obtained by multi-stage process [12], involving rough nitrogen jet-  
46  
47 milling, fine CW (tungsten carbide) bead nano-milling, decontamination, hot acid treatment  
48  
49 and then moderate ( $\text{RCF} = 4000 \text{ g}$ ) centrifugation of the water suspension of the nano-milled  
50  
51 product. The water suspension of FND obtained was then centrifuged at high-speed ( $\text{RCF} =$   
52  
53  $15000 \text{ g}$ ): the supernatant contained the finest fraction of FNDs having a mean size of a  
54  
55 couple of tens of nm (named fFND) whereas the pellet contained the coarse fraction, named  
56  
57 cFND [19]. The typical high-resolution transmission electron microscopy (HRTEM) images  
58  
59  
60

of the fFND particles show ensemble of particles of cubic diamond with sizes around or below 20 nm having well round shapes with completely indistinguishable facets and ribs (see Figure S2, [19]). Dynamic light scattering (DSL) measurements done on the water suspended fFND sample well agree with the HRTEM observations providing the size distribution of the differential number of particles having maximum at  $\sim 18$  nm and full width at half maximum (FWHM)  $\sim 14$  nm (see Figure S3(b), [19]).

Figure 1 summarizes the origin of all MD and ND samples at different stages of the fabrication process and TABLE I provides brief descriptions and references where the sample properties are described.

**Figure 1.** Flow chart of different samples processing. A more detailed description of each sample is provided in TABLE I.

Aiming to test the charge transfer effect which may occur due to inter-particle contact interaction, samples of cFND and fFND were diluted by amorphous  $\text{SiO}_2$  nanoparticles (not shown in the TABLE I, for details see [19]).

X-band (frequency  $\nu = 9.4$  GHz) continuous wave EPR measurements on polycrystalline samples were carried out using a Bruker EMX - 220 spectrometer equipped

1  
2  
3 with Agilent 53150A frequency counter at room temperature (RT,  $T \sim 295$  K). Precise  
4  
5 determination of  $g$ -factors and densities of paramagnetic centers  $N_s$  were done by comparison  
6  
7 with the reference sample - well purified detonation ND powder with  $g = 2.0028(2)$  and  $N_s =$   
8  
9  $6.3 \times 10^{19}$  spins/g [26]. Evaluation of the electron spin-lattice and spin-spin relaxation times  
10  
11 ( $T_{SLe}$  and  $T_{SSe}$ , correspondingly) was done by analysis of the saturation dependencies of the  
12  
13 peak-to-peak intensities of the multicomponent central  $g = 2.00$  line following the technique  
14  
15 described in Ref. [27]. Spectra processing and simulation were done using Bruker's WIN-  
16  
17 EPR/SimFonia/XSophe and OriginLab software.  
18  
19  
20  
21

22 RT  $^1\text{H}$  and  $^{13}\text{C}$  NMR measurements on the MD and ND powders were carried out  
23  
24 using a Tecmag Libra pulse solid state FT-NMR spectrometer and Oxford 360/89  
25  
26 superconducting magnet. The measurements have been made in the external magnetic field  
27  
28  $B_0 = 8.0$  T, corresponding to  $^1\text{H}$  resonance frequency of 340.5 MHz and  $^{13}\text{C}$  resonance  
29  
30 frequency of 85.6 MHz, respectively. For additional details of NMR experiments see [19].

39  
40  
41  
42  
43  
44  
45  
46  
47  
48 Figure 2 shows raw (non-processed) experimental EPR spectra of all samples under  
49  
50 study recorded within the field scan range of 1 T at incident microwave power  $P_{MW} = 20$  mW  
51  
52 and 100 kHz magnetic field modulation amplitude  $A_{mod} = 1$  mT. These spectra are typical  
53  
54 EPR signatures of each sample. In general, each spectrum of non-irradiated samples (both  
55  
56 intact and milled) consists of some broad line(s) with  $g_{eff} > 2.00$  and intense narrow lines  
57  
58 within the region of  $g = 2.00$ . Irradiation/annealing add to these lines additional low intense  
59  
60

1  
2  
3 spectral features in the half-field region  $g = 4.00$  and satellite lines (marked by arrows in  
4 figure 2) symmetrically located on both sides of the intense  $g = 2.00$  lines. Each line (group  
5 of lines) was further recorded separately at the experimental setup providing the best spectral  
6 resolution and signal-to-noise ratio available. It should be noted that all EPR spectra and  
7 spectra parameters found for the coarser fraction of the FND sample (cFND) practically  
8 repeat the corresponding spectra and parameters of its precursor FND except increased  
9 content of magnetic impurities. Thus hereinafter these spectra and their description will be  
10 omitted from the Experimental section. On the other hand TABLE II and TABLE S1 in Ref.  
11 [19] include data on cFND samples as well.

25 After recent EPR studies on diamond powders [24,23,27] the following attribution of  
26 the features observed can be done:  
27

- 28  
29 (i) Intense EPR lines in the region of  $g = 2.00$  attributed to the primary paramagnetic defects  
30 with  $S = 1/2$ ;  
31  
32  
33 (ii) Broad EPR lines with  $g > 2.00$  attributed to para- and ferro-magnetic impurities (probably,  
34 surface weakly-bonded adsorbates) contained in the intact initial sample or  
35 appearing/disappearing during irradiation treatment, annealing, milling and purification.  
36  
37  
38  
39 Doubly integrated intensity of these lines ( $DI$ ) indicates the total amount of magnetic  
40 impurities in a diamond sample. The impurity content in starting MD samples was found to  
41 be strongly inhomogeneous and varies several times from batch to batch. Relative

**Figure 2.** RT X-band ( $\nu = 9.463$  GHz) EPR spectra (general view, non-processed) of MD and ND powders. All spectra were recorded in the same experimental conditions and their intensities are normalized per unit weight. The intense lines at  $g = 2.00$  are cut by vertical zooming. Arrows point out new EPR features appearing due to irradiation/annealing. Black trace: MD – initial commercial MD sample; red trace: FMD – MD sample after high-energy electron irradiation and annealing; green trace: ND – milled MD sample; blue trace: FND, milled FMD sample; magenta trace: fFND, fine fraction extracted from the FND sample.

concentrations of magnetic impurities (in arbitrary units per unit weight) are listed in TABLE

II;

(iii) EPR lines in the half-field (HF) region ( $g = 4$ ) appearing in all samples passed through high-energy electron irradiation and subsequent annealing. Following Ref. [23, 24] these lines are attributed to “forbidden” transitions in EPR spectra of triplet ( $S = 1$ ) paramagnetic centers like  $NV^-$  ( $g = 4.26$ ) and multi-vacancies ( $g = 4.00$ );

(iv) Satellite lines observed aside of intense  $g = 2.00$  lines and separated by  $\sim 100$  mT and  $\sim 200$  mT attributed to “allowed” transitions in EPR spectra of triplet  $NV^-$  centers [24].

The most intense EPR signal in the initial sample MD (Figure 3(a), black trace) demonstrates well-resolved polycrystalline hyperfine pattern. This hyperfine pattern originates in paramagnetic centers coming from a single unpaired electron anisotropically interacting with the  $^{14}\text{N}$  nucleus ( $I = 1$ ) in diamond, so-called P1 (or N0) [28]. The EPR parameters determined for these P1 centers by simulation are  $g_{\text{iso}} = 2.0024(2)$ ,  $A_{zz} = 4.06(2)$  mT,  $A_{xx} = A_{yy} = 2.91(2)$  mT, individual line width  $\Delta H_{\text{pp}}^{\text{Lorentz}} = 0.12$  mT. The total concentration of paramagnetic centers  $N_{S=1/2}$  in MD is estimated as  $4.9 \times 10^{18}$  spins/g (within 15% experimental error, see TABLE II).<sup>1</sup> EPR spectrum of the ND sample, obtained by milling of MD, results in similar complicated EPR signal (Figure 3(a) green trace) consisting of the same two independent unlike components which saturate at different microwave power levels (example of typical decomposition of such a signal may be found in Figure 2(d) of Ref. [27]). At low microwave power  $P_{\text{MW}}$  ( $P_{\text{MW}} \leq 200 \mu\text{W}$ ), when no component is saturated, the experimental spectrum (Figure 3(a), green trace) is a superposition of two intense signals: the signal of P1 centers and a singlet Lorentzian line, which overlaps with the central transition of P1 spectrum. The singlet line has the same (unresolved within the experimental error)  $g$ -factor, line width  $\Delta H_{\text{pp}} \sim 0.9$  mT and its  $DI$  is  $\sim 50\%$  of the total signal intensity which corresponds to  $N_{S=1/2} = 8.8 \times 10^{18}$  spins/g. As it is clearly seen in Figure 3(a), the amount of observable P1 centers in ND remains practically the same as in the initial MD. Thus, the increase in the total amount of  $S = 1/2$  defects is due to the new Lorentzian signal attributed to dangling bonds in diamond edges [27]. Figure 3(b) illustrates the EPR spectrum after high-energy electron irradiation and subsequent annealing of MD. EPR spectrum of the fluorescent FMD sample (red trace in Figure 3(b)) demonstrates noticeable reduction of the P1 signal

57  
58  
59  
60

<sup>1</sup> Here it is worth mentioning that the actual EPR spectrum of this sample consisting of MD crystallites is of quasi-polycrystalline type (partially oriented) and, in addition to the main true polycrystalline features, some less intense features appear on the wings of hyperfine  $\Delta m_I = \pm 1$   $zz$ -components and around the sharp central  $\Delta m_I = 0$  component - due to angular dependent “allowed” hyperfine transitions originating from large crystallites.

**Figure 3.** RT X-band ( $\nu = 9.462$  GHz) EPR spectra, region of  $S = 1/2$  signals, as function of samples processing: (a) effect of milling, black trace - MD, green trace - ND; (b) effect of high energy electron irradiation and annealing, black trace - MD, red trace - FMD; (c) effect of milling of irradiated/annealed sample, red trace - FMD, blue trace - FND; (d) after extraction of the fine fraction, blue trace - FMD, magenta trace - fFND, purple trace – tenfold zoom of fFND spectrum, arrows point out weak hyperfine  $\Delta m_l = \pm 1$   $zz$ -components. All spectra were recorded in the same experimental conditions at  $P_{MW} = 200$   $\mu$ W, normalized per unit weight and plotted in comparable scales.

( $N_{S=1/2} = 3.6 \times 10^{18}$  spins/g) and its broadening ( $\Delta H_{pp}^{\text{Lorentz}} = 0.2$  mT), in comparison with the spectrum of starting MD (Figure 3(b), black trace). Figure 3(c) illustrates changes in the EPR spectrum due to milling of the fluorescent FMD sample. Milled fluorescent FND sample shows (Figure 3(c), blue trace) significant increase of the surface-originated dangling bond signal evidenced by signal broadening  $\Delta H_{pp} \sim 1$  mT (by WIN-SimFonia simulation), together with the newly appearing relatively narrow ( $\Delta H_{pp} = 0.23$  mT) Lorentzian-like line contributing to  $\sim 70\%$  of the total signal intensity. The latter corresponds to  $N_{S=1/2} = 8.1 \times 10^{18}$  spins/g. Extraction of the fine fraction from the FND sample leads to drastic decrease of the low- and high-field hyperfine components of P1 signal in the EPR spectrum of fFND (Figure 3(d) magenta and purple traces). Thus, the spectrum of the fFND sample represents the superposition of two Lorentzian lines: relatively broad line with  $\Delta H_{pp} \sim 1.1$  mT ( $\sim 80\%$  of total

1  
2  
3 intensity) and a narrow one with  $g = 2.0026(2)$  and  $\Delta H_{pp} \sim 0.3$  mT. Total concentration of  $S =$   
4  
5  
6  $1/2$  spins in fFND shows twofold increase in comparison with its precursor FND ( $N_{S=1/2} = 1.6$   
7  
8  $\times 10^{19}$  spins/g). Data on electron relaxation found for both P1 and dangling bond components  
9  
10 show a reduction of  $T_{SLc}$  in result of any treatment of the initial MD sample whereas  $T_{SSc}$   
11  
12 values remain quite short and practically unchanged. Spin-lattice relaxation times of both  
13  
14 types of defects are strongly affected by milling and depend on the mean particle size of the  
15  
16 resulting product obtained by fractionation. For details see Supplemental Materials [19].  
17  
18  
19

### 22 3. EPR spectra in the HF region ( $g = 4$ ) 23 24 25 26

27 Initial micron sized sample MD shows no signals within the HF region. The same is  
28  
29 correct for the milled sample ND – see overlapping black and green traces in Figure 4. On the  
30  
31 other hand irradiated and annealed MD as well as its milled derivatives show intensive  
32  
33 characteristic signals with  $g = 4.26(1)$  in that region – see Figure 4(a), red trace. Spectra of  
34  
35 FMD and FND also show weak line with  $g = 4.19(1)$ .<sup>2</sup> Milling of the FMD sample to FND  
36  
37 causes  $\sim 30\%$  reduction of the characteristic  $g = 4.26$  signal as well as smoothing of the  
38  
39 quasi-crystalline features – see Figure 4(a) and (b), blue traces. Coarse fraction of the FND  
40  
41 sample (cFND) provides the same (within the experimental error) HF signals (not shown).  
42  
43 Fine fraction of the FND sample (fFND) shows further considerable (about an order of  
44  
45 magnitude) reduction of the  $g = 4.26$  signal, practical disappearance of  $g = 4.19$  signal and all  
46  
47 quasi-crystalline features, and rise of the new signal with  $g = 4.00(1)$  which intensity at those  
48  
49 partially saturated excitation conditions becomes comparable with the intensity of the  $g =$   
50  
51  $4.26$  signal – see Figs. 4(a) and (b), magenta trace. Unfortunately, low signal-to-noise ratios  
52  
53 for both HF signals in fFND do not allow reliable evaluation of the electron relaxation times.  
54  
55  
56  
57  
58  
59

60 <sup>2</sup> Additional less intense features on the higher-field wing of the  $g = 4.26$  signal in the spectrum of FMD (Fig. 4(b)) appear due to the quasi-polycrystalline origin of this sample, that has been discussed above.

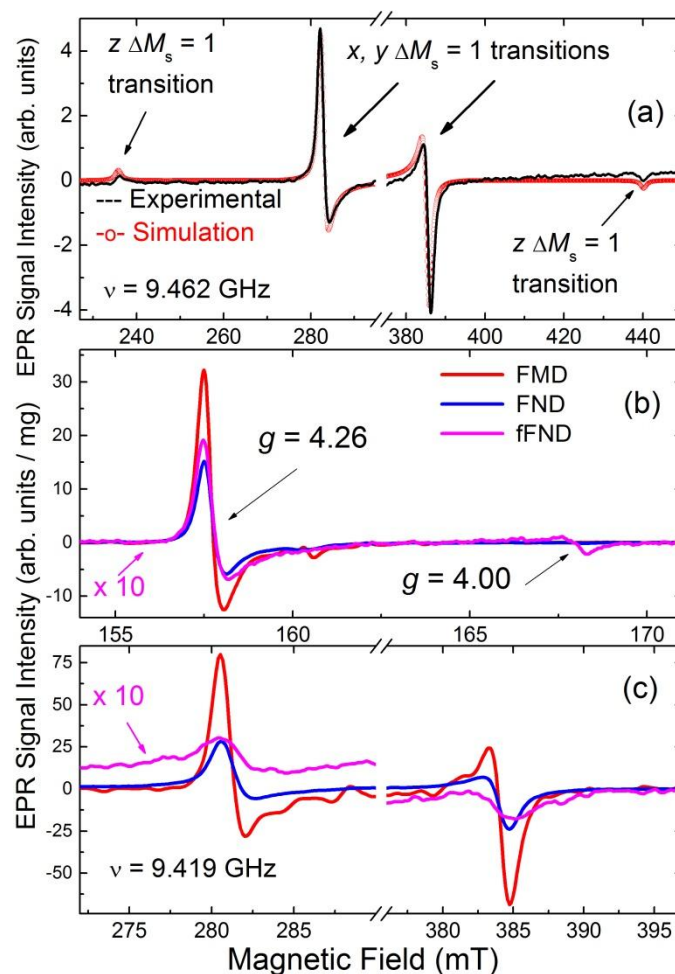

Saturation dependencies measured for FMD and FND coincide and provide estimated values  $T_{\text{SLe}} \sim 10^{-5}$  s and  $T_{\text{SSe}} \sim 10^{-8}$  s. Figure 5(b) shows HF EPR spectra of fluorescent diamond powders FMD, FND, and fFND recorded at relatively low  $P_{\text{MW}} = 2$  mW power. Comparing the spectrum of fFND (Figure 5(b), magenta trace) with the corresponding spectrum in Figure 4(b) recorded at tenfold  $P_{\text{MW}}$  reveals that the  $g = 4.26$  signal saturates at lower  $P_{\text{MW}}$  than the  $g = 4.00$  one signal, indicating longer  $T_{\text{SLe}}$  for defects responsible for the  $g = 4.26$  signal.

**Figure 4.** Partially saturated HF X-band ( $\nu = 9.463$  GHz) EPR spectra recorded at RT,  $P_{\text{MW}} = 20$  mW,  $A_{\text{mod}} = 1$  mT, number of coherent acquisitions  $n_{\text{acq}} = 100$ , black trace - MD, red trace - FMD, green trace - ND, blue trace - FND, magenta trace - fFND: (a) general view; (b) tenfold Y-scale zoom of spectra in Figure 4(a). All spectra were recorded in the same experimental conditions and normalized per unit weight. Broad impurity signals are subtracted. Black traces in both (a) and (b) are practically masked by the green ones.

#### 4. EPR spectra of satellite lines

1  
2  
3  
4  
5  
6 Low intensity satellite lines are observed only in the irradiated/annealed FMD sample  
7  
8 and its derivatives (FND, cFND and fFND). Neither the initial MD nor the milled ND  
9  
10 samples show any EPR lines in the corresponding magnetic field regions. Black traces in  
11  
12 Figure 5(a) show zoomed satellite lines in the EPR spectra of FMD, recorded at low  $P_{MW}$   
13  
14 (intense EPR signals in the  $g = 2.00$  region are not plotted there). Red traces in Figure 5(a)  
15  
16 represent simulated polycrystalline spectrum of triplet ( $S = 1$ ) paramagnetic centers obtained  
17  
18 using WIN-SimFonia software and the following spin-Hamiltonian (SH) parameters:  
19  
20  $\Delta H_{pp}^{\text{Lorentz}} = 1$  mT;  $g_{\text{iso}} = 2.003$  and zero field splitting parameters  $D = 0.0950$  cm $^{-1}$  and  $E =$   
21  
22  $0.0003$  cm $^{-1}$ . Figure 6(c) demonstrates evolution of satellite lines in the process of milling and  
23  
24 further fractionation of  
25  
26  
27  
28  
29

**Figure 5.** RT X-band EPR spectra of satellite and HF lines. (a) black trace – experimental spectra of satellite

lines in FMD recorded at  $P_{\text{MW}} = 100 \mu\text{W}$ ,  $A_{\text{mod}} = 1 \text{ mT}$ ,  $n_{\text{acq}} = 100$  and  $\nu = 9.463 \text{ GHz}$ , red trace – polycrystalline spectrum of triplet ( $S = 1$ ) centers simulated using the following SH parameters:  $\Delta H_{\text{pp}}^{\text{Lorentz}} = 1 \text{ mT}$ ;  $g_{\text{iso}} = 2.003$ ;  $D = 0.0950 \text{ cm}^{-1}$ ;  $E = 0.0003 \text{ cm}^{-1}$ ; (b) HF lines and (c)  $x, y$  satellite lines in irradiated/annealed samples: red trace - FMD, blue trace - FND and magenta trace - fFND (plotted at tenfold zoom). Spectra (b) recorded at  $P_{\text{MW}} = 2 \text{ mW}$ ,  $A_{\text{mod}} = 0.3 \text{ mT}$ ,  $n_{\text{acq}} = 400$ ,  $\nu = 9.419 \text{ GHz}$ ; spectra (c) recorded at  $P_{\text{MW}} = 100 \mu\text{W}$ ,  $A_{\text{mod}} = 1 \text{ mT}$ ,  $n_{\text{acq}} = 100$ ,  $\nu = 9.419 \text{ GHz}$ . Spectra of all diamond samples in each frame are recorded in the same experimental conditions and normalized per unit weight. Broad impurity signals are subtracted.

the FMD sample. Comparison of the same evolution in the HF  $g = 4.26$  lines (Figure 5(b)) with the corresponding satellite lines (Figure 5(c)) reveals that upon milling and, especially, extraction of the fine fraction the reduction of the peak-to-peak intensities (and, respectively, signal-to-noise ratios) of the satellite lines is more pronounced than that of the HF lines.

## B. NMR

RT  $^{13}\text{C}$  spectra ([19], Figure S4(a)) reveal symmetric narrow singlet lines with chemical shift 35 ppm characteristic of  $sp^3$  carbons of diamond [29]. The sample treatment causes a decrease in the line width, increase in spin-spin relaxation time  $T_{2\text{n}}(^{13}\text{C})$  and shortening of  $^{13}\text{C}$  NMR spin-lattice relaxation times:  $T_{1\text{n}}(^{13}\text{C})$  vary from 98 to 6.7 s ([19], Figure S4(b), TABLE SI), which correlates with the increase in the density of paramagnetic defects [29]. This correlation as well as the stretched exponential character of the relaxation are attributed to the interaction of nuclear spins with paramagnetic defects, both inherent P1 and processing-driven dangling bonds detected by EPR.

RT  $^1\text{H}$  NMR measurements reveal noticeable difference in the proton spectra within this series of samples. While initial larger particle size samples MD and irradiated/annealed FMD samples show no observable proton signal, the milled ND sample (Figure S4(c) and TABLE SI) shows relatively broad line 8.6 kHz [19]. FND, cFND and fFND samples reveal

1  
2  
3 narrow symmetric singlets ([19], Figure S4(c)) characteristic of mobile water molecules  
4  
5 adsorbed on the nanodiamond surface [29]. More details on  $^{13}\text{C}$  and  $^1\text{H}$  NMR spectra and  
6  
7 relaxation in studied samples can be found in Supplemental Material [19].  
8  
9

## 10 11 12 13 **IV. Discussion**

### 14 15 *1. Magnetic impurities*

16  
17  
18  
19  
20 EPR data allow direct tracking of the presence of magnetic contaminations in  
21  
22 polycrystalline diamond samples. The initial commercial samples MD demonstrate a  
23  
24 moderate level of magnetic (both para- and ferro-magnetic) impurities (see Figure 2 and  
25  
26 TABLE I.) These contaminations originate most probably from the HPHT synthesis. The  
27  
28 irradiation/annealing process introduces additional magnetic contamination. Thus, the total  
29  
30 intensity of the magnetic signal per unit mass in the fluorescent FMD sample is an order of  
31  
32 magnitude larger than the same in the initial sample. The presence of significant amount of  
33  
34 ferromagnetic impurities is sufficient to explain both broadening of  $^{13}\text{C}$  NMR line and  
35  
36 shortening of  $^{13}\text{C}$  spin-lattice relaxation time (see [19], Figs. S4(a) and (b)). In contrast, the  
37  
38 total amount of the main intrinsic EPR spectrum broadening agent - inherent paramagnetic  
39  
40 defects - shows  $\approx 30\%$  reduction in the FMD sample in comparison with the initial MD sample.  
41  
42 It is reasonable to suppose that these contaminations come from the irradiation accessories or  
43  
44 from the annealing chamber. On the other hand, diamond samples which passed through  
45  
46 milling and subsequent fractionation processes (ND, FND, cFND and fFND, respectively)  
47  
48 show quite low contamination levels (Figure 2 and TABLE II) which is in a good agreement  
49  
50 with the corresponding treatments including special decontamination procedures in which  
51  
52 metallic impurities are removed, among others (see TABLE I and [19]).

## 2. *Main sources of intrinsic paramagnetism*

EPR clearly indicates that the main paramagnetic defect in initial synthetic sample MD is P1 center originating from single isolated substitutional nitrogen [28]. Non-saturated (at  $P_{\text{MW}} = 2 \mu\text{W}$ ) width of the central  $\Delta m_I = 0$  hyperfine line  $\Delta H_{\text{pp}} = 0.12(1)$  mT corresponds to  $\sim 100$  at. ppm of paramagnetic impurities [30]. This number is in perfect agreement with the total amount of paramagnetic centers estimated by EPR as  $4.9 \times 10^{18}$  spins/g. Here it is worth mentioning that, according to the manufacturer of the initial MDs, nitrogen content in these Ib type samples does not exceed 150 at. ppm. It means that most of nitrogen in MD takes part in the creation of isolated substitutional defects P1. Of course, P1 is not the only paramagnetic defect in MD: analysis of saturation curves indicates the presence of some carbon-inherited defect like dangling bonds. Moreover, P1 spectra recorded at high incident power ( $P_{\text{MW}} > 1$  mW) reveal additional weak doublet signal with the splitting between the doublet lines of 3.2 mT (not shown) which saturates at much higher  $P_{\text{MW}}$  levels than P1. Strong differences in saturation curves behavior of hyperfine components as well as estimated relative intensities make the attribution of these lines to P1 centers associated to naturally abundant  $^{15}\text{N}$  ( $I = 1/2$ ,  $\sim 0.34\%$ ) not relevant. Thus, this doublet indicates the presence of paramagnetic centers of other types than P1 or dangling bonds in these MDs. However, the prevailing intrinsic defect in MD is P1.

Irradiation/annealing treatment does not make new  $S = 1/2$  defects appearing, but does affect initial P1 signal. Figure 3(b) clearly indicates both the reduction of the amount of P1 centers and an about twofold broadening of P1 center hyperfine lines in the fluorescent FMD sample. Electron spin-lattice relaxation time drops down as well (Figure S4(c), [19]). Moreover, the  $^{13}\text{C}$  NMR measurements of this sample also show line broadening and reduction of nuclear spin-lattice relaxation time (Figures S5(a) and (b), [19]). It is known that

1  
2  
3 the presence of paramagnetic defects is the main factor affecting electron and nuclear  
4 relaxation in diamonds [27,29,30]. Thus, the reduction of the number of paramagnetic defects  
5  
6 observed in the FMD sample contradicts the broadening of EPR and NMR lines as well as the  
7  
8 shortening of relaxation times found in FMD. It may be suggested that irradiation/annealing  
9  
10 changes structural properties of MDs directly affecting both nuclear and electron relaxation.  
11  
12 The reduction of P1 defects in FMD may be due to the cumulative effect of high-energy  
13  
14 irradiation and subsequent high temperature annealing.  
15  
16  
17  
18

19  
20 Milling affects basic paramagnetic properties of synthetic MDs much more seriously  
21  
22 than irradiation/annealing. Thus, from EPR spectra of milled ND one infer the total amount of  
23  
24  $S = 1/2$  paramagnetic defects increases by almost a factor of two compared to MD (Figure  
25  
26 3(a)). Considering the P1 content remains practically the same, the new dangling bond signal  
27  
28 (which was practically not observed in the initial MD sample) becomes the evident feature in  
29  
30 the EPR spectrum. In this sample the amount of dangling bond-type defects is comparable to  
31  
32 that of P1. In contrast to the FMD case these fabrication-driven defects are the ones  
33  
34 responsible for shortening EPR and NMR spin-lattice relaxation times. The same is observed  
35  
36 for the milled and processed irradiated/annealed sample FND: the total amount of  
37  
38 paramagnetic defects here is practically the same as in ND, but since the amount of P1 in its  
39  
40 starting FMD sample is lower than in initial non-irradiated MD, the dangling bond signal is  
41  
42 the prevailing feature in the EPR spectrum of FND (Figure 3(c)).  $^{13}\text{C}$  nuclear relaxation times  
43  
44 in ND, FND and cFND sample are found to be the same within the experimental error, which  
45  
46 perfectly corresponds to practically the same densities of main paramagnetic defects in these  
47  
48 samples. On the other hand both FND and cFND demonstrate noticeable reduction of  
49  
50 electron spin-lattice relaxation in P1 centers ([19], Figure S3(c)). It occurs due to the  
51  
52 combined effect of structural changes originated in irradiation/annealing (one of the factors  
53  
54 affecting line width and relaxation in the ND sample) and increasing spin-lattice relaxation  
55  
56  
57  
58  
59  
60

1  
2  
3 rates due to new paramagnetic defects induced by milling. Suggested location of the dangling  
4 bond defects are at surface and interface layer of ND particles.  
5  
6

7  
8 The effect of the milling to fine fractions on paramagnetic defects seems to be more  
9 complicated. The total amount of main paramagnetic defects in fFND grows almost twice in  
10 comparison with its precursor FND – up to  $1.6 \times 10^{19}$  spins/g. However the analysis of EPR  
11 signals line shapes points out some transformations of EPR signals observed in the precursor.  
12  
13 On the one hand, EPR spectrum of fFND (red trace in Figure 2(d)) shows subsequent  
14 increase of the broad Lorentzian line due to dangling bonds. At the same time the hyperfine  
15  $\Delta m_I = 1$  components of the P1 signal, which are found to be practically unchanged after  
16 irradiation/annealing and milling (see Figure 3(c)) almost disappear in fFND. Only zooming  
17 the spectrum (blue trace in Figure 3(d)) reveals some traces of those components.  
18  
19 Interestingly, the remaining hyperfine P1 components in fFND are not broadened in  
20 comparison with the same signals in FND or cFND. Thus, the real decrease of the  
21 conventional P1 signal is observed here. On the other hand, a new narrow Lorentzian signal  
22 with  $g = 2.0026(2)$  and  $\Delta H_{pp} \sim 0.3$  mT emerges in the spectrum. After decomposition into two  
23 Lorentzians, we infer that the narrow signal contributes to  $\sim 20\%$  of the total  $DI$  which  
24 corresponds well to the contribution of the P1 signal into the spectrum of the precursor FND.  
25  
26 One may suggest that in the fine fraction, extracted from FND, the characteristic P1 signal  
27 transforms into the narrow Lorentzian line, originating from the same P1 defects. Indeed, the  
28 P1 defects are intrinsic ones and located in the bulk of MDs and, most probably, are hardly  
29 affected by the milling process. For instance, milling practically does not affect the P1  
30 content (Figure 3(c)). It is worth mentioning that this ND sample is the only one containing  
31 an enormous (over  $1 \times 10^{19}$  spins/g) density of paramagnetic dangling bonds. Thus both  
32 dipole-dipole and exchange interactions of the P1 defects with dangling bonds confined in  
33 nanoparticle become the main factor determining the line shape of the EPR signal, like it has

been recently observed in detonation NDs [23]. In this case exchange averaging of hyperfine structure causing so-called exchange narrowing may form a new signal of the same P1 defects: the narrow Lorentzian line observed in the EPR spectrum of fFND. Following this hypothesis the residual weak hyperfine lines observed in the EPR spectrum of fFND at higher gain may be due to P1 centers in diamond crystallites of larger sizes ( $> 40$  nm), naturally occurring in fine ND powders in small but not vanishing quantities ( $< 0.3$  wt. %) (see Figure S3(c) for the population mode with smallest sizes which characterizes isolated single crystallites, [19]). Detailed study of the line shape dependence of P1 polycrystalline EPR spectrum on diamond particle size will be reported elsewhere.

### 3. *NV* centers induced by irradiation/annealing

Recent studies [23, 24] allow unambiguous attribution of the HF line with  $g = 4.26$ , accompanied by the satellite lines (symmetrically located on both sides of the  $g = 2.00$  transitions and separated by  $\sim 100$  mT and  $\sim 200$  mT), to negatively charged triplet ( $S = 1$ ) nitrogen vacancies  $NV^-$ . This attribution is based on the solid ground of specific line shape of the polycrystalline EPR spectrum as well as SH parameters determined both directly from the spectrum and by simulations. Thus, following these signals provides researchers with reliable tool to track appearance and evolution of  $NV^-$  centers as well as to estimate their content in samples under study. EPR data allow concluding that both initial synthetic MD and its milled derivative ND contain no  $NV^-$  centers traceable by EPR - see overlapping black and green traces in Figure 4. These samples also show no pronounced fingerprints of  $NV^-$ -type photoluminescence. Irradiation/annealing turns the initial MD sample to the fluorescent one (FMD). This transformation is accompanied by clear appearance of new features in EPR spectrum of FMD: strong narrow (non-saturated line width  $\Delta H_{pp} = 0.5$  mT) HF line with  $g =$

1  
2  
3 4.26 due to “forbidden”  $\Delta M_S = 2$  transitions in polycrystalline EPR spectrum of  $NV^-$  centers  
4  
5 (red trace in Figs. 4 and 5(b)) and set of low- and high-field satellite lines with  $\Delta H_{pp} \sim 1.5$  mT  
6  
7  
8 due to “allowed”  $\Delta M_S = 1$  transitions in the same spectrum (Figure 5(a) and (c)).  
9

10  
11 Double integration of the entire  $NV^-$ -related spectrum (i.e. all “allowed” and  
12  
13 “forbidden” lines excluding the  $g = 2.00$  region of very strong main paramagnetic signals,  
14  
15 which in the simulated EPR spectrum of  $NV^-$  contributes to the total  $DI$  less than 10%)  
16  
17 provides estimation of  $NV^-$  content in FMD as  $5.4 \times 10^{17}$  spins/g which, making simple  
18  
19 volume/mass calculations, corresponds to  $\sim 3 \times 10^{12}$   $NV^-$  centers per each 150  $\mu\text{m}$  FMD  
20  
21 particle. Milling of fluorescent MDs leads to a weak broadening of all  $NV^-$ -related lines in  
22  
23 EPR spectra of the FND and cFND samples ( $\Delta H_{pp} = 0.6$  mT and 2 mT for the “forbidden”  
24  
25 and “allowed” line, correspondingly) and about 30% reduction of  $DI$  of that characteristic  $g =$   
26  
27 4.26 line (blue trace in Figure 5). Following the aforementioned procedure, double  
28  
29 integration of all  $NV^-$ -related lines provides  $NV^-$  content in FND as  $3.6 \times 10^{17}$  spins/g  
30  
31 corresponding to  $\sim 660$   $NV^-$  centers per each 100 nm FND particle. Extraction of the fine  
32  
33 fraction (the fFND sample, average particle sizes below 20 nm) reveals more pronounced  
34  
35 broadening of EPR lines (magenta traces in Figs. 5, 6(b) and 6(c),  $\Delta H_{pp} = 0.7$  mT and  $\sim 4$  mT  
36  
37 for the “forbidden” and “allowed” lines) as well as drastic decrease in the  $NV^-$  centers content  
38  
39 down to  $5.4 \times 10^{16}$  spins/g. The latter number corresponds to a single  $NV^-$  center per 3÷4  
40  
41 (assuming 15 nm mean size) diamond nanoparticles. It could be suggested that, likewise the  
42  
43 case of P1 signals described above, EPR signals of  $NV^-$  centers observed for the fFND  
44  
45 sample originate from single nanocrystallites of larger sizes ( $> 40$  nm, like those in FND).  
46  
47 However, significant line broadening of all  $NV^-$ -related EPR signals registered in fFND vote  
48  
49 against such a model. Thus, one can suppose that  $NV^-$  centers in small (size  $< 20$  nm) fFND  
50  
51 particles are infrequent defects.  
52  
53  
54  
55  
56  
57  
58  
59  
60

It should be noted that changes in  $DI$  of the “forbidden” line agree quite well with the

1  
2  
3 changes in the  $NV^-$  content obtained by the correct procedure of double integration of the  
4 entire  $NV^-$ -related EPR spectrum. Thus, the EPR spectrum of “forbidden” line in the HF  
5 region may be used as a reliable tool for comparative estimations of the  $NV^-$  content in  
6 fluorescent NDs even in the cases when weak “allowed” transitions are not (or hardly)  
7 observed (see, for instance, Ref. [23]).  
8  
9

10 Let us analyze the evolution of the  $NV^-$  content in the diamond samples under study.  
11  
12  $NV^-$  centers do not exist in the non-irradiated samples: both initial and milled ones. The EPR  
13 features attributed to  $NV^-$  appears only in the FMD sample and its pulverized derivatives, i.e.  
14 in the samples passed through the corresponding irradiation/annealing treatment. The highest  
15 density of  $NV^-$  is observed in the micron-sized sample FMD. Upon milling to 100 nm (FND,  
16 cFND) this density decreases by one third. It means that 30% of  $NV^-$  defects, most probably  
17 located within or closer to interface layers were quenched by milling which is usually  
18 accompanied by excessive heating, formation of paramagnetic dangling bonds etc. Other  $NV^-$   
19 centers in this sample (as well as in the irradiated/annealed FMD sample) are located in the  
20 bulk of the diamond particle and, thus, are almost unaffected (not quenched) by the treatment.  
21  
22  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38

39 The above findings seem to disagree with fluorescence microscopy observation  
40 combined with atomic-force microscopy size measurement [13]. The optical study reports  
41 that in the sample analogous to fFND (mean particle size of ~8 nm) ~25% of the particles  
42 carry at least one  $NV$  color center. Let us point out that the photoluminescence reported in  
43 Ref. [13] also includes the contribution from the neutral  $NV^0$  centers. It was recently reported  
44 that, due to the larger influence of surface electron traps in smaller particles, the proportion of  
45 negatively charged  $NV^-$  defects, with respect to its neutral counterpart  $NV^0$ , decreases with  
46 the size of the ND [15]. These observation where done on isolated FND spincoated on a  
47 cover glass. However, in our EPR experiment inter-particle interactions could play a role too.  
48  
49 In order to ruled out the effect of inter-particle interactions on the surface electron trapping  
50

1  
2  
3 process, we carried EPR measurements on the diluted cFND:SiO<sub>2</sub> and fFND:SiO<sub>2</sub> samples  
4  
5 allow shedding light on the effect of inter-particle interactions on the surface electron  
6  
7 trapping process. Upon dilution by SiO<sub>2</sub> the NV<sup>-</sup>-related EPR features for both coarser and  
8  
9 fine nanoparticles behave exactly in the same manner as the features responsible for the main  
10  
11 paramagnetic defects: no changes in SH parameters and line width, just proportional  
12  
13 reduction of signals intensities. In the case where inter-particle interactions had played a role  
14  
15 one would have observed deviations from the proportional reduction for the fine sample.  
16  
17 Such a deviation is not observed so we can exclude the involvement of inter-particle  
18  
19 interactions into the process of surface induced charge state conversion of single NV defects  
20  
21 hosted in NDs which solely comes from surface electron traps.  
22  
23  
24  
25  
26

27 Extrapolation of data presented in Ref. [15] indicates that in NV containing NDs  
28  
29 having sizes smaller than 10 nm NV<sup>0</sup> centers are about 50% of total NV-related defects. It  
30  
31 should be noted that, in spite of its spin singlet origin ( $S = 1/2$  ground state) NV<sup>0</sup> center is  
32  
33 practically EPR silent due to the dynamic Jahn-Teller coupling which broadens the EPR  
34  
35 lines dramatically reducing detection sensitivity [31]. Therefore, these centers do not  
36  
37 contribute to any (especially NV<sup>-</sup> related) EPR signals. Hence it may be concluded that just  
38  
39 ~12% of the fFND particles carry at least one EPR active NV<sup>-</sup> center. This estimation is in a  
40  
41 good agreement with the EPR findings reported above.

#### 48 *4. Other HF EPR signals*

49

50 Figure 4(a) clearly shows that, in addition to the characteristic NV<sup>-</sup>-originated  $g =$   
51  
52 4.26 signal, other two HF signals appear during irradiation/annealing and milling of the initial  
53  
54 sample. These are the  $g = 4.19$  signal, observed in FMD and coarse ND fractions (FND,  
55  
56 cFND), as well as the weak  $g = 4.00$  signal observed in both coarse and fine fractions. In the  
57  
58 fine fraction fFND intensity of the latter signal becomes comparable with the intensity of the  
59  
60

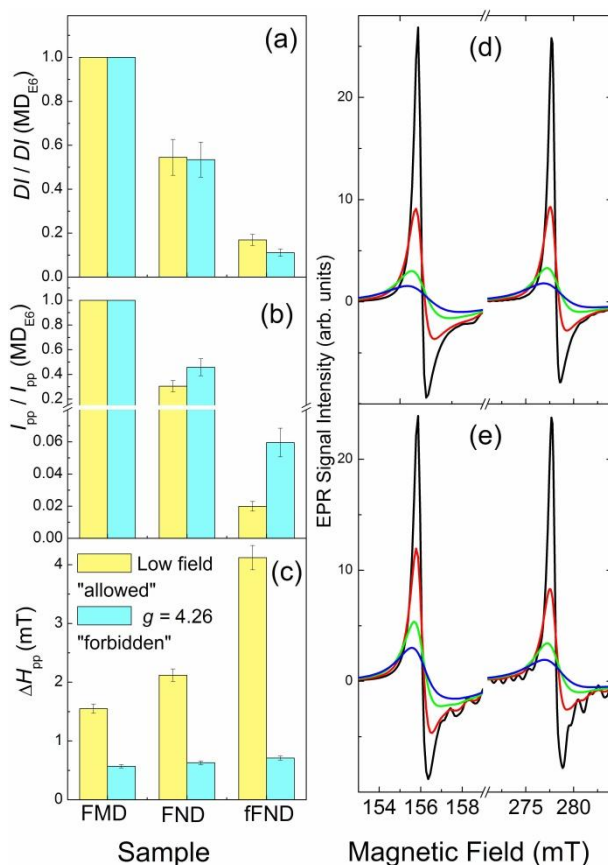

1  
2  
3  $g = 4.26$  signal – see Figure 4(b), magenta trace. Both  $g = 4.19$  and  $g = 4.00$  lines are not  
4  
5 accompanied by observable “allowed” lines – most probably due to low abundance of these  
6  
7 triplet centers. Following the attribution of all narrow HF signals to “forbidden”  $\Delta M_S = 2$   
8  
9 transitions in polycrystalline EPR spectra of some triplet centers [23, 24], one may suggest  
10  
11 that the weak additional HF features found in this study belong to other triplet centers with  
12  
13 SH parameters differing from those for the  $NV^-$  defects. One may ascribe the  $g = 4.19$  line to  
14  
15 triplet defects with  $D$ -value smaller than that for the  $NV^-$  center ( $0.0950 \text{ cm}^{-1}$ ). Spectra  
16  
17 simulations provide that the  $g = 4.19$  position corresponds to  $D \sim 0.08 \text{ cm}^{-1}$ . Detailed study of  
18  
19 the irradiation induced centers of this type in other irradiated diamond samples will be  
20  
21 reported elsewhere. The same considerations done for the  $g = 4.00$  signals provide  $D \sim 0.03$   
22  
23  $\text{cm}^{-1}$ . Recently similar signals were found in HF EPR spectra of NDs manufactured by  
24  
25 detonation and other dynamical synthesis techniques [23] and attributed to some triplet  
26  
27 defects TR2 which do not relate to atomic nitrogen substitutions in the diamond lattice and,  
28  
29 therefore, are caused solely by carbon-inherited defects, namely intrinsic multivacancy  
30  
31 defects [23]. Strengthening of the  $g = 4.00$  signals just in the EPR spectra of the fine fraction  
32  
33 fFND supports the hypothesis proposed in Ref. [23]. Indeed, the fine fraction fFND is  
34  
35 characterized by the enormous content of the milling induced singlet paramagnetic defects  
36  
37 which, in turn, increases the probability of these defects coupling.

48 *5. Can “allowed” transitions be observed in EPR spectra of  $NV^-$  containing nano-diamond*  
49  
50 *powders?*  
51  
52  
53  
54

55 Ref. [23] reports on thorough but unsuccessful attempts to observe any traces of EPR  
56  
57 lines which could be attributed to “allowed” transitions in EPR spectra of polycrystalline  
58  
59 NDs obtained by dynamic synthesis techniques (detonation, laser ablation etc.). On the other  
60

1  
2  
3 hand, characteristic HF signals with  $g = 4.26$  attributed to “forbidden” transitions in EPR  
4 spectra of  $NV^-$  centers [24] were registered for all above mentioned ND samples. It was  
5 suggested that some specific broadening of just the “allowed” lines causes such a puzzling  
6 situation [23]. Some speculations on the mechanisms responsible for the disappearance of  
7 “allowed” lines in EPR spectra of NDs have been discussed there. Careful analysis of data  
8 reported in this study promises to shed light onto this problem. Figs. 6(a) – (c) illustrate  
9 changes in EPR parameters of  $g = 4.26$  “forbidden” line and one (low field) of the “allowed”  
10 satellite lines, obtained from the experimental spectra of the diamond series under study (Figs.  
11 5(b) and (c)). It is found that  $DI$  of both “allowed” and “forbidden” lines drop down equally  
12 on milling – see Figure 6(a). On the other hand, as a result of this milling the peak-to-peak  
13 intensity  $I_{pp}$  of the “forbidden” line undergoes less dramatic decrease than the same of the  
14 “allowed” line (Figure 6(b)). The drop in the “allowed” line intensity is accompanied by  
15 strong broadening of just this line (Figure 6(c)) that correlates with the  $DI$  changes found for  
16 both lines. Thus, the main reason for the disappearance of EPR lines corresponding to the  
17 “allowed” transitions in EPR spectra of  $NV^-$  containing NDs is the stronger broadening of the  
18 “allowed” lines in comparison with the broadening affecting the lines attributed to “forbidden”  
19 transitions. Let us speculate on the mechanisms which could be responsible for such a  
20 selective broadening. Figure 6(d) presents the  $g = 4.26$  “forbidden” lines and low field  
21 “allowed” ones obtained by XSophe simulation of the polycrystalline EPR spectrum of  $NV^-$   
22 centers in diamond (SH parameters - in figure caption) as a function of the homogeneous  
23 broadening of individual Lorentzian lines. Here it is clearly seen that both lines are broadened  
24 in the same manner providing the same drop in peak intensities. Thus, the origin of the  
25 asymmetry in line broadening may be found in the mechanisms responsible for  
26 inhomogeneous EPR line broadening in spectra of disordered (or partially ordered) system.  
27 Among possible mechanisms of such a disorder one can consider so-called  $D$ -strain –

distributed zero field interaction [32] or, in other words, slight differences in zero field splitting parameters in SH of  $NV^-$  centers in various micro- and nano-crystallites. These differences may be either intrinsic or induced by processing such as milling or surface treatment. Figure 6(e) shows changes in the above mentioned simulated EPR spectra as a function of  $D$ -strain,  $\Delta D$ , obtained at fixed individual line width  $\Delta H_{pp}^{\text{Lorentz}} = 0.57$  mT. Figure 6(e) shows that appearance of  $D$ -strain broadens “allowed” line and, correspondingly, decreases its peak intensity more effectively than the “forbidden” one. Comparing experimental spectra of Figs.6 (b) and (c) with those extracted from the simulations, one can find that in the starting irradiated/annealed FMD sample the distributed zero-field splitting is  $\Delta D \sim 0.0010$  cm $^{-1}$ .

**Figure 6.** (a) - (c) Changes in EPR parameters of the low field “allowed” (light yellow) and  $g = 4.26$  “forbidden” (light cyan) lines in the experimental EPR spectra of  $NV^-$  centers (see Figs. 4(b) and (c)) come from micronization and nano-milling: (a)  $DI$  normalized to the corresponding  $DI$  values in the spectrum of MD sample; (b) normalized peak-to-peak intensity  $I_{pp}$ ; (c) line width  $\Delta H_{pp}$ . (d) - (e) XSope simulations of the  $g =$

1  
2  
3 4.26 “forbidden” lines (153 – 159 mT region) and low field “allowed” lines (271 – 284 mT region) in  
4 polycrystalline EPR spectra of triplet  $NV^-$  centers with SH parameters  $g_{xx} = g_{yy} = 2.0027$ ;  $g_{zz} = 2.0029$ ,  $D =$   
5  $0.0950 \text{ cm}^{-1}$ ,  $E = 0$ ,  $\nu = 9.34 \text{ GHz}$ : (d) as function of the individual line width  $\Delta H_{pp}^{\text{Lorentz}}$ , black trace – 0.5 mT,  
6 red trace – 1 mT, green trace – 2 mT, blue trace – 3 mT; (e) as function of  $D$ -strain,  $\Delta D$  (at  $\Delta H_{pp}^{\text{Lorentz}} = 0.57$   
7 mT), black trace – 0, red trace –  $0.0015 \text{ cm}^{-1}$ , green trace –  $0.0030 \text{ cm}^{-1}$ , blue trace –  $0.0045 \text{ cm}^{-1}$ . Each of EPR  
8 spectra in (d) and (e) is normalized to the same  $DI$  value. Narrow crystalline-like features on  $\Delta D = 0$  curves in  
9 (e) are XSophe –simulation artefacts.

18  
19

20 This is the natural  $D$ -strain resulting from irradiation/annealing. Milling induces  
21 intensification of  $D$ -strain to  $\sim 0.0020 \text{ cm}^{-1}$ . However, for smaller nano-particles obtained by  
22 fractionation - fFND sample, the  $D$ -strain model stops working. Indeed, in spite of almost  
23 threefold broadening (in comparison with the starting FMD sample) of the “allowed” line, the  
24 “forbidden” line remains quite narrow – see Figure 6(c). One can suppose that in small  
25 (size  $< 20 \text{ nm}$ ) nano-particles carrying, in addition to  $NV^-$  centers, dozens of other  
26 paramagnetic centers (like dangling bonds) other mechanisms of inhomogeneous line  
27 broadening take place.

## 41 *6. Hydrogen in fluorescent diamonds*

42  
43  
44  
45

46 The absence of NMR-detectable proton signals in the initial MD and  
47 irradiated/annealed FMD samples undoubtedly indicates that both surface and bulk of these  
48 micro-diamond particles contain bound hydrogen in quantities below the detection threshold  
49 of the solid state NMR machine in use. It should be noted that surface of these micron-sized  
50 crystallites seems to be hydrophobic and contain even no detectable water molecules usually  
51 providing relatively narrow (and, thus, easily observed)  $^1\text{H}$  NMR lines. On the other hand,  
52 samples which have undergone milling and subsequent processing/fractionation do show well  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 observable  $^1\text{H}$  NMR signals which indicate a modification of their surfaces. Thus, surfaces of  
4 FND, cFND and fFND show clear hydrophilic properties – they adsorb water molecules  
5 responsible for the narrow  $^1\text{H}$  NMR lines in Figure S4(c), Ref. [19] (blue and magenta traces,  
6 correspondingly) as well as for the single exponential magnetization recovery. This  
7 hydrophilic character is likely to come from carboxylic groups produced during the chemical  
8 decontamination procedure. The same treatment also produces hydroxyl groups, which  
9 together with carboxylic groups are necessary to stabilize aqueous NDs suspension. In  
10 contrast to FND, cFND and fFND, ND displays a broad  $^1\text{H}$  NMR line in sample indicating the  
11 presence of dipole-dipole coupling of proton spins, which means that the surface of this  
12 nanodiamond is partially terminated by hydrogen atoms forming rigid hydrocarbon and  
13 hydroxyl groups. This  $^1\text{H}$  NMR line broadening is characteristic of NDs, in which hydrogen  
14 atoms at the surface are irregularly positioned, presumably forming more hydrogenated spots  
15 of limited sizes alternating with less hydrogenated or nearly non-hydrogenated zones [29].  
16 Moreover, the width of the  $^1\text{H}$  NMR line in MD sample is found to be dependent on the delay  
17 between the echo pulses ( $\tau_d$ ) and decreases with increasing  $\tau_d$  – see green and olive traces in  
18 Figure S4(c), Ref. [19]. Such a behavior of the NMR spectrum may be described in terms of  
19 superposition of a variety of components showing different widths and  $T_2$ . For the long  $\tau_d$ , the  
20 broad components with short  $T_2$  are dephased and thus not observed in the experiment [33].  
21 Contribution of the long  $T_2$  proton species to the entire NMR signal is relatively small: the  
22 long  $\tau_d$  spectrum (olive trace) in Figure S4(c), Ref. [19] was recorded at tenfold increased  
23 number of coherent acquisitions comparing to the spectrum measured with short  $\tau_d$ .  
24 Comparing proton NMR data in the ND and FND samples of the same particle sizes (they  
25 passed through the same micronization) one can conclude the surfaces in these sample are  
26 different. We suggest that this difference is due to the FND irradiation/annealing treatment.  
27 This treatment somehow reconstructs the surface of diamond particles making them more

## 8 9 10 **V. Conclusions**

11  
12  
13  
14  
15 We conclude that magnetic resonance techniques are powerful and reliable tools for  
16  
17 accurate step-by-step tracking of complex changes in purity, magnetic and structural  
18  
19 properties of synthetic HPHT micron sized diamonds that occurs in the process of fabrication  
20  
21 of fluorescent diamond nanocrystals. EPR reliably reveals characteristic signatures of NV<sup>-</sup>  
22  
23 triplet ( $S = 1$ ) defects induced by high-energy electron irradiation in non-fluorescent MDs and  
24  
25 tracks transformation of these defects during two-stage milling and fractionation. The  
26  
27 concentration of NV<sup>-</sup> defects in irradiated/annealed MD sample is  $5.4 \times 10^{17}$  spins/g. It is  
28  
29 shown that in the coarse fractions of milled fluorescent nanodiamonds the concentration of  
30  
31 EPR-active NV<sup>-</sup> defects drops down by 30% whereas in the finest fraction the same  
32  
33 concentration drops by one order of magnitude. The latter fact allows determination of the  
34  
35 lower size limit in fabrication of fluorescent ND particles and, thus, is of the high  
36  
37 technological importance [34]. Our results are consistent with single particle fluorescence  
38  
39 measurements. Moreover they indicate that to efficiently create fluorescent nanodiamonds  
40  
41 with size  $< 10$  nm, several times higher concentration of NV<sup>-</sup> defects is necessary, than that  
42  
43 obtained by irradiation/annealing of commercial HPHT MDs having regular nitrogen  
44  
45 concentration of  $\sim 140$  ppm. In addition we observed that the increase of specific surface area  
46  
47 of diamond particles rises the amount of carbon-inherited singlet ( $S = 1/2$ ) paramagnetic  
48  
49 defects (up to  $1.6 \times 10^{19}$  spins/g in the fine fluorescent ND fraction) as well as carbon-  
50  
51 inherited triplet multivacancy defects. We ascertained that, on reduction of the particle size  
52  
53 below the 20 nm limit, the EPR lines corresponding to “allowed” transitions in spectra of NV<sup>-</sup>  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 centers become practically unobservable, whereas “forbidden” lines remain the reliable  
4 fingerprint of the presence of NV<sup>-</sup> centers in small nanodiamond systems. The same reduction  
5  
6 causes disappearance of characteristic hyperfine satellites in spectra of P1 centers. This study  
7  
8 clearly shows that magnetic resonance techniques being applied to polycrystalline diamond  
9  
10 samples should provide convenient quantitative approach for the optimization of each step of  
11  
12 synthesis (and further to industrial scaling of fabrication) of fluorescent nanodiamonds,  
13  
14 aiming their applications to optical imaging and magnetic sensing.

26

27 **Figure 6.** (a) - (c) Changes in EPR parameters of the low field “allowed” (light yellow) and  $g$   
28  $= 4.26$  “forbidden” (light cyan) lines in the experimental EPR spectra of  $\text{NV}^-$  centers (see  
29  
30 Figs. 5(b) and (c)) come from micronization and nano-milling: (a)  $DI$  normalized to the  
31  
32 corresponding  $DI$  values in the spectrum of FMD sample; (b) normalized peak-to-peak  
33  
34 intensity  $I_{\text{pp}}$ ; (c) line width  $\Delta H_{\text{pp}}$ . (d) - (e) XSophe simulations of the  $g = 4.26$  “forbidden”  
35  
36 lines (153 – 159 mT region) and low field “allowed” lines (271 – 284 mT region) in  
37  
38 polycrystalline EPR spectra of triplet  $\text{NV}^-$  centers with SH parameters  $g_{\text{xx}} = g_{\text{yy}} = 2.0027$ ;  $g_{\text{zz}}$   
39  
40  $= 2.0029$ ,  $D = 0.0950 \text{ cm}^{-1}$ ,  $E = 0$ ,  $\nu = 9.34 \text{ GHz}$ : (d) as function of the individual line width  
41  
42  $\Delta H_{\text{pp}}^{\text{Lorentz}}$ , black trace – 0.5 mT, red trace – 1 mT, green trace – 2 mT, blue trace – 3 mT;  
43  
44 (e) as function of  $D$ -strain,  $\Delta D$  (at  $\Delta H_{\text{pp}}^{\text{Lorentz}} = 0.57 \text{ mT}$ ), black trace – 0, red trace – 0.0015  
45  
46  $\text{cm}^{-1}$ , green trace – 0.0030  $\text{cm}^{-1}$ , blue trace – 0.0045  $\text{cm}^{-1}$ . Each of EPR spectra in (d) and (e)  
47  
48 is normalized to the same  $DI$  value. Narrow crystalline-like features on  $\Delta D = 0$  curves in (e)  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60 are XSophe –simulation artefacts.

TABLE I. The set of samples used in this study.

<i>Designation</i>	<i>Source</i>	<i>Description</i>	<i>Reference</i>
MD	Element Six Ltd., Shannon Airport, Shannon, Co Clare, Ireland	Synthetic micron-sized HPHT diamond crystals of PremaDia™ PDA999 series with a high crystalline quality, high impact strength, thermal stability, uniform well-faceted particle shape and of type Ib, nitrogen mean content of about 150 at. ppm. Appearance: transparent microcrystals with mean size ca. 150 $\mu\text{m}$ of yellow-lemon color.	See information from the manufacturer <a href="http://www.e6.com">http://www.e6.com</a>
ND	“Nano4Drugs” Project	MD sample after milling, decontamination in hot acids, oxidation, dispersion in water and washing by centrifugation. The product was extracted from neutral water supernatant. The nanometric sample is too much aggregated and polydispersed to be able to measure a mean particle size. However electron microscopy shows that most crystallites have a size below 100 nm. Appearance: fine gray powder.	10 – 13

1				
2				
3	FMD	“Nano4Drugs”	MD sample homogeneously treated by 10	10 – 13
4				
5		Project	MeV electron irradiation and subsequent	
6			annealing at 800 °C during 2 hours in	
7			secondary vacuum. Appearance:	
8			transparent microcrystals of violet color.	
9				
10				
11

1  
2  
3 the secondary vacuum. Electron  
4  
5 microscopy shows that most crystallites  
6  
7 have a size below 100 nm. Appearance:  
8  
9 fine gray powder.  
10  
11

12  
13  
14  
15 fFND “Nano4Drugs” *Fine* fraction of FND, obtained in the 10 – 13  
16  
17 Project supernatant after additional centrifugation  
18  
19 of an aqueous dispersion of FND. FND  
20  
21 aqueous dispersion was fractionated by  
22  
23 centrifugation either at 4000 *g* for 30  
24  
25 minutes or 15000 *g* for 3 minutes (this  
26  
27 work). The supernatant sample is still  
28  
29 polydispersed [19]. Transmission  
30  
31 electron microscopy shows that most  
32  
33 crystallites have sizes about 15 nm. DLS  
34  
35 on water suspended sample provides  
36  
37 maximum of the size distribution of the  
38  
39 differential number of particles at ~18  
40  
41 nm, FWHM ~14 nm. The solid material  
42  
43 specially extracted from light supernatant  
44  
45 part was dried in the secondary vacuum.  
46  
47 Appearance: fine gray powder.
