32 **1. Introduction**

33
34
35

36 Given the growing use of nanomaterials in daily life products and their many promising
37
38 applications in biomedicine, humans are expected to be increasingly exposed to nano-objects.
39
40 Consequently, many research efforts are presently focused on the life cycle and toxicity of nano-
41
42 sized materials.^[1, 2] However, the emerging field of nanotoxicity must be considered from
43
44 different angles. While most toxicology studies warn about the effects of nanomaterials on
45
46 biological functions (cytotoxicity, biopersistence, immunogenicity, genotoxicity...), it is also
47
48 essential to understand the transformation of nano-objects in living environment in order to
49
50 unravel the mechanisms determining their fate.^[3] By examining the influence of the biological
51
52 medium on the structure and physical properties of nano-objects, the material science approach

5
6
7 opens up a new way to evaluate the life cycle of nanoparticles and their biodegradation products
8
9 and provides relevant information on the design of safer and more efficient nanomaterials.

10
11 In addition to the nature of the materials and surface properties,^[4, 5] the morphology and
12
13 architecture of nanostructures are crucial determinants of their physical properties and outcome in
14
15 the organism.^[6] Multicore assembly of nanoparticles have been proposed for medical applications
16
17 due to enhanced properties as contrast agent for imaging, nanoheaters for thermotherapy and
18
19 mesoporous drug carrier for sustained drug delivery.^[7-12] The capability of multicore structures to
20
21 disintegrate into smaller entities might be a key advantage to penetrate tumor environment,
22
23 reduce biopersistence and facilitate degradability and/or excretion.^[13, 14] Therefore there is a
24
25 crucial need in controlling the biodegradation of such structures by following their physical
26
27 properties and morphological transformations. In spite of the tremendous potential of iron oxide
28
29 nanoparticles (NPs) in the biomedical field, not enough attention has been paid to their
30
31 biodegradation mechanisms.^{[15, 16][17-22]} As most inorganic nanomaterials interacting with cells,
32
33 iron oxide NPs are rapidly confined within intracellular lysosomes, where they are exposed to the
34
35 combined effect of acidic pH around 4.7, digestive enzymes and iron chelators involved in iron
36
37 regulation. Recently, we have evidenced that the biotransformation of iron oxide nanospheres and
38
39 nanocubes takes place in this lysosomal environment, resulting in a transfer of iron from
40
41 synthetic particles to ferritin proteins.^[18, 23] However, although *in vivo* experiments are necessary
42
43 to understand the pathway for biotransformation of inorganic NPs, the impossibility of analyzing
44
45 the atomic structure and properties of the same NPs over time in living environment, prevents the
46
47 understanding of the atomic-scale mechanisms leading to the degradation products. The
48
49 methodology reported here gives the opportunity to follow both the magnetic and structural
50
51 transformations of multicore maghemite nanoflowers (NFs) in a medium mimicking intracellular

7 lysosomal environment. The combined use of aberration-corrected high resolution transmission
8
9 electron microscopy (HRTEM) and magnetic measurements allows confronting atomic-scale and
10
11 macroscopic information on the biodegradation mechanisms of iron oxide NFs. Through this
12
13 magneto-structural approach, we aim to establish the link between the structural degradation of
14
15 the multicore NFs and the critical alterations of their hyperthermic power and their Magnetic
16
17 Resonance Imaging T_1 and T_2 contrast effect. Therefore, we provide a deeper understanding of
18
19 the harmful influence of cellular medium on the therapeutic and diagnosis effectiveness of
20
21 complex iron oxide nanostructures. Finally, we suggest that the coating of a protective gold layer
22
23 on maghemite, in addition to potentiate the efficiency of nanostructures for many biomedical
24
25 applications, is an interesting strategy to slow-down the degradation kinetic of the iron oxide
26
27 multicore structures.

32 33 34 35 **2. Results**

36
37
38
39
40 Iron oxide nanoflowers consist of an isotropic assembly of cores, forming nearly spherical porous
41
42 supercrystals (**Figure 1a**). During the polyol synthesis of the nanoflowers, the merged cores
43
44 rotate to share the same crystalline orientation and then minimize their surface energy.^[24]
45
46 Therefore, NFs exhibit a mono-crystalline inverse spinel FCC structure. Recently we have shown
47
48 that the distinctive architecture of multicore iron oxide nanoparticles accounted for their
49
50 outstanding efficacy as both heating mediators for magnetic hyperthermia and MRI contrast
51
52 agent.^[10] The magnetic properties of multicore particles have been compared to those of single
53
54 cores, revealing a cooperative behavior due to exchange interactions between the cores
55
56 constituting the particles. This collective magnetic behavior of internal cores was possible due to
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 the crystal continuity at the core interface, which also ensured a continuity of spin orientation. As
8
9 a consequence, the multicore particles showed enhanced susceptibility compared to single core,
10
11 while maintaining a superparamagnetic behavior due to a reduced surface anisotropy. The
12
13 combination of their high susceptibility, high saturation magnetization and low magnetic
14
15 anisotropy for particles of 24 nm size were responsible for their outstanding heating power and
16
17 MRI relaxivities. Hence those biocompatible water-dispersed multicore particles, which are made
18
19 of pure iron oxide, hold great promises for biomedical applications.

26 **2.1 Time evolution of magnetic properties in the lysosome-like medium**

27
28 The reactivity and degradation of multicore NFs were first monitored by measuring the evolution
29
30 of their magnetic properties in a medium mimicking the lysosomal environment. A suspension of
31
32 multicore NFs (10 mM iron concentration) was exposed to an acidic buffer at pH 4.7
33
34 supplemented with 20 mM citrate for a period of 23 days at 37°C. This simple medium
35
36 containing citrate as iron chelators has been shown to efficiently trigger the degradation of single
37
38 core iron oxide nanoparticles used as MRI contrast agent.^[23, 25] This medium was first proposed
39
40 by Arbab et al^[26] to mimic lysosomal environment. The field-dependence of the magnetization
41
42 was first probed at 310K by VSM measurements on the NF colloidal suspension. As observed in
43
44 Figure 1b, the magnetization was reversible (no hysteresis) and was rapidly saturating when
45
46 increasing the magnetic field beyond 200 kA/m, regardless of the incubation time in the
47
48 lysosome-like buffer. However, in the meantime, the saturation magnetization of the suspension
49
50 exponentially decreased, losing 83% of its initial value after 23 days in the acidic buffer (Figure
51
52 1b, **Table 1**). This loss of magnetization could be explained by the complete dissolution of some
53
54 nanoparticles in the acidic medium and/or by their transformation into less magnetic structures. A
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 closer view into the low field magnetization (Figure 1c) shows that the initial susceptibility is
8
9 also diminished over time in the acidic medium. This suggests that the particles are being
10
11 transformed and potentially break down their multicore structure. Indeed the distribution of the
12
13 “effective” magnetic size of the particles can be deduced from a fit of their magnetization curve
14
15 by a Langevin function weighted by the magnetic size distribution^[25] (see Table 1 and **Figure S1**
16
17 **in Supplementary Materials**). The initial multicore nanoparticles show a broad log-normal
18
19 distribution of their magnetic sizes centered around 14 nm (Figure 1d). As discussed in our
20
21 previous work,^[10] this effective magnetic size is larger than the TEM size of each constitutive
22
23 core (10.6 nm). Consistently the saturation magnetization M_S of NFs is $82 \text{ A.m}^2.\text{kg}^{-1}$ (close to the
24
25 bulk value of maghemite) while it is reduced to $58 \text{ A.m}^2.\text{kg}^{-1}$ for 10.6 nm single cores.^[10] Upon
26
27 exposure to the acidic citrate buffer, the magnetic size of particles tends to diminish and after
28
29 three weeks, the distribution becomes narrow around a mean diameter of 12.2 nm, suggesting the
30
31 loss of their multicore organization. In line with macroscopic magnetization measurements,
32
33 electron microscopy confirms the physical transformation of NFs (**Figure 2**): the multicore
34
35 initial structures (with a mean TEM diameter of 24 nm) seem to dissociate into smaller single
36
37 cores over time. At day 23, some degraded structures clearly coexist with some single cores,
38
39 resulting in a bimodal distribution of TEM size. After three months, the scarce resilient particles
40
41 all appear as single core with a mean size of 8-10 nm (Figure 2).
42
43
44
45
46
47
48
49

50 Ferromagnetic resonance (FMR) spectroscopy also provides a nanometrology method to
51
52 investigate the spin dynamics in nanoparticles and its evolution in the acidic medium. Initial
53
54 multicore particles show a complex asymmetric resonance spectrum at 9.25 GHz comprising
55
56 several absorption lines, whereas single cores of 10.6 nm exhibit a single symmetric resonance
57
58 centered on 3 kOe. The asymmetry of the resonance spectrum of the multicores can be ascribed
59
60
61
62
63
64
65

1
2
3
4
5
6
7 to the exchange interactions at the core boundary, while the broad spectrum of single core is
8 attributed to a large surface anisotropy.^[10, 27] Here we observe that, upon degradation in the
9 lysosome-like, FMR spectra evolve from the asymmetric shape characteristic of the multicore to
10 the symmetric shape of the single core (Figure 1e). In addition the area of the absorption
11 spectrum (FMR absorption signal), which is a measure of the ferrimagnetic materials in the
12 suspension,^[25] rapidly decreases over time in acidic buffer (Figure 1f) in line with the decrease of
13 saturation magnetization. This supports the hypothesis that NFs are degraded into single cores,
14 while an increasing mass of iron is released from ferromagnetic lattice and forms non-magnetic
15 chelates with citrate. It is worthy to note that the transition from asymmetric to symmetric FMR
16 line occurs from day 3 to day 5, suggesting that exchange interactions at the core boundaries
17 might be early affected. Because some multicore structures are still observed on TEM at time
18 points up to three weeks, we hypothesize that magnetic hallmarks of NFs are debased in acidic
19 medium before the complete degradation of multicore organization as observed by TEM.

36
37

38 The next step was to investigate how such structural and magnetic transformations of NFs might
39 affect their efficiency for therapeutic and imaging applications. The specific absorption rate
40 (SAR) of nanoparticles was measured in an alternating magnetic field of $24 \text{ kA}\cdot\text{m}^{-1}$ at a
41 frequency of 520 kHz. The SAR, determining the heating power of nanoparticles, is governed by
42 key parameters of nanoparticles which comprise their magnetic anisotropy, size, susceptibility
43 and saturation magnetization.^[28, 29] Recently, we have shown that the nanostructuring of single-
44 core to multi-core structure increases the SAR from 150 W/g to 1604 W/g.^[10] Here the exposure
45 to acidic medium has a dramatic effect on the SAR. After 6 days, the heating power decreases by
46 70%, from 1761 W/g to 552 W/g, and fall to no more than 19 W/g after 23 days (**Figure 3a,**

6
7 nanostructuration but also undeniably reflects the dissolution of nanoparticles. Altogether it
8
9 highlights the potential deterioration of heating efficiency of multicore nanoparticles that are
10
11 uptaken by cells (including cancer cells) and underwent lysosome degradation.
12

13
14 Finally we focused on the contrast properties of NFs for magnetic resonance imaging. The use of
15
16 superparamagnetic nanoparticles as MRI contrast agent relies on the accelerated relaxation of the
17
18 magnetization of water protons diffusing in local magnetic fields created by particles. The spin-
19
20 lattice (r_1) and spin-spin (r_2) relaxivities are defined as the increase of the longitudinal and
21
22 transverse relaxation rate of the medium (here water or acidic buffer) induced by 1mM of the
23
24 magnetic agent (here iron). The improvement of sensitivity in MR sensing and imaging requires
25
26 an optimization of both r_1 and r_2 in the application medium. As magnetic nanoparticles are
27
28 readily internalized by cells *in vitro* and particularly by macrophages *in vivo*, the persistence of
29
30 their contrast properties within intracellular lysosomes is an important concern for the success of
31
32 long term cell tracking by MRI. However little is known on the outcomes of nanoparticle
33
34 degradation in lysosomes,^[26] partly because a number of environmental factors, including
35
36 nanoparticles distribution, aggregation, magnetic interactions and lysosomal confinement,^[30, 31]
37
38 actually change the relaxivities of intracellular nanoparticles. NFs possess very large r_1 and r_2
39
40 relaxivities that surpass that of single core particles and may be attributed to their multicore
41
42 structure.^[10] More particularly the nuclear magnetic resonance dispersion (NMRD) profile, which
43
44 provides r_1 measurements over a wide range of ^1H resonance frequency (0.015 MHz to 40 MHz)
45
46 or equivalently of the magnetic field strength (0.35 mT to 0.94 T) demonstrates for NFs a
47
48 monotonous decrease of r_1 relaxivity with increasing frequency and exceptionally high relaxivity
49
50 value at low fields. Such behavior is unusual for superparamagnetic particles which generally
51
52 show a maximum of r_1 at a field which depends on the dynamics of the particle magnetic
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6 moment.^[32] However Lévy et al established that the low field longitudinal relaxivity could be
7
8 considerably enhanced and could make disappear the typical r_1 maximum when the fluctuations
9
10 of the transverse component of the particle magnetic moment are slowed down.^[33] As NFs are in
11
12 the limit of the superparamagnetic regime, this model could account for their exceptionally high
13
14 relaxivity at low fields. In the present study, we measured the NMRD profile of NFs at different
15
16 time-points in the lysosome-like medium. As expected from the loss of nanoparticles
17
18 magnetization reported above, the longitudinal relaxivity dramatically diminished at long time in
19
20 the acidic medium regardless of the ^1H resonance frequency (Figure 3b). However, at short times,
21
22 we first observed a 25% decrease of the r_1 relaxivity as soon as NFs are transferred from water to
23
24 acidic medium (0 day) which accentuates to 73% after one day and then retrieve 45% of its initial
25
26 value in water at day 3 and continuously decreases at longer time-points. The transverse
27
28 relaxivity r_2 measured at 20 MHz exhibits a similar variation over time in lysosome-like medium
29
30 (Figure 3d). To understand this non-monotonous temporal variation of relaxivities, we recall the
31
32 importance of nanoparticle aggregation on their relaxation properties. Indeed very large clusters
33
34 of particles cannot be detected by NMRD profile: their corresponding r_1 is too small at the used
35
36 magnetic fields.^[34] Agglomeration of nanoparticles above a critical volume also diminishes the
37
38 transverse relaxation rate r_2 .^[35, 36] Here, nanoflowers might be more prone to aggregation than
39
40 single cores due to their large diameter and enhanced magnetic interactions. We thus investigated
41
42 the colloidal stability of NFs by magnetically-induced birefringence measurements, a previously
43
44 described method that probe the orientational dynamics of magnetic particles in response to a
45
46 magnetic field.^[37] Interestingly the mean hydrodynamic diameter of NFs was more than doubled
47
48 in acidic medium in comparison to the initial water suspension (91.5 nm versus 37 nm) and
49
50 further increased after one day (101.4 nm), indicating the formation of small aggregates of
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 citrate-coated NFs at pH 4.7 (Table 1 and Figure 3e). Beside such small aggregates that remain
8
9 dispersed in the suspension, we also observed some large sedimenting agglomerates that were not
10
11 probed by the birefringence experiment. Nevertheless from day 2 in acidic medium, the whole
12
13 suspension becomes limpid and the hydrodynamic diameter starts to decrease and fall down to 18
14
15 nm, below the initial value in water. This suggests that the degradation of magnetic properties
16
17 and of multicore organization reduces the propensity of particles to form aggregates or chains and
18
19 that the degrading particles become isolated while diminishing in size (Figure 2). In line with
20
21 these results, the temporal evolution of relaxivities results from the interplay between the
22
23 aggregation effect until day 2, the disaggregation effect at intermediate time (which increases r_1)
24
25 and the progressive loss of magnetic materials (which further decreases r_1 and r_2). To test this
26
27 hypothesis, we changed the anionic monomeric citrate coating of NFs for a polymeric anionic
28
29 coating made of poly(acrylic) acid (PAA). PAA-coated NFs have a larger hydrodynamic size in
30
31 water (70 nm) compared to citrate-coated NFs, but are less aggregated in the acidic medium due
32
33 to steric hindrance and reduced dipole-dipole interactions (**Supplementary Figure S2**).
34
35 Consistently their hydrodynamic diameter slowly diminishes in the acidic buffer and the r_1
36
37 relaxivity progressively decreases with time mainly due to the loss of magnetic properties. In
38
39 contrast to the relaxivity measurements which are very sensitive to the local arrangement of
40
41 particles,^[36] the type of coating –PAA versus citrate – has a marginal effect on the loss of
42
43 nanoparticle magnetization and FMR absorption which reflect similar diminution of magnetic
44
45 materials. Hence while the transient aggregation of citrate-coated NFs strongly impact relaxivities
46
47 at short times, the gradual deterioration of magnetic properties and multicore structure plays in
48
49 concert to diminish r_1 and r_2 at longer time. Interestingly, the shape of the NMRD profile at the
50
51 longest time investigated (14 days) was shifted to higher magnetic field in comparison to the

initial shape, showing a shoulder that is characteristic of smaller single core particles, suggesting the loss of cooperative magnetic behavior (Figure 3c). This interpretation can be quantitatively confirmed by fitting the NMRD profiles. The usual equations for relaxation induced by superparamagnetic nanoparticles^[32] were used and the corresponding NMR sizes extracted. These sizes correspond to the minimal approach distance between the water molecules and the magnetic particles – as a consequence, they are larger than the magnetic core size but smaller than their hydrodynamic size, which is verified in our case (see Table 1). As NFs are in the limit between the low and high anisotropy energy limit, the obtained parameters must be carefully interpreted. The *rigid dipole model* of Levy et al^[33] was also used for comparison and correctly fit the data with similar NMR sizes. During the first 6 days, some NFs (with a slightly smaller size than the initial one) remain in the solution while large aggregates cannot be detected by NMRD profiles. At day 14, the obtained NMR size is twice smaller, which is consistent with the fact that a large amount of NFs is degraded into smaller isolated single cores.

In conclusion, we have shown that monitoring the macroscopic properties of an assembly of multicore nanoparticles, such as their magnetic and FMR properties, heating power or MR relaxivity, provides an accurate methodology to follow their degradability and to predict their behavior in a simple model of intracellular environment. It is worth noticing that both magnetic and structural properties of the NF remain unaltered over several months into water (**see supporting information, Figure S3**). In what follows, we focus on the evolution of single particles at the nanoscale in order to highlight the mechanisms of degradation.

2.2 Atomic-scale investigations of the degradation mechanisms

1
2
3
4
5
6
7 The nanoparticle degradation was characterized at the atomic level using aberration-corrected
8
9 HRTEM on NFs flatly deposited on a lacey carbon-coated TEM grid. The grid was immersed
10
11 into the acidic buffer for different time periods, and the nanoparticle evolution was probed after
12
13 each immersion step. First, about 100 isolated NFs were localized on the grid and identified to
14
15 monitor their degradation kinetic. This statistical analysis summarized in **Figure 4a** reveals the
16
17 high reactivity of NFs structures in the lysosome-like medium. Indeed, the atomic structure of all
18
19 the isolated particles is damaged after only 30 minutes of immersion. However, although the NFs
20
21 promptly show signs of structural degradation, these latter do not systematically induce the
22
23 complete dissolution of NFs. The percentage of totally dissolved NPs increases from 5 % after 30
24
25 minutes to 45 % after 100 minutes and stays below 50% after 140 minutes. This asymptotic
26
27 behavior is consistent with the many single core nanoparticles observed in the lysosome-like
28
29 medium after several weeks of immersion (Figure 2) and indicates that these single core
30
31 structures are much more stable in the medium than the multi-core architecture of the initial NFs.
32
33 As previously observed on nanocubes,^[23] the degradation is faster on two dimensional grid in
34
35 comparison to the suspension probably due to a larger ratio of available citrate chelators per
36
37 particle. In addition the spatial organization of iron oxide NPs has also a strong influence on their
38
39 reactivity to the lysosome-like medium.^[23] While the acidic medium always causes severe
40
41 damages to the structure of isolated NFs, the aggregation of NFs significantly slows down their
42
43 degradation kinetic (see **supporting information, Figure S4**). The reinforced stability of large
44
45 three-dimensional assemblies may relate to the reduced accessibility of iron oxide surface for the
46
47 chelating agents. Thus agglomeration tendency of nanoflowers, which occur following
48
49 internalization into early endosomes and lysosomes,^[10] could severely diminish their reactivity
50
51 and short time degradation kinetics in the organism.
52
53
54
55
56
57
58
59
60
61
62
63
64
65

Following at high resolution the degradation of individual NFs sheds light on the atomic process involved in the transformation of multicore nanoparticles with promising magnetic properties into poorly magnetic single core. As observed in Figure 4b-c, the gradual corrosion of the NP surface results in a clear size decrease of the NFs, but the initial atomic arrangement of nanoparticles is maintained throughout the degradation process. This result confirms that the alteration of the NF atomic-structure in intracellular-like environment is controlled by surface reactivity mechanisms. Simultaneously, we observe the formation of holes into the atomic structure of the NFs which appears as brighter contrast on TEM images. The atomic-scale study of this milling process shows that these holes are formed on structural defaults of the initial NFs (Figure 4c). Indeed, the multicore architecture of the NFs gives rise to porous atomic surfaces. These pores are more vulnerable to chelating agents either because of the change in coordination number due to surface curvature and defects, or because of a possible lack of protecting coating inside these nanocavities. Consequently, the degradation kinetic is faster inside the pores and their size increases from 1 to 20 nm² within the first minutes of immersion. Surprisingly, the structure of the resulting holes reveals that the corrosion mechanisms are also influenced by the thermodynamic properties of the iron oxide structure. Indeed, when the degraded NFs are oriented along the [001] zone axis the enlarged pores consist in rectangular patterns sharing the same orientation. By comparing the structural information from the direct and Fourier spaces, we observe that the rectangular holes are oriented along the [400] and [040] directions. The formation of these {400}-type facets suggests that these particular surfaces are less reactive (i.e. more stable in the buffer medium) and consequently the degradation kinetic is slower along the [400]-type directions. This result is consistent with the degradation of iron oxide nanocubes,^[23] which preferentially occurs on small {220} facets than on large {400} facets. Nevertheless, this higher

1
2
3
4
5
6
7 stability remains insufficient to avoid the step by step degradation of iron oxide NFs. The gradual
8
9 corrosion of the iron oxide surfaces, which is enhanced through the pores of the NFs structure,
10
11 inevitably induces a size reduction of the multicore particles and leads to the separation of the
12
13 single cores. This mechanism is consistent with the long term TEM observation described in
14
15 Figure 2 showing that single core NPs are mainly found in the lysosome-like solution after three
16
17 weeks of immersion.
18
19
20
21
22

23 **2.3 Slowing-down the degradation kinetic with a gold-protective layer**

24
25 Among many parameters influencing the fate of NPs inside cells (size, shape, composition...),
26
27 the key role of nanoparticle functionalization has been reported. ^{[23][38]} By raising the first barrier
28
29 against environmental reagent, the nature and distribution of organic/inorganic coating might be a
30
31 crucial determinant of the degradability of nanoparticles. Here, we investigate the influence of
32
33 gold inorganic coating on the corrosion of iron oxide NP in lysosome-like media. Gold layers
34
35 with nominal thicknesses of 3, 5 and 7 nm were physically deposited by pulsed laser deposition
36
37 over NF samples. Bragg filtered high resolution imaging was used to generate chemical maps
38
39 exhibiting the distribution of both Au and iron oxide within the nanostructures and then analyze
40
41 the morphology of the gold layers depending on its nominal thickness. The isolated gold clusters
42
43 observed on the NFs with the thinnest protective layer (**Figure 5a**, nominal thickness of 3 nm)
44
45 reveals the poor wetting properties of gold over iron oxide. To minimize its interface energy the
46
47 gold layer tends to reduce its cover rate by forming isolated 3D islands over the NFs. By
48
49 increasing the quantity of Au, this Volmer-Weber growth mode leads to a percolated film over
50
51 the magnetic NPs (Figure 5b, nominal thickness of 5 nm). Finally, NFs coated with a continuous
52
53
54
55
56
57
58
59
60
61
62
63
64
65

granular Au layer were obtained with a nominal thickness of 7 nm (Figure 5c). The true thickness of this full metal layer is 3 nm.

These three types of core-shell nanostructures were then immersed into the buffer medium for different time periods, and the nanoparticle evolution was probed after each immersion step by using both Bragg filtered high resolution TEM and energy dispersive X-ray (EDX) nano-analysis.

By combining the imaging and analytical capabilities of TEM we can quantitatively characterized the degradation of the magnetic cores as a function of the incubation time, by following their size reduction and the evolution of the Fe/Au composition ratio within individually-analyzed core-shell NPs. Chemical imaging of the magnetic cores before incubation and after 45 minutes in the lysosome-like medium illustrates that isolated Au clusters and percolated Au films cannot prevent the fast size-reduction of the iron oxide NFs (**Figures 6a** and **6b**). On the contrary, continuous Au shells seem to be an efficient shield layer against surface corrosion, since the size of the fully-covered magnetic cores remains almost constant in the acidic medium (Figure 6c).

EDX nano-analyses reinforce this conclusion, given that the Fe/Au composition ratio within single core-shell NPs remains constant when the gold layer is continuous, where as it decrease by 25% and 70 % over one hour, for gold layers consisting in percolated film and isolated clusters, respectively (Figure 6d). These nano-scale analyses reveal that the kinetic of degradation of the iron oxide NFs clearly depends on the cover rate of the Au layer: the lower the cover rate, the better the accessibility for the chelating agent and consequently the faster the corrosion of the magnetic cores. It is worth noticing that there is currently great interest in the development of such NPs composed of magnetic cores with plasmonic shell layers that combines magnetic and plasmonic properties for theranostic applications.^[39-41] In that regard, gold layers are promising candidates because of their shape-dependent plasmonic properties and their biocompatibility.

1
2
3
4
5
6
7 Here, we shed light on the protective properties of gold layers that could also be exploited to
8
9 avoid a too fast annihilation of the magnetic properties of iron-oxide nano-objects due to the
10
11 deterioration of their atomic-structure in cell compartments. This potential application of gold
12
13 nano-shields arises from their very low biodegradability, as gold is mostly inert to chemicals it
14
15 should encounter inside the body.^[42] It is interesting to note that the thickness and morphology of
16
17 the gold coating (here obtained by physical deposition) could be modulated in order to tune the
18
19 degradation rate of NFs. Whenever this gold shield strategy could be achieved with colloidal
20
21 chemical synthesis of core-shell nanocomposites, ^{[43, 44][45][46]} it would give the unique
22
23 opportunity to control the degradability of NFs so that they keep their magnetic properties for the
24
25 time of therapeutic treatment and degrade at longer time to be locally processed by iron
26
27 metabolism or eliminated by biliary excretion. This concept of hybrid nanostructures with
28
29 materials possessing different reactivity to their environment opens new route for the modulation
30
31 of nanoparticle fate in the organism. Further studies are necessary to assess this strategy *in vivo*.
32
33
34
35
36
37
38

39 **3. Conclusions**

40
41
42 In conclusion, we have presented a valuable methodology to monitor nanoparticle
43
44 biodegradability from macroscopic to nanometric levels. We manage to correlate the atomic scale
45
46 transformations of multicore monocrystalline nanostructures to the evolution of their magnetic
47
48 properties over time in lysosome-like medium. The remarkable cooperative behavior of the iron
49
50 oxide nanoflowers is progressively impaired in lysosomal acidic medium due to the porous
51
52 widening and dissociation of single cores. Hence intracellular uptake should rapidly jeopardize
53
54 the NF's outstanding properties for magnetic hyperthermia and MRI detection, while it enables
55
56 dissociation and further dissolution of nanocrystals. The balance between crystal corrosion,

release of iron species and local processing of iron by iron storage protein should be finely regulated in order to avoid toxic effect due to Fenton reaction. Hence it should be advantageous for both therapeutic efficiency and safety issue to control the intracellular degradation rate of nanostructures. In that regards, we demonstrate that the organization of iron oxide NPs has a significant impact on their reactivity in lysosome-like medium, since aggregation provides protection against degradation, while separation encourages the transformation processes. We also suggest a strategy using gold nanoshield at the surface of the particles to modulate their degradability and ultimately their long term fate in the organism.

4. Experimental Section

Nanoflower synthesis: magnetite NFs were synthesized following the procedure described in Hugounenq et al^[24] which uses alkaline hydrolysis of FeCl₃·6H₂O and FeCl₂·4H₂O with stoichiometric ratio in a mixture of polyols (diethylene glycol (DEG) and Nmethyldiethanolamine (NMDEA), 1:1 w/w) at 220 °C.

The choice of the solvents, the nature of the precursors, progressive heating to 220°C (2 °C per min) and constant stirring at 220°C for 12 hours were critical factors to obtain multicore monocrystalline nanostructures with monodisperse size. A 8M solution of iron nitrate was added to the particles and heated at 80 °C for 45 min to achieve a complete oxidation of the magnetite nanoparticles into maghemite. After another treatment with 10% nitric acid, the particles were washed and redispersed in water. At this stage, the aqueous dispersion of NFs was stable in acid or basic conditions with a point of zero charge near pH 7.3. Citrate anions were grafted to NF surface by adding 0.3 mol of sodium citrate per 1 mol of iron element in order to ensure colloidal

1
2
3
4
5
6 stability at physiological pH. Alternatively, NFs were coated with polymeric poly(acrylic) acid
7
8 (PAA) by ligand exchange. To achieve a stable coating, a large excess of PAA molecules were
9
10 added to the nanoparticles suspension in acidic conditions (pH 2). At this pH the PAA molecules
11
12 are weakly charged and the nanoparticles can be washed using magnetic decantation to remove
13
14 the excess of PAA. The nanoparticles are then redispersed by increasing the pH to 9 by adding a
15
16 concentrated solution of NH_4OH . The nanoparticles suspension is then dialyzed in water using a
17
18 12kDa membrane to remove the remaining free PAA molecules.
19
20
21

22
23 ***Magnetic measurements:*** Magnetization measurements were carried out on a with a Quantum
24
25 Design MPMS-5S SQUID magnetometer. All magnetic measurements were performed in
26
27 solutions around 10 mM in iron and the data were corrected from the diamagnetic contribution of
28
29 water and sample holder. The field-dependent magnetization curve was measured at 310K in the
30
31 range between 0 and 3 Tesla. The distribution of apparent magnetic size was obtained from the fit
32
33 of magnetization curve using a Langevin function weighted by a log-normal distribution of
34
35 magnetic diameter (characteristic diameter d_{mag} , polydispersity index σ) as previously
36
37 described.^[25]
38
39
40
41

42
43 Ferromagnetic resonance (FMR) spectra were obtained using a Varian ESR spectrometer
44
45 operating at 9.26 GHz (X band) with following parameters: microwave power = 1 mW,
46
47 modulation frequency = 100 kHz, modulation field = 10 Gauss. FMR spectra were recorded at
48
49 room temperature for 2 μL of NF suspension at iron concentration of 10 mM. Quantification of
50
51 the remaining magnetic iron in the suspension was obtained by double integration of the FMR
52
53 spectrum and comparison to a calibration curve of non-degraded NFs. It was verified that
54
55 paramagnetic iron species that could be released in the medium were not contributed to the FMR
56
57 signal at room temperature.
58
59
60
61

Hyperthermia Measurement. The evaluation of heat generation was performed with a home-built magnetothermal setup^[28] consisting of a resonant RLC circuit with a 16 mm coil. The field amplitude was fixed to 24 kA/m and the frequency to 520 kHz. 300 μL of the NF solution was put inside the thermalized coil and the temperature was probed with a fluoro-optic fiber thermometer (Luxtron Corp., CA) every 0.7 s.

The SLP was calculated using the following formula:

$$SAR = \frac{1}{m_e} \left(\sum_i c_i m_i \frac{dT}{dt} \right) \quad \text{where } m_e \text{ is the total mass of the iron, } c_i \text{ is the specific heat, and}$$

m_i is the weight of the different species in solution (particles and water) and dT/dt is the slope of the initial temperature increase. The mass of iron was measured by flame atomic absorption spectroscopy.

NMRD experiments: The frequency dependence of the ¹H longitudinal relaxation time $1/T_1$ in NF aqueous suspensions was recorded over the frequency range of 0.015 to 40 MHz using a Spinmaster FFC-2000 fast-field cycling NMR relaxometer (Stelar SRL, Mede, Italy).

The temperature of the samples was maintained at 37°C using a thermostated airflow system. All of the ¹H magnetization recovery curves were singly exponential within experimental error, and the random errors in fitting T_1 were always less than 1%. T_2 was measured using the CPMG pulse sequence on a 20MHz Bruker minispec. The relaxivity r_1 was obtained by normalizing the relaxation rate $(1/T_i - 1/T_{\text{water}})$ with the iron concentration of the sample determined by Inductively coupled plasma mass spectroscopy.

Magnetically-induced birefringence experiment: The change in hydrodynamic diameter caused by the onset of aggregation was determined by means of a magnetically-induced birefringence experiment which is described in detail elsewhere.^[47] Briefly, in the presence of an external

1
2
3
4
5
6
7 magnetic field, the NF suspension acquires a birefringence Δn ($\Delta n = n_{\parallel} - n_{\perp}$, n_{\parallel} and n_{\perp} being the
8
9 optical indexes, respectively, in the direction of the magnetic field and perpendicular to it), due to
10
11 the alignment of optical axes of the nanoparticles along the field and the subsequent alignment of
12
13 their optical anisotropy axes. This birefringence induces a phase lag φ proportional to Δn , which
14
15 is measured through a polarizer and analyser. The NF suspension sample is submitted to a pulsed
16
17 vertical magnetic field (100 Oe) and the transmitted light $I(t)$ is collected on the photodetector
18
19 (PD). The birefringence decay is averaged over a large number of pulses (typically 512, total time
20
21 of measurement 20s) and analysed using a stretched exponential. The distribution of
22
23 hydrodynamic diameter is deduced from stretched exponential parameters as previously
24
25 described.^[37]
26
27
28
29

30
31 **Aberration-corrected HRTEM:** TEM investigations were performed with the JEOL ARM 200F
32
33 microscope operating at 200 kV. This microscope is equipped together with a CEOS aberration
34
35 corrector and a cold field emission gun.^[48, 49] Lacey carbon TEM grids (agar) were used to
36
37 follow the degradation mechanisms by HRTEM. The recognizable patterns of the lacey carbon
38
39 film facilitate the step-by-step following of the nanostructure alteration. Bragg filtered high
40
41 resolution imaging is a method of choice to study the structure of non-miscible nanohybrides.
42
43 This post-acquisition image processing consist in calculating the inverse Fourier transform of the
44
45 power spectrum of an HRTEM image, on which a well defined spatial frequency is selected with
46
47 a low-pass filter. This technique is also called digital dark field imaging since the low pass filter
48
49 plays the same role as the objective aperture in conventional dark field imaging.^[50, 51] By
50
51 selecting suitable reflections for the crystal lattice of gold or iron oxyde, one obtains a chemical
52
53 mapping exhibiting the distribution of the two species in the nanoparticles. One displays in fact
54
55 the part of the nanocrystal where distances between interference fringes (i.e. atomic planes)
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7 correspond to the selected reflections on the power spectrum. We note that such a chemical
8
9 imaging required a clear visibility of the atomic structure on the whole studied nanocrystal. In
10
11 that regard, we greatly benefit from sub-angstrom resolution imaging that allows observing the
12
13 atomic structures of both gold and iron oxide almost independently their orientation.
14

15
16 ***Deposition of the gold protective layers:*** The gold layers were produced over the iron oxide NFs
17
18 by pulsed laser deposition in a high vacuum chamber at room temperature.^[52, 53] The pressure in
19
20 the chamber is greater than 10^{-8} Torr. A typical target – substrate configuration was used to
21
22 deposit Au by PLD using a KrF excimer laser working at a wavelength of 248nm with pulse
23
24 duration of 25 ns at a repetition rate of 5Hz. The laser energy was 250mJ. The deposition rate of
25
26 Au vapor phase was controlled by an *in situ* quartz crystal monitor, which indicates the nominal
27
28 thickness of deposited materials on the quartz surface, in a continuous thin film approximation.
29
30 Gold layers with nominal thicknesses of 3, 5 and 7 nm were prepared. As the iron-oxide
31
32 nanoparticles are obviously not a smooth substrate, the nominal thickness of the deposited gold
33
34 does not correspond to the true thickness of the gold layer.
35

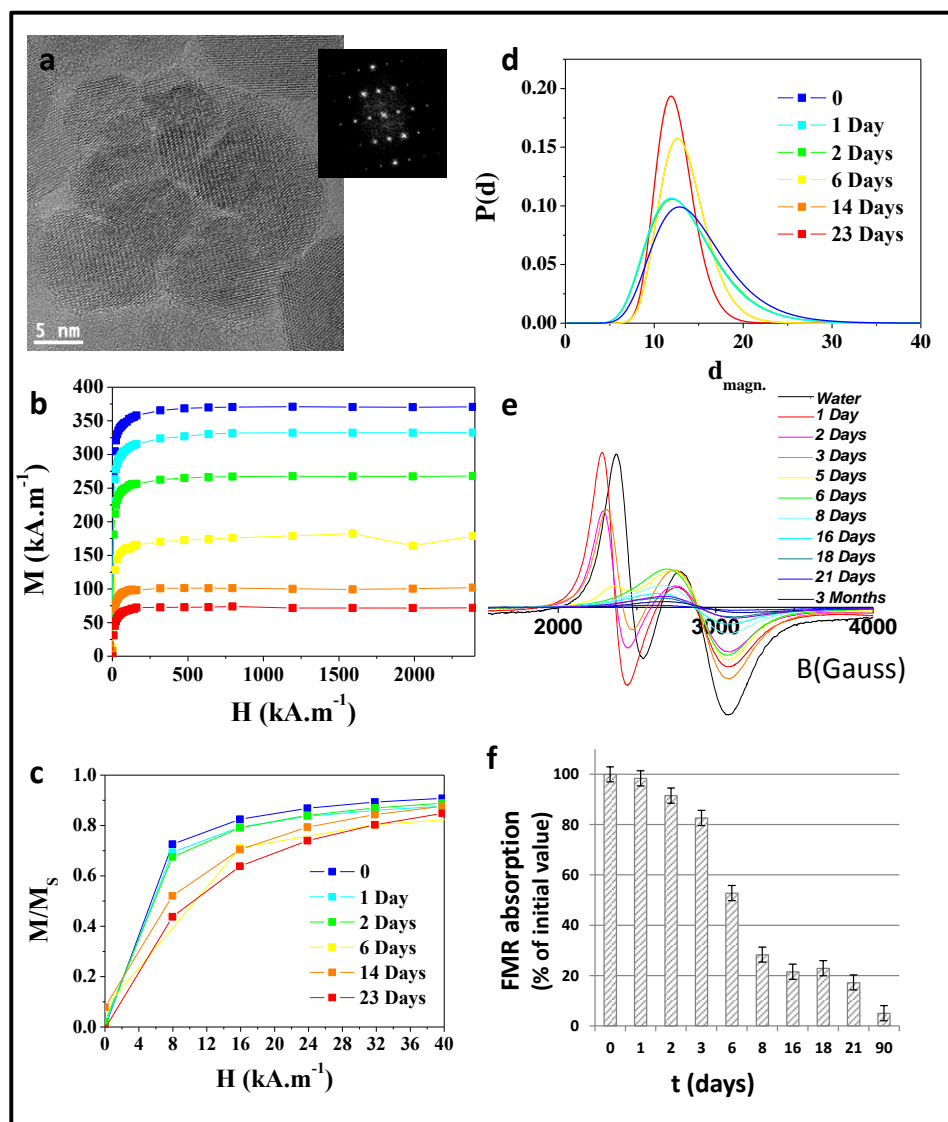

Figure 1: Representative TEM micrograph of the mesoporous multicore nanoflowers (24 nm diameter) synthesized by a polyol method (a). High resolution image and corresponding Fourier transform (inset) show that NFs are single-crystals composed of smaller maghemite cores sharing a common crystalline orientation. Magnetization measurements demonstrate a deterioration of their magnetic properties when exposed to the lysosome like medium for different times. Both saturation magnetization (b) and initial susceptibility (c) are decreasing over time. The corresponding distribution of apparent magnetic diameter d_{mag} (deduced from the fit of magnetization curves, see supporting information S1) becomes narrower when increasing exposure to the acidic medium (d). Ferromagnetic resonance (FMR) spectrum evolves from the initial multiline shape to a single line spectrum characteristic of single core nanoparticles (e). Quantification of the FMR absorption signal provides the percentage of magnetic iron in a particulate form (f). The loss of magnetic iron in lysosome like medium is well correlated with the diminution of saturation magnetization.

Figure 2: Representative TEM micrograph of nanoflowers at different time points (day 0, day 21, day 90) in the lysosome like medium and corresponding distribution of the TEM particle size (bar is 50 nm).

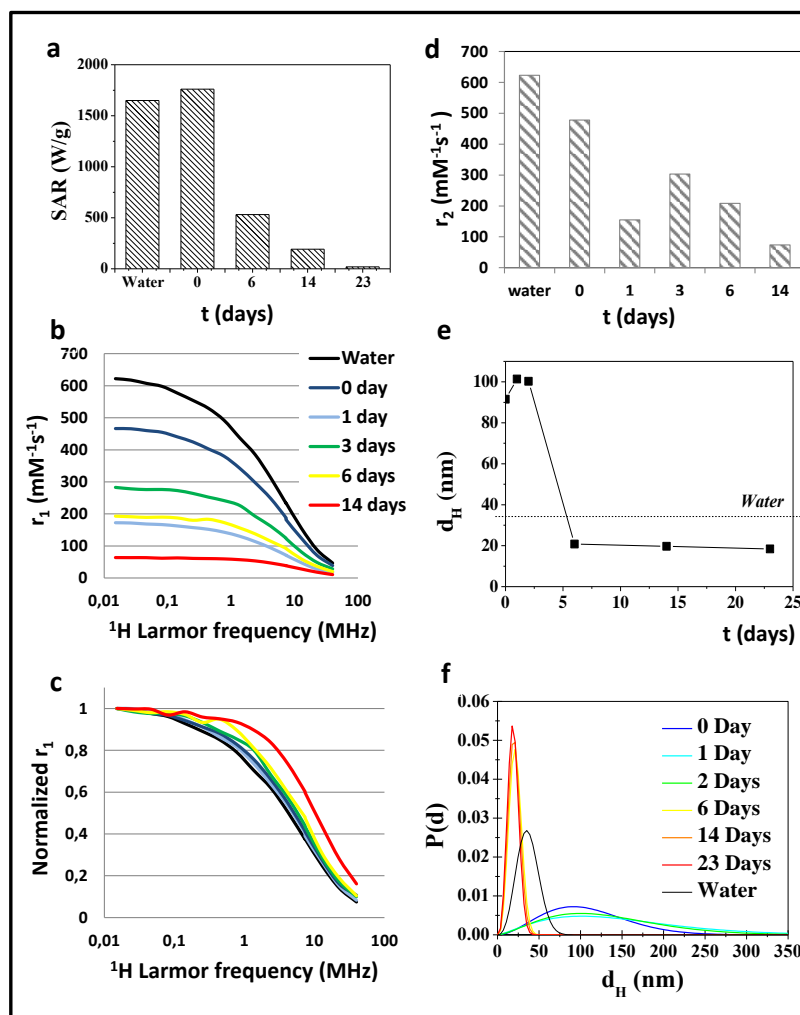

Figure 3: Degradation of nanoflowers in the lysosome like medium impairs their efficiency for magnetically induced hyperthermia and magnetic resonance imaging. The specific absorption rate (SAR) in a magnetic field of 24 kA/m and 520 kHz decreases over time in the acidic medium (a). The NMRD profile of NFs, representing longitudinal relaxivity r_1 as function of the proton Larmor frequency, shows a non-monotonous diminution of relaxometric properties over time (b) and the normalized NMRD profile (normalization by the relaxation rate at 0.015 MHz) is also modified at day 14 (c). The transverse relaxivity r_2 determined at 20 MHz follows the non-monotonous evolution of longitudinal relaxivity (d). To understand such behavior, the distribution of hydrodynamic volumes of NFs was determined from magnetically-induced birefringence experiments. The mean hydrodynamic diameter and the whole distribution of hydrodynamic diameter are represented in (e) and (f), respectively. The initial increase of hydrodynamic volumes reveals the onset of aggregation as soon as citrate-coated NFs are transferred from water to lysosome like medium. The citrate-coated NFs tend to desaggregate from day 3 to day 6 in the lysosomal medium and their mean hydrodynamic volume is reduced to 18 nm indicating the rapid disintegration of the NF structure into single core nanoparticles. We note the parallel evolution of r_1 and r_2 in the lysosome like medium, which first decreases due to

aggregation, then increases at day 3 due to disaggregation and then continuously decrease due to the loss of magnetic iron in the solution. At the the longest time, the appearance of a low frequency shoulder in the normalized NMRD profile is indicative of particles with lower magnetic moment and increased rotational mobility (c).

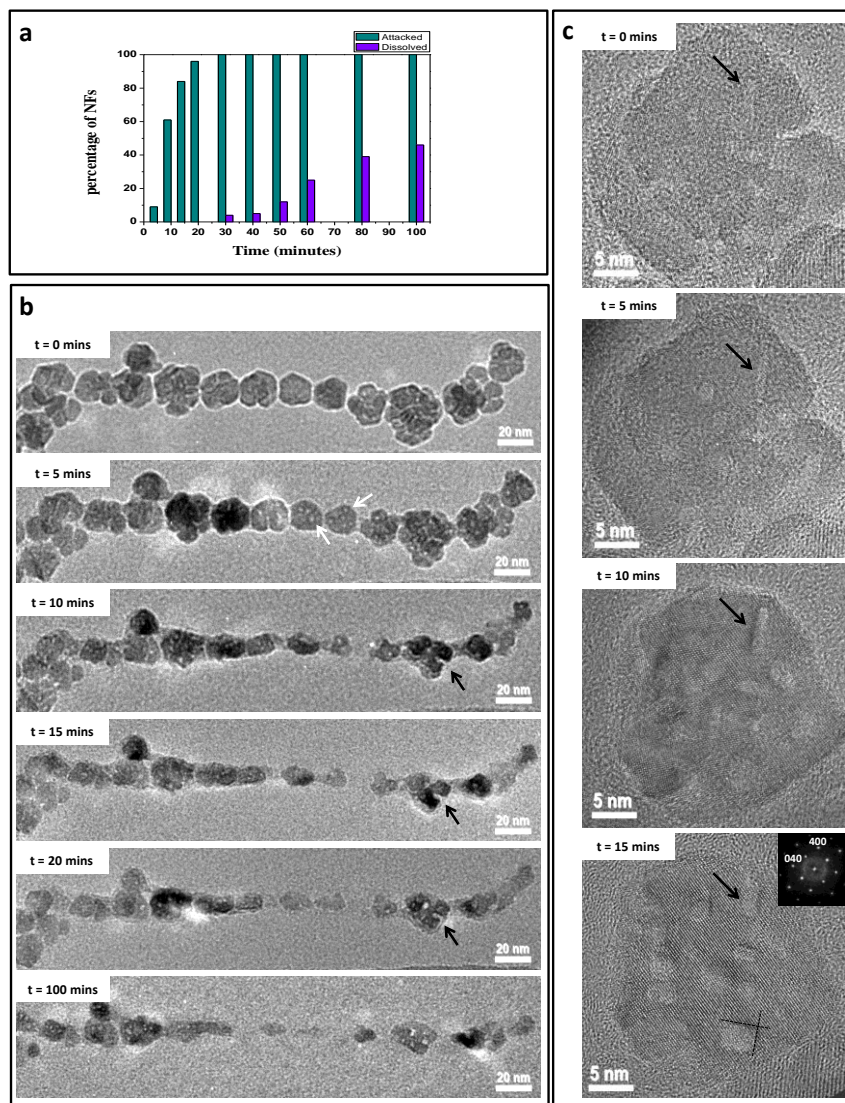

Figure 4: TEM monitoring of NF degradation in a lysosome-like medium. (a) Evolution of the percentage of attacked (green) vs totally dissolved isolated NFs (violet) over time of incubation in the lysosome-like medium (100 NFs were analyzed) (b) Low-resolution TEM monitoring of NFs degradation in the lysosome-like medium (time of incubation is indicated in the top left corners of the images). The NFs which consist in multicore nanoparticles in the initial state are gradually eroded. The white arrows indicate the formation of holes inside the structure (bright spot on the NPs) while the black arrows highlight the slipping process of the multicores

 7 nanostructures. After 100 min in the lysosome-like medium some NFs totally dissolved and only
 8 single-core clusters are observed. (c) High-resolution TEM monitoring of the degradation of a
 9 single NF in the lysosome-like medium. The black arrows show the milling process of a hole
 10 inside the atomic structure of the NF. The holes are formed on defaults (pores) that are observed
 11 on the initial NF ($t = 0$ min). After 15 minutes of immersion the holes present rectangular shapes
 12 (indicated by dashed lines) oriented along the [400] and [040] directions of the inverse spinel iron
 13 oxide structure here oriented along the [001] zone axis (the FFT of the image is seen in insert).

TOC figure:

**Biodegradation mechanism of iron oxide monocrystalline nanoflowers
and tunable shield effect of gold coating**

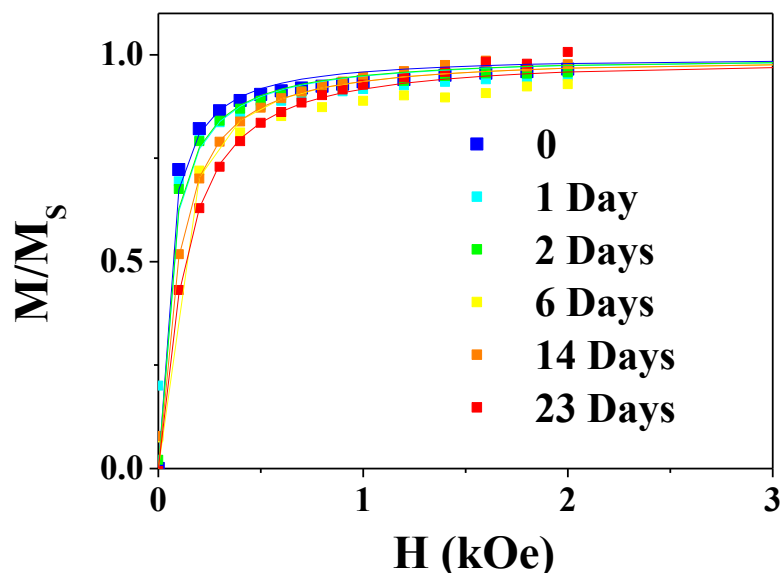

Table of contents entry

By following the magnetic and structural transformations of multicore maghemite nanoflowers in a medium mimicking intracellular lysosomal environment, we have unraveled the mechanisms involved in the critical alterations of their hyperthermic power and their Magnetic Resonance imaging contrast effect. To overcome this harmful influence of cellular medium on the effectiveness of iron oxide-based nanomaterials, we demonstrate that the inert activity of gold nanoshells can be exploited to modulate their degradability.

Supporting Information

	M_s (kA/m)	χ_0	Fit Langevin (LogNormal)	
			$d_{\text{magn.}}$ (nm)	σ
0	367.4	33.6	14.0	0.30
1	329.9	28.3	13.0	0.30
2	268.0	21.7	13.2	0.30
6	174.3	7.2	13.1	0.20
14	101.1	5.3	13.1	0.20
23	71.5	4.0	12.2	0.17

Figure S1: Fit (solid lines) of the magnetization curves of citrate-coated nanoflowers (300K) using a Langevin function weighted by the log-normal distribution of magnetic diameter d_{mag} (polydispersity index σ) displayed in the table. The table also indicates the saturation magnetization M_s and initial susceptibility χ_0 of NFs for different times (in days) in the lysosome-like medium.

Figure S2: Comparison of magnetic properties of PAA-coated NFs and Citrate-coated NFs in the degradation medium. Evolution of saturation magnetization (a), FMR absorption signal (b), Specific Absorption Rate SAR (c) and hydrodynamic diameter (d) as function of time in the lysosome-like medium. (e) NMRD profile and (f) r_2 relaxivity at 20 MHz of PAA-coated NFs at different time-points.

Figure S3: Structural stability of NFs over several months in water. TEM images of NFs (a) just after synthesis, (b) 6 months after synthesis.

The magneto-structural properties of the NFs were firstly studied just after their synthesis. These results were reported in [Iartigue et al. *ACS Nano* **2012**, *6*, 10935]. The study of NFs biodegradation reported here started 6 months after the synthesis of the NPs. The close similarities between the magnetic measurements reported in [Iartigue et al. *ACS Nano* **2012**, *6*, 10935] and the ones reported here before the insertion of the NFs in the lysosome-like medium (namely in water) demonstrate that the long-term aging of the NFs in water has no impact on their magnetic properties. This result is consistent with the structural stability of the NFs observed by TEM over several months in water (Figure S3). Therefore, the degradation processes observed in the lysosome-like medium allows clearly evaluating the drastic effects of a model biological environment on the structure and properties of iron oxide NFs.

Figure S4: Very slow degradation of a large aggregate of citrate-coated NFs followed by TEM.
