## ABSTRACT

We present radiometric, palaeoclimatological, palaeoenvironmental and archaeological data for the period 40 000–8000 cal BP in the Jura Mountains (eastern France). These mountains culminate at ~1700 m a.s.l. and are today characterised by a semi-continental climate. During the Last Glacial Maximum, the range supported a local ice cap. While recent data suggest a possible early ice-cap development during MIS 4, the chronology of the regional LGM and following deglaciation has still to be refined. The complete disappearance of the local ice cap at ca 17 000–16 600 cal BP marked the beginning of accumulation of sediment archives in the Jurassian lakes and mires, which favoured the reconstruction of past changes in climatic and environmental conditions, in addition to faunal remains found in caves and in archaeological sites. Three main successive stages may be distinguished regarding the history of societies. The first stage at ca 40 000–18 700 cal BP was characterized by very few archaeological sites with only discontinuous intermittent occupations, always located outside the Jura range. The second stage, around 18 700–11 700 cal BP, corresponded to an increase in the population density, as suggested by an increasing number of archaeological sites and a progressive colonisation of elevated areas of the Jura Mountains. The third stage at ca 11 700–8000 cal BP coincided with a reinforcement of settlement in the lowland areas as well as a development of long-term occupations in elevated areas. The millennial-scale GS-1 cold event had a more long-lasting and stronger impact on societies than did the 200 year-long 8.2 ka cold event.

Upper/Late Palaeolithic–Mesolithic societies

## 1. Introduction

Following the aims of the INTIMATE Working Group 4, the present paper endeavours to provide a tentative synthesis of palaeoclimatic, palaeoenvironmental and archaeological data for the period 60–8 ka in the Jura Mountains. Along the border between eastern France and western Switzerland, the Jura Mountains are a medium-sized range mainly composed of Mesozoic

limestone. Their western slope is characterised by a succession of plateaus from around 300 to ~800 m a.s.l. To the east, the 'Haute Chaîne' is marked by a folded structure and culminates at ~1700 m a.s.l. with an abrupt transition to the Swiss Plateau located at ~400/500 m a.s.l. At present, the climate of the region is semi-continental with strong contrasts between seasonal temperatures. The mean annual temperature is ~9°–10 °C in Besançon and Geneva, but only ~3°–4 °C at the highest parts of the range. Due to the influence of westerlies and the orographic effect, the annual rainfall ranges from ~1000 mm in Besançon to ~2000 mm in the most elevated areas. Concerning the present-day vegetation, the plateaus are dominated by deciduous forests (*Quercus*, *Fraxinus*, *Fagus*) and the Haute-

Chaîne by *Abies-Picea* forests above 800–900 m a.s.l. and (subalpine) meadows above ~1400–1500 m a.s.l. Over three decades, numerous multidisciplinary papers have been dedicated to the second half of the Holocene and the possible interactions in the Jura Mountains between climate variations, environmental changes and the history of the first agricultural societies (e.g. Gauthier, 2004; Pétrequin et al., 2005; Magny et al., 2009). However, relatively few studies have focused on the time interval from 40 to 8 ka, and they often deal with the Jura range only in part, depending on the space, the time interval, and/or the domains considered (palaeoclimates, palaeoenvironments, archaeology) (e.g. Wohlfarth et al., 1994; Leesch, 2000; Cupillard and Perrenoud-Cupillard, 2003; Leesch et al., 2012; Cupillard et al., 2013). In this general context, the paper attempts (1) to present available palaeoclimatic, palaeoenvironmental and archaeological data to document the 40–8 ka time window in the Jura Mountains, and (2) to outline a tentative reconstruction of possible changes in societies in relation to changes in climatic and environmental conditions. Finally, 1) we point out some methodological problems in the development of this synthesis, 2) we propose a general model of regional archaeological evolution, and 3) we develop remarks regarding further investigations for a better understanding of past interactions between climate, environment and societies.

## 2. Palaeoenvironmental and palaeoclimatic data

### 2.1. The Last Glacial extent in the Jura Mountains

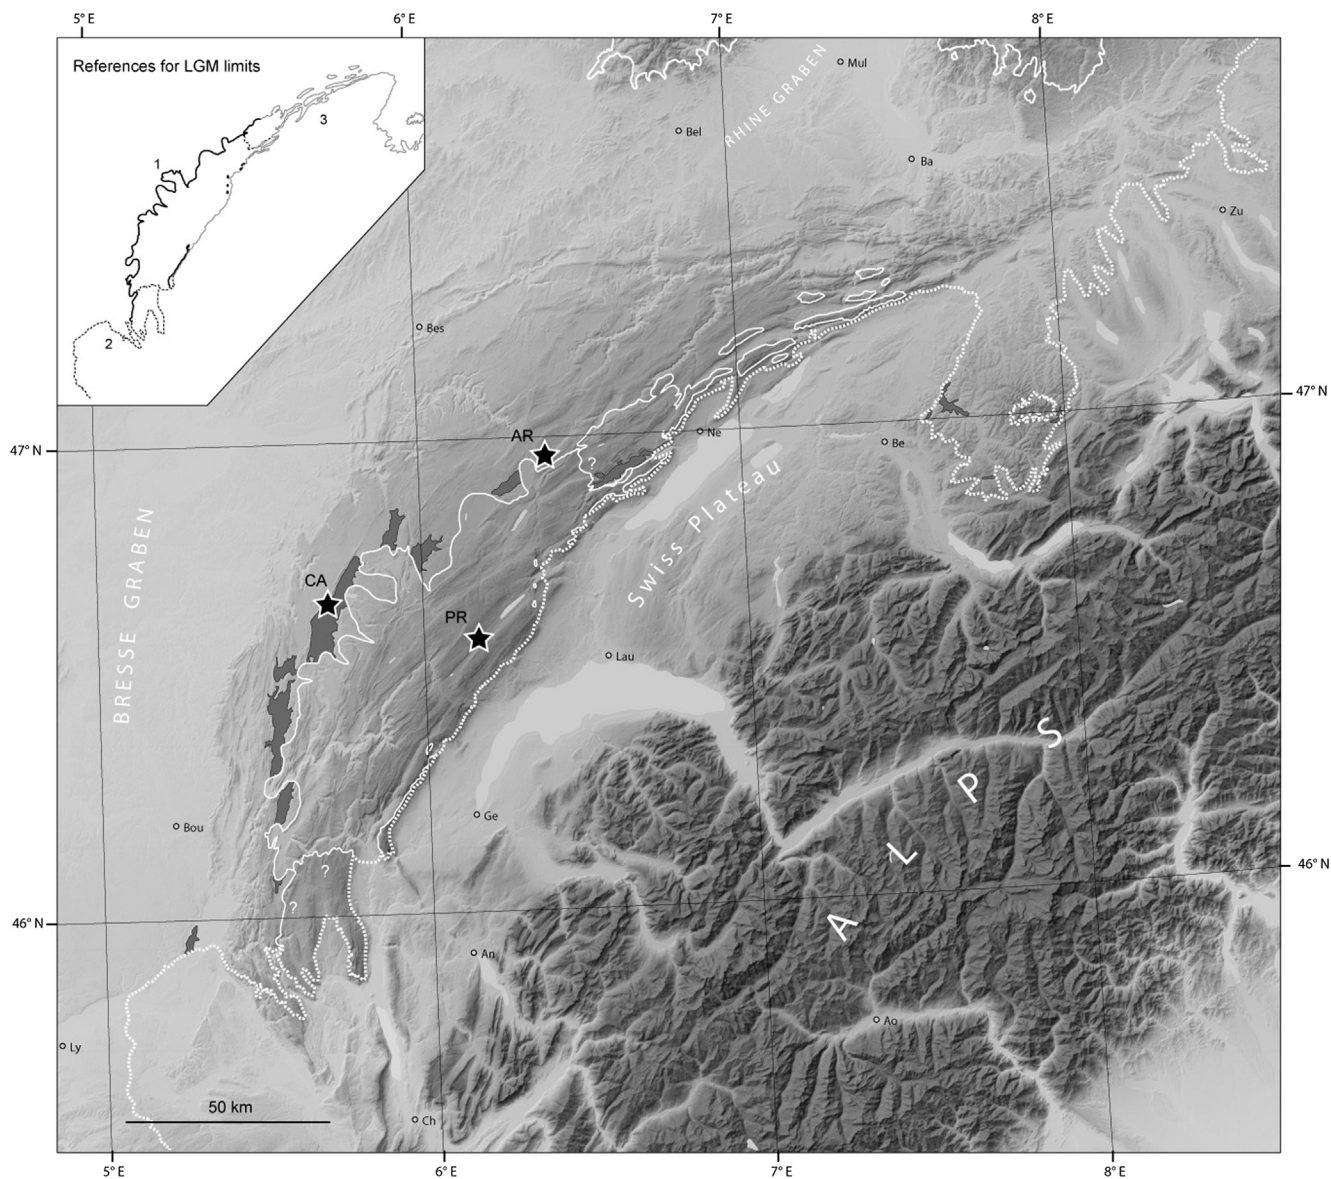

In the Jura Mountains, only the last glacial extents are currently recorded by glacial deposits (Campy, 1992; Buoncristiani and Campy, 2011). The most extensive glaciation represented by lines of strongly eroded end moraines shows a westward extension to the Jura/Bresse limit around 300 m a.s.l. According to palynological studies (Beaulieu de, 1984; Beaulieu de and Reille, 1989) and multi-approach dating studies on proglacial deposits (Dehnert et al., 2010) in neighboring areas, this morainic complex, called External Moraine Complex (EMC), is related to the classical Riss Glaciation and is correlated to Marine Isotope Stage (MIS) 6. The last main ice extent, the so-called Last Glacial Maximum (LGM), is identified by a large number of exposures and the palaeogeography of glacial limits for the Jura and northwest Alps can be drawn with relative confidence. The proposed limits (Fig. 1) are compiled from Campy and Arn (1991), Campy (1992), Coutterand (2010), and Schlüchter et al. (2010). These authors have synthesized several previous studies. During the LGM, a discrete icecap covered the Jura Mountains. The Internal Moraine Complex (IMC) indicates a more limited westward extension than the EMC. Ice did not extend below 530 m a.s.l. on the western margin where ice tongues have impounded some large proglacial lakes. The ice cap culminated around 1800 m a.s.l. in the central part of the Jura and only some of the higher summits of the upper range emerged from the eastern slope of the glacier (nunataks). On the eastern margin of the Jura, the icecap flowed in contact with the Rhone glacier at the mean altitude of 1200 m a.s.l. The petrographical nature of deposits of the IMC, exclusively local calcareous material, demonstrates that during the LGM, the Rhone glacier never penetrated the Jura Mountains. Due to the lack of studies and the unclear disposal of moraines, geometry and limits of the northern and the southern ends of the Jura icecap are still unclear. However, north of 47°N, it seems that the icecap was scattered in small units limited to the highest part of the relief (Aubert, 1965; Schlüchter et al., 2010). Southwards, Buoncristiani and Campy (2004) propose a maximum extension of the icecap to the edge of the Rhone Glacier. Coutterand (2010)

indicates a disconnected limit and a termination of the Jura glacier close to 46°N.

The chronology for the IMC is not clear. Biotic remains have never been found in the moraines and the calcareous material, subjected to weathering and pedogenetic processes, does not allow for classical luminescence or cosmogenic dating. Based on the examination of outcrops of the Combe d'Ain proglacial lake filling (mainly the assemblage of delta sediments and moraines) (Fig. 2), Buoncristiani and Campy (2004) show that IMC was marked at its margin by three stages of stabilization during the advance and five episodes of stabilization in the course of glacial recession (Fig. 2). Comparison with  $\delta^{18}\text{O}$  data from GISP2 (Grootes et al., 1993) allows a possible chronology for the last glacial maximal advance at 27 500–24 000 cal BP and glacial retreat at 24 000–19 000 cal BP. That chronology, indicating a maximal extent during the MIS 2 at 24 000 cal BP, is notably consistent with the synchronous extent of the Rhine-Linth glacier on the northern Swiss Plateau (Preusser et al., 2011) and in phase with the Rhone glacier variations (Ivy-Ochs et al., 2004; Triganon et al., 2005; Guiter et al., 2005).

Further north from the Combe d'Ain, the recent discovery of a section near Arçon at 850 m a.s.l., located on the limit of the LGM glacier extension, reveals a two-phase glacial extent for the IMC (unpublished data). The sequence consists of two main outwash glaciofluvial gravel deposits situated within a thin lacustrine complex (Fig. 2). This intermediate unit is composed of silt to sand layers with, at least, four centimetric peat horizons. The radiocarbon dates give an infinite chronology for the older peat horizon (>51 000 BP – lab. ref. POZ 42964) and 48 600–44 600 cal BP (lab. ref. POZ- 4265) for the uppermost one. This unit indicates a temperate climate and definitely an unglaciated area. Chronology and sediment characteristics lead to a possible correlation with the Gossau-interstadial-Complex in lowland Switzerland (Preusser et al., 2003) at the end of MIS 3. Based on the dating of the lacustrine unit, the basal glaciofluvial unit could correspond to a first early/lower Würmian glacial advance during MIS 4, according to the data from the Swiss Plateau (Preusser and Schlüchter, 2004) and the Evian Plateau (Guiter et al., 2005) (Fig. 2). The top glaciofluvial unit corresponds to an outwash deposit linked with a second and a last extent (or readvance?) of the glacier. Because of its location on the IMC, this deposit must be considered as synchronous of the Combe d'Ain ice front. Paleogeography and timing of the glacial retreat in the inner Jura after 19 000 cal BP remain unclear and poorly studied. Moraines and subglacial deposits related to the retreat indicate a progressive reduction of the ice cap from the external limits to the upper range (Campy, 1992). However, the discovery of a mammoth skeleton at Praz Rodet (Fig. 2) in a proglacial deposit of the Vallée de Joux (Weidmann, 1969; Aubert, 1971), at 1050 m a.s.l. in one of the upper valleys of the Jura Mountains, highlights the terminal stage of the melting. The recent dating of the mammoth (Lister, 2009) indicates that the valley, and probably the almost entirely upper range of the Jura, were ice-free at 17 000–16 600 cal BP.

LGM environmental change had a major impact on the terrestrial biota, particularly well documented in the Jura area (Fig. 3). Mammal faunal species responded at a different rate according to their individual ecologies and the degree of constraints they had to cope with. During pre-LGM times, there is evidence of a first wave of extinction concerning the cave bear and probably also the cave hyena. The earliest definite radiocarbon dated cave bear comes from Rochedane, and yielded a radiocarbon date of 23 900 ± 110 -100 BP (28 730–28,500 cal BP, one sigma range) (Bocherens et al., 2013). This date which corresponds to the period just before the glacial advance of the

**Fig. 1.** Maximal extent of the glaciers and ice cap in the Jura Mountains (white line) and the Northern Alps (white dotted line) during the Last Glacial Maximum (LGM). Grey areas correspond to temporary proglacial lakes. In the inset, numbers refer to the authors for the limits: 1 (black line) = (Campy, 1992) and (Buoncristiani and Campy, 2004); 2 (dotted line) = (Coutterand, 2010); 3 (grey line) = (Schlüchter et al., 2010). Black stars refer to the sites mentioned: CA = Combe d'Ain glacial complex; PR = Praz Rodet mammoth; AR = Arçon site.

LGM is consistent with the pattern found in Western and Central Europe (Pacher and Stuart, 2009). This dated cave bear specimen also documents a longer survival of the specific genetic lineage *Ursus spelaeus* in the French Jura in contrast to the Swabian Jura (Southwestern Germany) where it was replaced by the *Ursus ingressus* type of cave bear around 31 500 cal BP (Münzel et al., 2014). A late survival of the cave hyena (*Crocota spelaea*) to the Late Glacial in the French Jura was previously suggested by the direct radiocarbon dating of a femur from the Grappin cave (Cupillard and Welté, 2006). However, the stable isotope analyses performed since this publication on the same bone have revealed that it was misidentified and belongs to a herbivore (Drucker, unpublished data). There is thus so far no clear data of attested hyena during the post-LGM period, and therefore no data from the French Jura speaks against the general pattern of extinction of the cave hyena before the LGM (Stuart and Lister, 2007).

## 2.2. Lateglacial period (ca 17 000–11 700 cal BP)

The local ice cap prevented the accumulation of sediment in the lake basin of the Jura Mountains during the Last Glacial Maximum. As a consequence, the pollen records documenting the vegetation history in the region begin only with the deglaciation, i.e. after ca 17–16 ka cal BP (Oldest Dryas pollen zone) for the highest parts of the range (Campy et al., 1985). The Lateglacial vegetation of the Jura Mountains and their western and northern margins has been revealed by 18 palynological records (Wegmüller, 1966; Richard, 1988, 1996; Ruffaldi, 1993, 2009; Schoellammer, 1998; Bégeot, 2000; Bégeot et al., 2000; Bégeot, 2006; Leroux et al., 2008). The cores analysed were collected at different altitudes ranging from 198 m to 1370 m (Fig. 4) in various geomorphological contexts such as lakes (i.e. Lakes Saint Point, Chalain, Abbaye, Etival, Bellefontaine, and Petit Maclu), mires with residual lakes (Cerin, Lautrey, Onoz and les Cruilles (CH)), bogs

**Fig. 2.** Chronology of the Last Glacial Maximum in the Jura Mountains compared to the Alpine glacial system and the Greenland ice sheet climate (NGRIP). The NGRIP oxygen isotopes curve is based on the INTIMATE event stratigraphy (Blockley et al., 2012) for the period 48–0 ka, and the NGRIP Project data (NGRIP Members, 2004) for the period 75–48 ka. The GISP2 oxygen isotopes record (Groote et al., 1993) associated to the Combe d'Ain glacial stages refer to Buoncrisiani and Campy (2004). Data for the Alpine glacial system are from Preusser et al. (2011) for the Rhine-Linth glacier and Triganon et al. (2005) for the Rhône glacier (Evian Plateau).

(Creux du Coure (CH) and Arinthod), and marshes (Pré Mourey, Le Locle-Col des Roches (CH), le Miroir, Morteau-Montlebon and Mont Roux (CH)).

Despite the geographical heterogeneity, the pollen records provide very similar trends of main taxa that characteristically

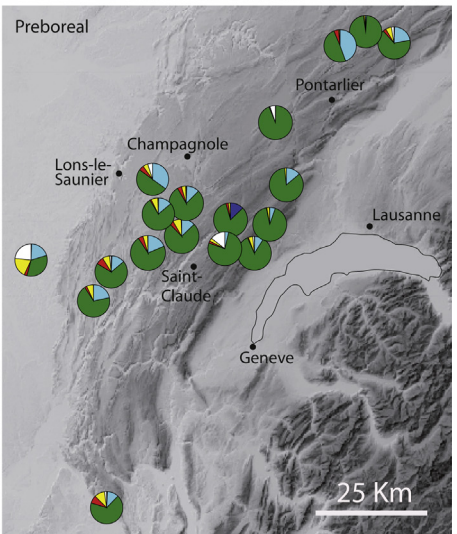

dominate the Lateglacial i.e. *Juniperus*, *Betula*, *Pinus*, *Artemisia* and *Poaceae* whose percentages are shown in Fig. 1. The regional biostratigraphy was inferred by correlation of common pollen events which were supposed to be synchronous : the start of the Bølling pollen zone was indicated by the first consequent increase

**Fig. 3.** AMS radiocarbon and isotopic records of selected fauna species from the Jura area. The latest date (2 sigmas) is given for the extinct species (*Panthera leo*, Stuart and Lister, 2011; Bocherens et al., 2011; *Coleodonta antiquitatis*, Cupillard and Welté, 2009; *Mammuthus primigenius*, Bridault and Chaix, 2009). The earliest date is given for *Capreolus capreolus*, unpubl. For the three other herbivore hunted species, *Rangifer tarandus*, *Equus ferus* and *Cervus elaphus*, the time range is given as well as the number of dates. The bone collagen  $\delta^{15}\text{N}$  values of reindeer over time reflect the intensity of soil processes which depends mainly on the temperature and permafrost influence (e.g. Drucker et al., 2012). Increasing soil activity as a result of decreasing permafrost intensity lead to increasing  $\delta^{15}\text{N}$  values in soils, plants and animals of the ecosystem. The diamonds in dark grey correspond to reindeer remains found in archaeological sites that were not accessible during the main part of the Last Glacial Maximum. The bone collagen  $\delta^{13}\text{C}$  values of red deer are an indicator of the density of the forest cover. Under a dense canopy, the depleted  $\delta^{13}\text{C}$  values of plants are passed on to the large herbivores feeding regularly on them (e.g. Drucker et al., 2008, 2011a). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

of the pioneer shrub values (*Hippophae*, *Juniperus* and *Salix*), the Older Dryas biozone was marked by an increase in Non Arboreal Pollen (NAP) values, the beginning of the Allerød pollen zone corresponds to an increase in *Pinus* values, the transition to the

Younger Dryas pollen zone was marked by the increase of *Artemisia* values which decrease at the onset of the Preboreal pollen zone. As most profiles from pioneer studies have not been radiocarbon dated, the chronological context was deduced by comparisons with

 *Juniperus* percentages  
 *Betula* percentages

 *Pinus* percentages  
 *Poaceae* percentages

 *Artemisia* percentages  
 *Cyperaceae* percentages

dated sequences, in particular the well radiocarbon-dated and high-resolution pollen records from Lake Lautrey which appear to show strong similarities with the Gerzensee and Greenland palaeoclimatic records (Magny et al., 2006).

In general, the base of the profiles was dominated by high percentages of herbaceous pollen, mainly *Artemisia*, Poaceae and other heliophilous taxa including Chenopodiaceae and *Helianthemum*. These palynological data indicate a largely open herbaceous landscape and can be correlated with the Oldest Dryas pollen zone (GS-2, before ca 14 600 cal BP; Blockley et al., 2012). Low *Pinus* values (less than 20%) occurred as a result of long distance transport (Fig. 4). The spread of shrubby vegetation in response to climate warming of the Bølling pollen zone (GI-1e) was characterized at first part by the dominance of *Juniperus* percentages in the lowest altitude up to around 1000 m asl and secondly by the dominance of *Betula* percentage at lowest altitude and *Juniperus* percentages at around 1000/1100 m asl. Pollen evidence for an altitudinal distribution of the shrubby suggests that *Betula* and *Juniperus* reached ~800/1000 m asl and ~1000/1200 m a.s.l. respectively. This is confirmed by the presence of macroremains of *Betula* (*B. pendula*, *B. nana* and *B. pubescens*) in the Bølling infilling from Lautrey (800 m asl) but not in the Bellefontaine sample (1093 m). The highest sites remained covered by steppe-like herbaceous vegetation and the occurrences of tree (essentially *Betula*) pollen were attributed to pollen transport from the valleys. Fig. 4 shows the drop in *Pinus* values in the second part of the Bølling for two northern sites (Saint point and Morteau Montlebon) that could suggest the regional migration of this taxa from the north. The Older Dryas cold event (ca 14 050–13 850 cal BP) was recorded as a regressive phase in the vegetation succession with an increase in NAP values associated with the increase in *Juniperus* percentages in sites below 800 m a.s.l. and with the increase of *Pinus* values in the highest sites. This last event can be interpreted as the expansion of *Pinus* forests from the north via the higher altitude areas or as a result of long distant transport into treeless areas above 800 m a.s.l. The absence of arboreal macrofossils in the Older Dryas infilling from the Bellefontaine and Mont Roux seems to indicate the depletion of the vegetation in altitude zones in response to the colder climate, but this should be verified by other macrofossils studies for this altitude. The regional immigration of pine forests was confirmed by the gradual but consistent rise of *Pinus* percentages during the Allerød (ca 13 850–12 700 cal BP). However, high values of *Juniperus* and NAP in the first part of the zone revealed that the landscape remained open. The forests became denser towards the end of the zone, as shown by the decrease of light demanding taxa. The presence of *Betula* macrofossils (wood and fruit) in the whole of the sequence from the Lautrey site combined with high pollen values of this taxa indicated that it remained a significant element in the vegetation at this altitudinal range. The presence of *Pinus* in the vicinity of Bellefontaine Lake and Mont Roux was attested by the occurrence of some needles in the sediment. There was no evidence for *Pinus* stands below 1000/1100 m a.s.l. The Younger Dryas pollen zone (ca 12 700–11 700 cal BP) was recorded by a major rise in NAP

values and a return of low *Juniperus* values. The low altitude site of Le Miroir was dominated by Cyperaceae rather than by *Artemisia*. *Betula* decreased in all sites. *Betula* macroremains disappeared from the sequence of Lautrey as did the *Pinus* macroremains of Bellefontaine and Mont Roux. A large reduction of the forested surface areas over a large part of the Jurassian massif seems to be recorded in response to cold climatic conditions.

With regard to the Lateglacial fauna, the available data taken as a whole (faunal spectra and isotopes) reveals a major phase of rapid ecosystem reorganisation at the end of Lateglacial, which is part of a multifactorial and longer process that spans from pre-LGM to Early Holocene. The human factor, because of the pressure of hunting and demographic expansion, is another piece of the puzzle, but difficult to measure directly for this period.

Typical large species of the Pleniglacial period are rare in the Lateglacial record. Woolly rhinoceros (*Coelodonta antiquitatis*), mammoth (*Mammuthus primigenius*), and cave Lion (*Panthera spelaea*) were on the final step of their extinction process (Stuart et al., 2004; Stuart and Lister, 2007; Lister and Stuart, 2008; Stuart and Lister, 2011), and the Jura area provides some of the latest specimens during GS-2a (Fig. 3; Bridault and Chaix, 2009; Cupillard and Welté, 2006). The presence of reindeer (*Rangifer tarandus*) is dated 23.8–22.5 ka in the northern Jura, in sites located away from the ice margins (Fig. 1). These animals fed on plants of very open habitat and poor soil maturity as shown by the relatively low  $\delta^{15}\text{N}$  values of reindeer bone collagen (e.g., Drucker et al., 2011b, 2012). Such areas at the periphery of recently deglaciated zones were subject to rapid recolonization by animal species, and reindeer were among the species best adapted to the prevailing harsh conditions. The existence of northern refugia in the vicinity of this Jura region may explain the early presence of reindeer there. This rapid recolonization reflects the high reactivity of the ecosystems, which could respond quickly to the retreat of the Jura glacier by a rapid re-expansion that probably favoured the survival of human populations. Reindeer was the main targeted game species, outstripped by the horse (*Equus ferus*) soon before the onset of the Bølling (GI-1e).

The arrival of red deer (*Cervus elaphus*) in the area started at the GS2a-GI-1e transition, when reindeer populations were already probably declining, but both species coexisted, as indicated by the remains of these two hunted cervids at Rochedane D1 (Doubs), where red deer is predominant (Bridault and Chaix, 2009). Red deer expansion took place in open habitats, as shown by the  $\delta^{13}\text{C}$  values of their bone collagen (e.g., Drucker et al., 2011a). In addition to climate change, interspecific competition could have been a worsening factor that firstly caused the regional demise of reindeer by 14 ka and later, the retreat of horse by 12 ka. No evidence has been found until now to support a reappearance of reindeer populations in the Jura area during the last cold oscillation (GS-1). The onset of the Bølling is therefore a key period: the pleniglacial legacy was vanishing and some species reputed as temperate-adapted, such as the red deer and moose (*Alces alces*), appeared and expanded. These two

**Fig. 4.** Pollen representation of main taxa from the Jura Mountains and marginal sites during the Lateglacial : In the lowest part : Le Miroir at 198 m a.s.l. (Richard, 1996), Arinthod at 450 m a.s.l., Chalain at 488 m asl (Wegmüller, 1966), Onoz at 560 m a.s.l. (Magny and Ruffaldi, 1994); In the middle part : Pré Mourey at 750 m a.s.l. (Cupillard et al., 1994), Morteau-Montlebon at 752 m a.s.l. (Campy et al., 1985), Cerin at 764 m a.s.l. (Ruffaldi, 1993, 2009), le Petit Maclu at 778 m a.s.l. (Wegmüller, 1966), le Lautrey at 788 m a.s.l. (Vannière et al., 2004; Peyron et al., 2005; Magny et al., 2006), Etival at 800 m a.s.l. (Richard, 1988), Abbaye at 871 m a.s.l. (Wegmüller, 1966), Saint-Point at 890 m a.s.l. (Leroux et al., 2008), Le Locle at 910 m a.s.l. (Schoellammer, 1998; Magny and Schoellammer, 1999; Magny et al., 2001) In the highest part : Les Cruilles at 1035 m a.s.l. (Wegmüller, 1966), Bellefontaine at 1093 m a.s.l. (Bégoat, 2000), Mont Roux at 1240 m a.s.l. (Bégoat, 2000; Bégoat et al., 2000), Amburnex at 1300 m a.s.l. (Wegmüller, 1966), Creux de Croue at 1370 m a.s.l. (Bégoat, 2000). Each pollen zone has been divided into two equal parts. Pie charts display the proportion of taxa at the middle level of the each “half zone”.

cervids probably benefited from the spread of shrubs and small trees that provided abundant grazing. A transitional state of the ecosystems is reflected in the non-analogous combination of taxa that characterizes the faunal spectra of this short stage. Despite the spread of woody plant species, the landscape was still very open and, thus, the impact of the faunal corpus change on the hunting strategy of the human population was probably more influenced by the differences in their ethology (large herds of migrating reindeer were replaced by small groups of territorial red deer and moose) than by the change of species composition (e.g. [Bridault and Chaix, 2009](#)). After the first warm oscillation, the fauna reorganisation seems to have accelerated and consolidated. Red deer become the predominant hunted species during the Allerød. Together with wild boar (*Sus scrofa*) and roe deer (*Capreolus capreolus*), they are the main prey species throughout the early Holocene.

### 2.3. The early to mid-Holocene (ca 11 700–7000 cal BP)

Pollen records of the Preboreal pollen zone (ca 11 700–10 200 cal BP) show a very similar picture to those observed during the second part of the Allerød. *Pinus* values were very high above 1000 m a.s.l. and their presence with *Betula* was attested by the occurrence of macrofossils at Bellefontaine and Mont Roux. Below 1000 m a.s.l., only the presence of *Betula* stands was confirmed by macroremains records at Lautrey.

From ca 10 200 to ca 9000 cal BP, during the Boreal pollen zone, *Pinus* remains dominant above 1100 m a.s.l. and masks *Corylus* which shows a clear domination everywhere else, while mesophilous trees expand, with a domination of *Ulmus* at the end of the pollen zone. The analysis of the peat-bog of Mouthé, in the high chain at 960 m a.s.l., shows abnormal variations in the hazel ratio at the end of the Boreal ([Cupillard et al., 1994](#)). These fluctuations could have a natural cause such as, for instance, spontaneous fires followed by regeneration of the vegetation ([Richard, 1995](#)), but might also result from human activity ([Cupillard, 2010](#)), but this needs to be confirmed by further studies.

Finally, the older Atlantic pollen zone (i.e. ca 9000–7000 cal BP) was characterized by an expansion of the *Quercetum mixtum*. However, the forest composition is closely related to the local climatic and edaphic conditions. Thus, the expansion of *Fraxinus* and *Tilia* depends on the altitude: above 1100 m a.s.l., *Tilia* shows relatively low percentage values, whereas it attains a maximum around 8000 cal BP at 1000 m a.s.l. and as early as 9000 cal BP below 800 m a.s.l. ([Beaulieu de et al., 1994](#)). The most ancient pollen from cereals found in the region was dated to the latter half of the Atlantic about 7700/7800 cal BP, and it is observed on two Jura sites ([Richard and Ruffaldi, 2004](#); [Gauthier and Richard, 2008](#)). This very early evidence must be questioned, even though similar evidence was observed near the lake of Zurich on the Swiss Plateau ([Haas, 1996](#); [Erny-Rodmann et al., 1997](#)) and in the upper Rhône valley ([Welten, 1982](#)). Around 7300/7000 cal BP, human impact and pollen from cereals are recognised at the lake of Chalain on the lower western plateau ([Richard, 1997](#)) and on different lacustrine or peat bog sequences of the high range ([Cupillard et al., 1994](#); [Buttler et al., 2002](#); [Gauthier, 2004](#); [Richard and Ruffaldi, 2004](#); [Leroux et al., 2008](#)). These various sites indicate that by that time, neolithisation was accomplished throughout the Jura, at least since 7300 cal BP ([Gauthier and Richard, 2008](#)).

Regarding the fauna, the depleted  $\delta^{13}\text{C}$  values of the red deer in the early Holocene indicate a high degree of closure of the forest canopy ([Drucker et al., 2011a](#)). In such a landscape, the acquisition of large game (i.e. the main animal food supply of the mesolithic

subsistence) probably involved a great change of hunting practices and settlement-procurement systems.

### 2.4. Quantitative estimates of climatic variations

Quantitative estimates of climatic variations in the Jura Mountains during the period 40–8 ka have been mainly reconstructed using pollen and chironomid data from lake sediment sequences. However, due to environmental conditions, i.e. the overall covering of the Jura Mountains by an ice cap above ~500 m a.s.l. and the quasi-absence of lake basins in the lower parts of the Jura, no data is available to establish a regional paleoclimate record for the interval 40–17 ka. Fortunately, the two sites of La Grande Pile (330 m a.s.l.) and Les Echets (267 m a.s.l.) located close to the northern and the southern extremities of the Jura Mountains ([Fig. 5](#)) have provided long pollen records which have been used for quantitative reconstructions of palaeoclimates during the whole Last Glacial/Interglacial cycle ([Guiot et al., 1989](#)). Both records suggest that the period 40–30 ka was characterised by relatively less cold and less dry conditions than the LGM marked by very cold and very dry conditions ([Guiot et al., 1989](#); [Guiot, 1990](#)). In addition, using pollen data showing only organic matter content and beetle data, [Guiot et al. \(1993\)](#) have indicated that the interval 60–15 ka in the palaeoclimatic record of La Grande Pile was punctuated by cold peaks in phase with Heinrich events defined in the North Atlantic Ocean.

The general retreat of the ice cap after ca 17–16 ka favoured the accumulation of sediments in the ice-free Jurassic lake basins and, as a result, the establishment of regional palaeoclimatic and palaeoenvironmental records for the Lateglacial and the early Holocene. Based on a multi-proxy reconstruction using pollen and chironomid data, the well-dated high-resolution palaeoclimatic record of Lake Lautrey spans the Late Glacial–early Holocene transition in the central Jura range ([Heiri and Millet, 2005](#); [Peyron et al., 2005](#); [Magny et al., 2006](#)). Major abrupt changes in climatic conditions appear to have been associated with the GS-2a/GI-1a, GI-1a/GS-1, and GS-1/Preboreal transitions. The temperature of the warmest month increased by ~5 °C at the start of GI-1 and by 1.5°–3 °C at the onset of the Holocene, while it fell by ~3°–4 °C at the beginning of GS-1. In addition, the pollen-based quantitative estimates suggest that the Lateglacial interstadial was punctuated by three successive minor cooling events by ~0.7°–2 °C possibly synchronous with the GI-1d, GI-1c2 ([Brauer et al., 2000](#)), and GI-1b oscillations. A comparison of temperature estimates obtained at Lake Lautrey with other quantitative reconstructions from neighbouring regions in west-central Europe show general agreement in identifying an identical succession of major warming (GI-1a, Preboreal) and cooling (GS-2a, GS-1) phases, but differences in the magnitude of the temperature changes reconstructed indicate difficulties concerning the methods of reconstruction and/or to the sensitivity or accuracy of the climatic indicators used ([Peyron et al., 2005](#); [Magny et al., 2006](#)).

Regarding the annual precipitation (PANN) and its seasonal distribution throughout the last Glacial–Interglacial transition at Lake Lautrey, the onset of GI-1 and Holocene coincided with a clear reactivation of the hydrological cycle with an increase in annual precipitation and available moisture, probably in connection with the retreat of sea ice and an increasing evaporation over the ice-free North Atlantic Ocean due to higher temperature ([Renssen and Isarin, 2001](#)). Given (1) that the abrupt warming in ca 14 700 and 11 700 cal BP corresponded to a major lowering of lake levels in the Jura Mountains ([Magny, 2001](#); [Magny et al., 2006](#)) and (2) that the sediment markers

## LAKE LE LOCLE (JURA MOUNTAINS)

## LAKE LAUTREY (JURA MOUNTAINS)

**Fig. 5.** Quantitative estimates of climatic parameters for the Lateglacial and early Holocene in the Jura Mountains using pollen, chironomidae, and lake-level data. Lower panel : the Lateglacial palaeoclimatic record from Lake Lautrey (from Heiri and Millet, 2005; Peyron et al., 2005; Magny et al., 2006). Upper panel: the early Holocene palaeoclimatic record from Lake Le Locle (from Magny et al., 2001). GDD5: growing degrees above 5 °C × days; PANN : annual rainfall; MTWA: mean temperature of the warmest month; E/PET: real evapotranspiration/potential evapotranspiration.

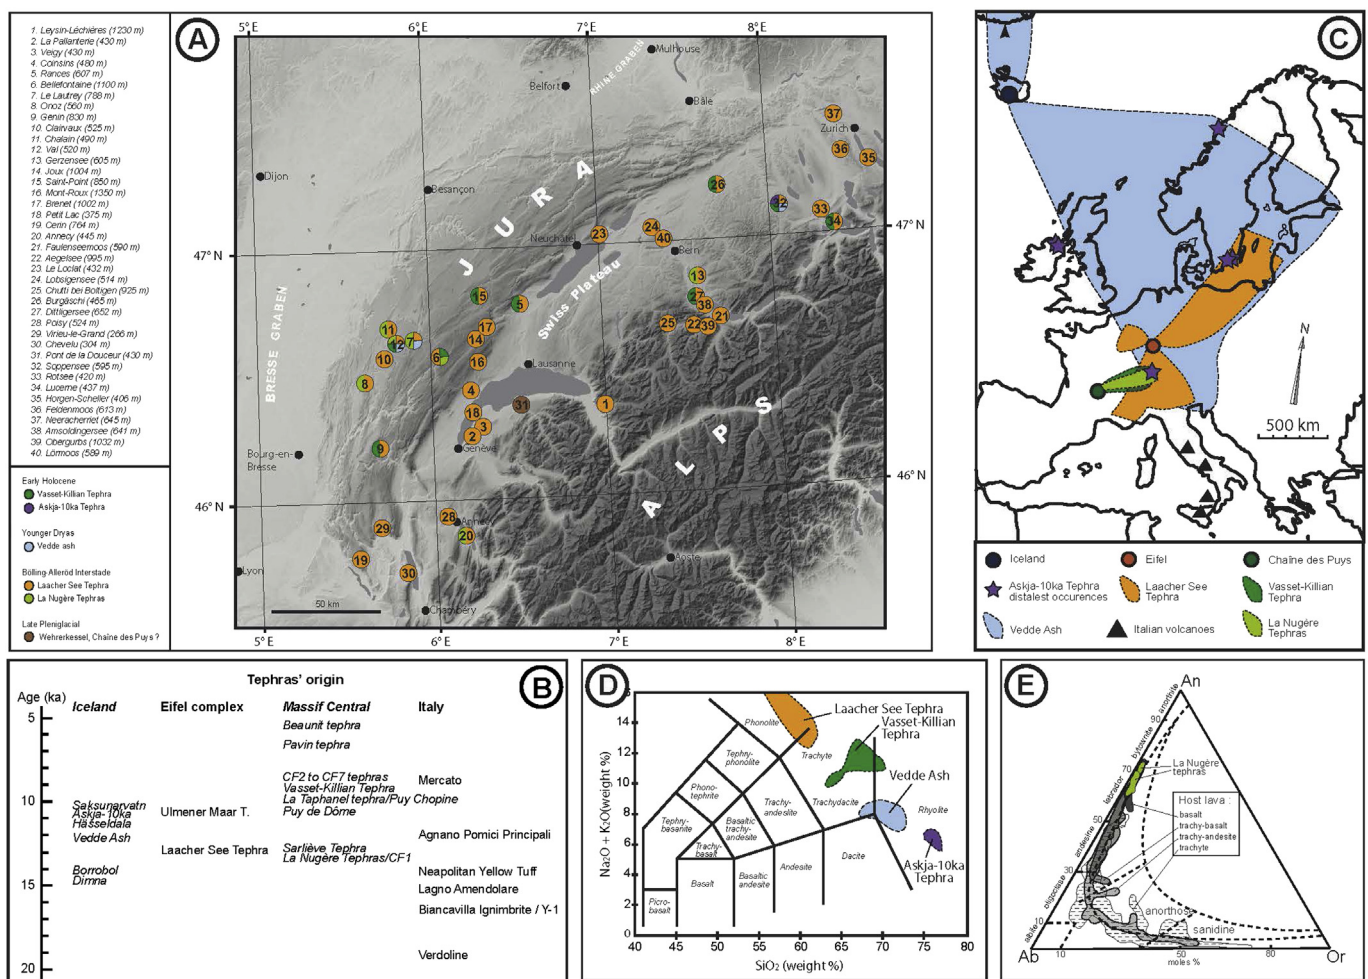

used for the reconstruction of past lake levels from during the warm season, quantitative estimates obtained at Lake Lautrey suggest dry summers and wet winters at the onset of the GI-1 and Holocene. GS-2a and GS-1 may have been characterised by

dry winters and wet summers. Such opposite patterns of seasonality may have reflected variations in the extension of the sea ice and the position of the storm track in agreement with AGCM experiments (Renssen and Isarin, 2001).

The early Holocene palaeoclimates in the Jura Mountains have been best documented by quantitative estimates obtained at Lake Le Locle, Swiss Jura, using pollen and lake-level data (Magny et al., 2001). Climatic parameters reconstructed here suggest that regional phases of higher lake-level conditions around 11 350–11 100 (Preboreal oscillation), 10 250–9900, 9550–9350 (Boreal oscillations), and 8400–8050 cal BP (8200 event) (Magny, 2013) coincided with an increase in annual precipitation by ~300 mm, a decrease in summer temperature by ~1.5°–2 °C, and a shortening of the growing season. This general pattern could have resulted from alternate southward–northward displacements of the Atlantic Westerly Jet Stream and its associated cyclonic track in response to both deglaciation events and variations in solar activity (Magny and Bégeot, 2004).

## 2.5. Tephrochronological data

In addition to data documenting palaeoenvironmental and palaeoclimatic changes, the sediment sequences studied in lakes and peat bogs of the Jura Mountains include tephra layers which offer key time-marker horizons for inter-regional correlations according to the INTIMATE strategy (Davies et al., 2002; Turney et al., 2006; Blockley et al., 2012). In this area and the Swiss Plateau, at least 40 sites have been studied since the Hofmann (1963) study carried out on Neeracherriet and Feldenmoos peatbogs (Switzerland) (Fig. 6-A). Some of the tephra described in lakes and peatbogs in French and Swiss Jura mountains are visible, usually observed as a greyish or dark layer depending on the host-sediment mineralogy, while the others are invisible to

the naked eye. Therefore, their detection is obtained either using magnetic susceptibility measurement with a 5 mm step along the cores (Jouannic, in prep.; Walter-Simonnet et al., 2008; Jouannic, in prep.), or by quantification of tephra glass shard concentration under an optical microscope in continuous (~1 cm<sup>3</sup>) samples of sediment prepared according to the process published by Blockley et al. (2004). Quantification under an optical microscope of the tephtras, especially acidic ones which cannot be detected by susceptibility measurement, is a long and exacting task. This is the reason why new rapid detection methods are currently being tested (Jouannic, in prep.; Caseldine et al., 1999; Kylander et al., 2012; Jouannic, in prep.). Assigning a tephra to a known eruption or a volcano can be made either by heavy mineral assemblage, phenocrystal chemistry, or chemical characterization of glass shards achieved by the analysis of major and minor elements using electron microprobe equipment. The latter method is now commonly used except when glass shards are too weathered for chemical analysis.

During the period 40–8 ka cal BP, many different volcanic complexes have been active in Europe (e.g. Iceland, the Eifel, the French Massif Central, Italy), generating a great number of tephtras deposited during the main eruptions (Fig. 6-B). North-west Europe, and especially eastern France and Switzerland, are in the centre of the area circumscribed by these points of eruption (Fig. 6-C). Six tephtra layers can be identified and characterized in lakes and peatbogs in the Jura Mountains and Swiss Plateau (Fig. 6-A).

The Icelandic volcanic complex is composed of two groups of volcanoes. Tholeiitic basalts are related to the Grimsvötn-Kverfjöll group situated in the Northern part of Iceland, when volcanoes from the southeast part of the island (Hekla and Katla) erupt alkaline basalts, olivine basalts and rhyolite (Jakobsson, 1979 in Davies et al., 2002). Some Icelandic tephtras have a wide dispersion (Davies et al., 2005; Pilcher et al., 2005; Blockley et al., 2007; Lane et al., 2011, 2012). In lakes and peatbogs of the Jura Mountains and Swiss Plateau two Icelandic tephtras were identified: the Vedde Ash (12 121 ± 114 a) and the Askja-10ka tephtra (10 702–10 991 cal BP) (Lane et al., 2011) (Fig. 6-C). The Vedde Ash is characterized by a bimodal basaltic-rhyolitic composition: in this area only the rhyolitic phase can be observed (Fig. 6-D). The Askja-10ka tephtra was described in only one site, the Soppensee (Lane et al., 2011). Its rhyolitic composition cannot be mistaken for the Vedde Ash's (Fig. 6-D).

The Eifel volcanic complex (near Bonn, Germany) generated two main tephtras (Fig. 6-B), but only the Laacher See Tephtra is observed as a visible layer in the region. It was dated to 12 880 ± 40 varve years (Brauer et al., 1999), 12 900 ± 560 years <sup>40</sup>Ar/<sup>39</sup>Ar (Van den Bogaard, 1995), and ca. 13 160 years from tree-ring analysis (Friedrich et al., 2004). This phonolitic tephtra (Fig. 6-D) is widespread in the North Atlantic region as well as in northern, southern, and continental Central Europe, where three phases with a different chemistry and manner of dispersion were identified (van den Bogaard and Schminke, 1985; Harms and Schminke, 2000) (Fig. 6-C).

The volcanoes of the Chaîne des Puys were very active during the Lateglacial and the Early Holocene (Fig. 6-B). Chemical analysis of tephtras and volcanic products from the Chaîne des Puys shows an evolution of basalts and trachy-basalts into trachytes (Maury et al., 1980; Boivin et al., 2004). Their dispersion is usually limited to Limagne and Monts du Forez (Etlicher et al., 1987; Juvigné and Gewalt, 1987; Vernet et al., 1990; Juvigné et al., 1992; Juvigné et al., 1996; Boivin et al., 2004), and their relative chronology was built by using four methods: pollen analysis, radiocarbon dating, thermoluminescence dating, and tephtric overlap (Vivent and Vernet, 2001; Vernet and Raynal,

2000; Boivin et al., 2004). In our region, the oldest tephtra occurrence corresponding to the Chaîne des Puys eruption was identified in only one site, Pont de la Douceur (Fig. 6-A), by Martini (1970). Martini related this tephtra layer to the Chaîne des Puys volcanoes owing to its late pleniglacial age (Blavoux and Brun, 1966) and its heavy mineral assemblage mostly composed of brown hornblende. Two very discrete tephtra layers have been deposited during the Allerød, before the Laacher See Tephtra (Walter-Simonnet et al., 2008). The chemical composition analysis of glass shards weathered into zeolites could not be carried out by using an electron microprobe. However, they have ages, mineral assemblages, and plagioclase chemical composition close to those of tephtras emitted by the Puy de la Nugère (ca 13 300 a) (Fig. 6-E).

The Vasset-Killian Tephtra (VKT), a trachytic tephtra (Fig. 6-A and D), was detected in nine sites, but chemically characterized only in Soppensee tephrostratigraphy by Lane et al. (2011). In the other sites, this tephtra was characterized only by its heavy mineral assemblage (Jouannic, in prep.; Martini, 1970; Eicher, 1987; Leroux et al., 2008; Jouannic, in prep.) or by correlation with magnetic susceptibility peaks (Schnellmann et al., 2006). However, the exact source volcano is unknown and the precise date of the eruption remains uncertain. In Soppensee, a new date of 9406–9265 cal BP for the VKT was proposed (Lane et al., 2011).

To sum up, with six different occurrences of tephtra layers deposited during the Late Glacial and Early Holocene, the Jura Mountains and Swiss Plateau area appear as an important tephrochronological bridge between northern and central Europe records and southern and western ones. These data outline the potential of tephtra layers as isochronous markers for developing more precise chronology and inter-site comparisons on common timescales. They also suggest the probable occurrence of other Lateglacial and Holocene cryptotephtras in eastern France records.

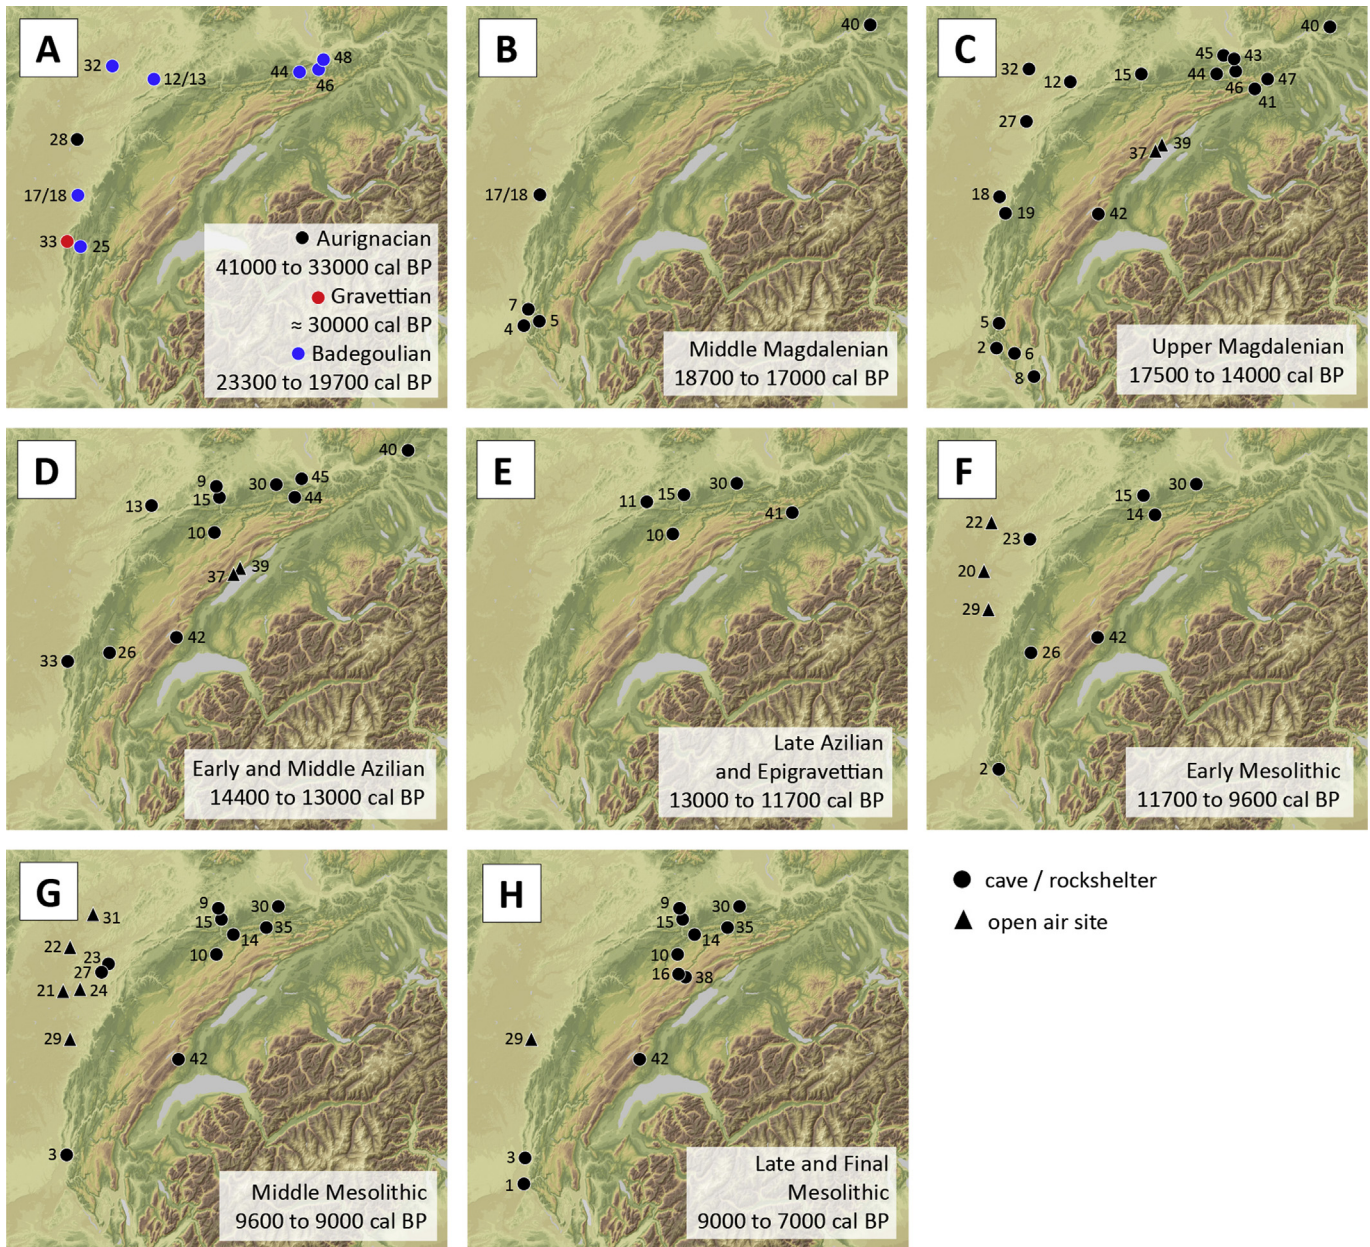

### 3. Archaeological data and cultural history

On both the French and Swiss sides of the Jura range during the last thirty years, the study of prehistoric sites has been greatly improved, firstly because of the achievements and the complete or partial publications of important rescue or programmed excavations, and secondly because new scientific research programmes have been undertaken to define the chronological framework of Upper Paleolithic, final Palaeolithic and Mesolithic cultures. This new research performed at 48 prehistoric sites (Table 1, Fig. 7) has yielded a huge set of environmental and archaeological data, and 256 new AMS dates which have been calibrated using the calibration software CALPAL (Danzeglocke et al., 2009; www.Cal.pal.de)(Appendix 1). This data now can be considered (at least as a first approximation) as representative of Palaeolithic and Mesolithic demography (Gamble et al., 2005; D'Errico et al., 2012) and indicates the main stages of human population between 40 000 and 8000 cal BP with cultural phases similar to those defined and radiocarbon-dated in neighbouring regions by Jaubert (2011), Leesch et al. (2012), and Gesquière and Marchand (2010). These well-dated sites constitute merely a sample of the recognised prehistoric sites, the number of which is not accurately known but is around seven hundred. The 256 AMS dates have mostly been already published but some of them are presented for the first time (Appendix 1). Half of them have been carried out on samples from excavations and the other half on samples from several investigations specifically aimed at chronology (Cupillard, 2008; Pion, 2000a; Pion and Mével, 2009; Szmjdt et al., 2010; Leesch et al., 2012, 2013; Drucker et al., 2011a, 2012; Cupillard et al., 2013).

**Table 1**

List of the Upper Palaeolithic, Final Palaeolithic and Mesolithic sites AMS dated in the French and Swiss Jura.

Number in Fig.7	Site	Locality	Country	District	Type	Altitude (m)	Excavation	Bibliography
1	Le Gardon	Ambérieu-en-Bugey	F	Ain	Cave	373	1985–2000	Voruz 2009

### 3.1. Aurignacian: from 41 000 to 33 000 cal BP (Fig. 7A)

As of 2013, evidence of Aurignacian culture is totally absent from Switzerland and from the Jura range (Leesch and Bullinger, 2013) and the only example of its kind is the Cave of La Mère Clochette at Rochefort-sur-Nenon located along the lower Doubs River on the western margins of the Jura range (Szmidi et al., 2010). On this site, excavated around 1900, five AMS dates have been made on bone or artefacts and fixed between 41 222–39 540 cal BP (OxA-19622) and 33 539–34 154 cal BP (Beta-150312). The results of greatest confidence seem to be those given by two samples treated by ultrafiltration, ie OxA-19622 : 41 222–39 540 cal BP and OxA-19621 : 40 464–38 120 cal BP (Szmidi et al., 2010). This occupation

corresponds to Proto-Aurignacian or Early Aurignacian culture, contemporary with MIS 3 and with a time range extending from GS-9 to GI-10 (Blockley et al., 2012). Close to this site, the Cave des Gorges at Amange (Jura) is a new, interesting stratigraphical sequence still being investigated, where the lowest layer US 4 provides few lithic artefacts and cold tolerant mammal fauna with 2 AMS dates of 40 666 to 38 641 cal BP (Bereiziat et al., 2012).

### 3.2. Middle Gravettian : around 30 000 cal BP (Fig. 7A)

Gravettian peopling is unknown in Switzerland and in the Jura range (Cupillard et al., 2013; Leesch and Bullinger, 2013). It seems to be present in the Prejurassic area, but recent TL dates between

17.6 and 10.1 ka do not fit with the Gravettian lithic industry (Lamotte et al., 2012). Nevertheless, the only one of its kind is the Cave of La Balme at Cuiseaux located on the western margins of the Central Jura range (Fornage-Bontemps, 2010; Cupillard et al., 2013; Leesch et al., 2013). On this site, excavated during the 1960s, faunal remains are very poor, and the lithic industry belongs to the Middle Gravettian, dated between 29 914 and 30 447 cal BP (Ly-3728 (GrA))(Fornage-Bontemps, 2010; Cupillard et al., 2013). Therefore, this occupation could be coeval with GS-5 and GI-4 (Lowe et al., 2008). This point shows that human peopling was possible along the western fringe of the range, 20 km from the front of the ice cap (Buoncristiani et al., 2002). Moreover, the study of the lithic industry shows that flints come mainly from local upper Cretaceous outcrops and seem to exclude an allochthonous occupation (Fornage-Bontemps, 2010).

### 3.3. Badegoulian or possible Early Magdalenian: from 23 300 to 19 700 cal BP (Fig. 7A)

Between 27 000 and 23 000 cal BP, the Jura range experienced a glacial advance and the climatic conditions must have been very harsh at its western margins (Buoncristiani et al., 2002). Solutrean culture, which in France, extends from 26 000 to 23 000 cal BP (Jaubert, 2011), is not present beyond the eastern part of the Saône River (Combiér and Montet-White, 2002; Tiffagom, 2006). The first stage of repopulation is dated between 23 300 and 21 400 cal BP at the end of the LGM during the glacial decay. Four sites produced 6 AMS dates. The best studied and documented site is Himmelried (Kastelhöhle-Nord), whose “middle layer” is attributed to the Badegoulian techno-complex, corresponding to the Type A Magdalenian techno-assemblage defined by Leesch (1993). At this site, 3 AMS dates performed on modified reindeer bones are placed between 23 051–23 775 and 21 788–22 468 cal BP (Sedlmeier, 2010; Leesch et al., 2012). In France, in the rock-shelter of Frétigny «La Baume Noire», two new AMS dates performed on reindeer bone of levels M4 et M5 are respectively placed at 22 804–23 338 cal BP and 21 454–22 172 cal BP (Drucker et al., 2012). They are contemporary with the Middle Kastelhöhle layer and Y-Höhle cave where a cut marked reindeer bone is dated between 22 466 and 23 021 cal BP (Leesch et al., 2012). These four sites lie in the time range corresponding to the extension of GI-2 and GS-2c. The second stage of peopling is dated between 21 000 and 19 700 cal BP during the second part of the deglaciation (GS-2b). Four sites with four reindeer and woolly rhinoceros skull AMS dates are involved: layer V of La Baume de Gigny (Jura) (Drucker et al., 2012), layer D of Rigney 1 (Cupillard and Welté, 2006), a part of layer C Grappin Cave in Arlay (Jura) (Drucker et al., 2012) and Kohler cave (Leesch et al., 2012). In these 4 cases, the cultural context is badly documented but we can suppose that they correspond to Late Badegoulian or Early Magdalenian short term occupations. The seven sites of these two stages are located in the Jura margins, at a low altitude between 220 and 462 m and between 20 and 50 km from the Jurassic or Alpine glacier fronts. They show that prehistoric groups can be found at the end of LGM, during ice melt. The well-identified and well-dated fauna remains show that the vegetation was sufficient to support these large species. On the other hand, lithic raw materials indicate regional origins which reflect regional sources of flint close to the Magdalenian ones, indicating that these prehistoric groups were not pioneers exploiting a new area, but were exploiting a familiar territory for a long time (Leesch et al., 2012). These new data obtained in the western part of Jura confirm as well the early recolonization of

Central Europe at the end of the LGM, already noted by several authors (Terberger and Street, 2002; Blockley et al., 2006).

### 3.4. Middle Magdalenian: from 18 700/18 000 cal BP to 17 000 cal BP (Fig. 7B)

The Middle Magdalenian is traditionally divided into different groups or ‘faciès’ (Leesch, 1993; Le Tensorer, 1998; Cupillard and Welté, 2006; Leesch et al., 2012). The first one is the Magdalenian “à navettes” only known in the French Jura at Arlay ‘Grappin’ (Cupillard et al., 2013). The second one is the Middle Magdalenian with triangles, “baguettes demi-rondes” and double bevelled antler points defining a Type B Magdalenian techno-assemblage on the basis of the lower layer at Birsek-Ermitage cave (Leesch, 1993). The third one is the Middle Magdalenian with points of Lussac-Angles and “baguettes demi-rondes à décor de tubérosités” corresponding to the Type C Magdalenian techno-assemblage defined at Kesslerloch (Leesch, 1993). At Arlay, the beginning of the first faciès is dated between 18 111–18 727 cal BP and 18 084–18 649 cal BP, i.e. the end of GS-2b, and its end might have occurred around 17 164–17 656 cal BP, i.e. the beginning of GS-2a. The Magdalenian with triangles is not well-dated at Birsek-Ermitage (Table 1), but in the cave of Chaze 2 in Arlay, which provides a triangle and a ‘baguette demi-ronde’, a woolly rhinoceros mandible is dated between 17 347 and 16 929 cal BP (Cupillard and Welté, 2006), i.e. the beginning of GS-2a (Table 1). On the site of Kesslerloch, the oldest new AMS dates could correspond to Middle Magdalenian, and in this case it would be fixed at least around 17 500 cal BP at the beginning of GS-2a (Leesch et al., 2012). All Middle Magdalenian sites are located on the margins of the Jura range and at low altitude. Although sites are mainly known in caves and rock-shelters, open-air sites of techno-assemblage B have been recognized in Switzerland and France (David, 1993; Leesch et al., 2012). The fauna is well-known and characterized with cold tolerant species including mammoth, woolly rhinoceros, reindeer, and horse. This shows that the vegetation could support these large herbivores. Moreover, some of these karst sites are very rich in lithic industries, bone and antler reindeer industries and portable art, such as the rock-shelter of la Colombière (Pion, 2000b; Paillet and Man-Estier, 2011), Grappin Cave (Cupillard and Welté, 2006, 2009) and Thaygen (Kesslerloch) cave (Höneisen, 1993; Le Tensorer, 1998). In Grappin Cave, the petrographic study of flints shows a large spectrum of flint resources which reflects a huge site catchment area along the Jura range (Cupillard and Welté, 2009).

### 3.5. Upper Magdalenian: From 17 500 to 14 000 cal BP (Fig. 7C)

Upper Magdalenian is undoubtedly the best known stage of the Upper Paleolithic because of the great number of caves and rock-shelters and because of the presence of two very well-preserved open-air sites in Neuchâtel (Monruz) and Hauterive (Champréveyres) where modern excavations have provided a very detailed palaeoenvironmental, chronological and palaeo-ethnological framework for Upper Magdalenian groups (Leesch, 1997; Morel and Müller, 1997; Bullinger et al., 2006). Today, 77 AMS dates have been obtained from 22 sites mainly located in lowlands under 600 m altitude, but two belong to the high range: Hostias ‘La Chênélaz’ (900 m) (Cartonnet and Naton, 2000) and Mont-la-Ville ‘Mollendruz’ (1088 m) (Pignat and Winiger, 1998). If the typology of Upper Magdalenian is well-established in the Swiss Jura range where Leesch et al. (1993, 2012) identified Types D and E Magdalenian techno-assemblages (Leesch 1993; Leesch et al., 2012), the chronological framework of these two techno-

assemblages is quite unequally documented. The Type D, characterised by “lithic industries dominated by backed bladelets, but not containing enough antler industry to distinguish them from techno-assemblage B” (Leesch et al., 2012, p. 7), is very well dated from the site of Monruz and Champréveyres, with 24 AMS dates from between 16 691–15 819 and 15 168–14 454 cal BP (Table 2). However, this chronological window could be reduced in time between 15 800 and 14 700 cal BP, a time range corresponding to the results of AMS dates from horse bone at Monruz and to the well-dated and very detailed pollen sub-zone CHb-1c in which Magdalenian levels are present (Leesch et al., 2012). On the other hand, the Type E Magdalenian assemblage, defined by “lithic industries with angle backed points, shouldered points, curve-backed points and backed bladelets”, known in a few rockshelters such as Kohlerhöhle and Kastelhöhle-Nord and in the open air site of Winznau-Köpfli, has not been recognised from open air lacustrine sites. New AMS dates from these latter 3 sites do not permit more precise data on the chronological stage of these industries. According to the chronological position of the Middle Magdalenian and of the Early Azilian occupations of Monruz and Champréveyres, the Upper Magdalenian would be theoretically dated between 17 000 and 14 000 cal BP, but we need to use reindeer AMS dates to check and detail this assertion on the basis of the best Upper Magdalenian assemblages. After the AMS dating from these sites, the Upper Magdalenian is placed between 17 419/16 792 cal BP and 14 189/13 819 cal BP, a time range which is coeval with GS-2a and GI-1d. Hence, its onset would overlap the end of the Middle Magdalenian and, on the other hand, its end would be contemporary with the Early Azilian. Some new AMS dates from Arlay (Grappin, layer C, pro parte), Kesslerloch pro parte and Mont-la-Ville (Mollendruz rockshelter, layer 5), indicate Upper Magdalenian occupation, but they need to be collaborated by further detailed studies. Generally, in the Jura area, the Upper Magdalenian is characterised by an increase of sites and by a large human dispersal enhanced by the development of large open air sites (Leesch and Bullinger, 2012), as well as the presence of the first human grave of Les Hoteaux (Pion, 2000b; Tillet, 2001). The majority of sites belong to GS-2a. Those of GI-1d are scarce and co-vary with a climatic improvement and the development of sparse forest coeval to the local disappearance of reindeer (Drucker et al., 2012).

### 3.6. Early Azilian and Middle Azilian : from 14 400 to 13 000 cal BP (Fig. 7D)

The first manifestations of Azilian culture, with its backed-curved points, were easily recognised at the open air sites of Champréveyres and Monruz along the Neuchâtel lake where they are dated between 14 400 and 14 000 cal BP, at the end of the Bölling, GI-1d (Leesch et al., 2004, 2012). Between 14 400 and 13 800 cal BP, well-dated occupations are scarce and lithic techno-assemblages are not typical and could be attributed to early Azilian. The sites in question are Thaygen (Kesslerloch, layer IIc pro parte), Mont-la-Ville (Mollendruz, layer C5 inf. pro parte), Büttenloch layer B, Meussia layer 3, (Cupillard, 2012b) and Cuiseaux (La Balme, Layer B). During the Alleröd, from the end of GI-1c to GI-1a, corresponding to the Middle Azilian, there is apparently a numerical increase of sites characterized by larger geographical dispersal (Cupillard and Bourgeois, 2008). Unfortunately, our data are unequally documented, as the well-dated sites are located in the northwestern part of the Jura. These sites are located below 550 m a.s.l., except Le Bichon (846 m). The 22 available radiocarbon dates from Alleröd belong mainly to the first part of this period, the end of GI-1c and GI-1b. Palynological studies show that all these sites were located below the treeline,

in an open pine-birch forest (Bégeot, 2000). Rochedane's layers C'1 and B show intensive occupations which provided a rich fauna dominated by red deer (Bridault, 1990), an abundant lithic industry (Thévenin, 1982), engraved and painted portable art (D'Errico, 1995) and scattered, well-dated human bones (Cupillard, 2008). In contrast, the other sites including Oberlag Layer S (Thévenin and Sainty, 1980), Rigney 2, and Bretonvillers (Cupillard, 2008) have smaller lithic and bone series and seem to be short-term occupations. The cave of Bichon is a very special case of a bear hunting accident (Morel, 1998; Chauvière, 2008). On the other hand, the study of lithic raw material shows the importance of regional flints, which indicate that the Jura range was no longer a barrier to exchanges (Cupillard and Bourgeois, 2008).

### 3.7. Late Azilian and Late Epigravettian: from 13 000 to 11 700 cal BP (Fig. 7E)

For the Younger Dryas, archaeological data are poor (Thévenin, 1982, 2002; Pion, 2004) and our precise knowledge is based only on four well-dated sites. These occupations in rockshelters are the layer R of Oberlag, the layer A4 of Rochedane (Drucker et al., 2011a), the layer D2 of Gigot at Bretonvillers and the layer III of Longeville (Cupillard, 2008). In addition, a part of layer II of Rislisberghöhle could be included in this small group of sites (Leesch et al., 2012). The lithic techno-assemblages from sites of Oberlag, Rochedane, Bretonvillers, and Longeville have been recently revised. Layers A4 of Rochedane and R of Oberlag may be attributed to the Late Epigravettian, while layers D2 of Bretonvillers and III of Longeville may be considered as belonging to the Late Azilian or to the Late Epigravettian (Fornage-Bontemps, 2013).

At Rochedane and Oberlag, the hunted fauna has been well studied : it is temperate and dominated by red deer (Bridault, 1990). Stone industries are made from local resources and the abundance of small geometric points at Rochedane (Fornage-Bontemps, 2013) reflects intensive hunting practices (Bridault, 1990) with the presence of engraved and painted portable art (D'Errico, 1995), whereas the three other sites are less documented (Fornage-Bontemps, 2013). These very late Final Palaeolithic occupations are all dated from the first part of GS-1 between 12 900 cal BP and 12 661 cal BP. The lack of <sup>14</sup>C dates between 12 600 and 11 700 cal BP must be emphasized. Could this situation be explained by climatic context or by changes in human use of landscape during the Younger Dryas? The latter hypothesis must be carefully examined, because palynological studies show a tripartite division of this biozone with a warmer phase between two colder phases (Bégeot, 2000).

### 3.8. Early Mesolithic: From 11 700 to 9600 cal BP (Fig. 7F)

The Preboreal saw the first appearance and the development of the Early Mesolithic, which corresponds to the first part of the First Mesolithic defined by Gesquière and Marchand (2010). This first Mesolithic settlement is characterised by a general increase of sites and of radiocarbon dates (Crotti and Cupillard, 2013). This period is marked as well by the appearance of important open air sites in the western lowlands, including Choisey les Champins, Ruffey a Daupharde, and Dammartin-Marpain sur la Prairie (Crotti and Cupillard, 2013). The rhythm of these occupations is not regular and varies with time. According to the calibrated <sup>14</sup>C dates, the oldest Mesolithic phase is isolated and is known only from the layer C2 at the open air site of Choisey les Champins 1 dated between 11 270 and 11 190 cal BP. The flint industry of this site shows northern influences, similar to Epi-ahrensbourgian traditions (Séara et al., 2002). Between this first occupation and the following

sites, there is a gap of several centuries. Most of the Early Mesolithic sites belong to the later part of the Preboreal and the beginning of the Boreal. This second phase of the Early Mesolithic is dated between 10 400 and 9600 cal BP in several open air sites including Dammartin-Marpain (Séara, 2010), Choisey Les Champins 1, and Ruffey A Daupharde (Séara et al., 2002) and in several rockshelters including Oberlag (Mannlefelden, layer Q), Mollendruz, layer 4<sup>e</sup> (Pignat and Winiger, 1998) and Hostias La Chênélaz, layer 2b (Cartonnet and Naton, 2000). As far as the Early Mesolithic is concerned, two main points must be emphasized. First, there is a chronological gap between the beginning of the Holocene and the earliest phase of the Early Mesolithic. Is there a link with the deterioration, the Remoray Phase, dated around 11 200 cal BP (Magny, 2004) and the Northern Mesolithic because of this climatic crisis? The second point is the consolidation phase of peopling at the end of Preboreal and the beginning of Boreal characterised by a wide dispersal of Beuronian and Sauveterrian groups, even in the Jura Range. This phenomenon is in conformity with the general climatic improvement demonstrated by palynology and climatic limnology (Magny, 2004).

### 3.9. Middle Mesolithic : from 9600 to 9000 cal BP (Fig. 7G)

The Middle Mesolithic corresponds to the second part of the First Mesolithic defined by Gesquière and Marchand (2010). During the main part of the Boreal, there is a wider dispersal of Middle Mesolithic sites. In the western lowlands, important open-air settlements of Dammartin-Marpain (Séara, 2010), Choisey Les Champins 1, and Ruffey A Daupharde (Séara et al., 2002) have been excavated and provide an important set of AMS dates showing a continuity of settlement during this period, despite “Boreal oscillations” dated between 9550 and 9350 cal BP (Magny, 2013). Many occupations are recognised as well in rockshelters as, for example, Bavans (Sous la Roche, layers 6 and 7), Ranchot (Les Cabônes, layer 3 pro parte), and Mollendruz, layer 4d (Pignat and Winiger, 1998). Beuronian and Sauveterrian groups exploited intensively all the altitudinal ecosystems, and base camps are found in the plains but also in the high ranges (Cupillard and Crotti, 2013). The discovery of scattered human bones at Ranchot layer 3 (Valentin, 1998) and of a very special grave at Ruffey-sur-Seille level R2 must also be emphasized (Valentin and Le Goff, 1998).

### 3.10. Late Mesolithic: from 9000 to 7000 cal BP (Fig. 7H)

This phase corresponds to the Second Mesolithic defined by Gesquière and Marchand (2010). The first part of the Early Atlantic and the beginning of the Late Mesolithic are characterised by the development of trapezes (Perrin et al., 2009). Only few sites are concerned; they are Oberlag « Mannlefelden I/J, Bretonvillers ‘Gigot, layer C2 pro parte’ (Cupillard, 2008), Ruffey ‘A Daupharde, layer R1 pro parte’ (Séara et al., 2002), Villers-le-Lac ‘Roche aux Pêcheurs, layer 5’ (Cupillard, 2010) and Mollendruz layer 4b (Pignat and Winiger, 1998). This first phase of the Late Mesolithic began around 9000 cal BP. The rareness of this initial stage of Second Mesolithic must be stressed, and the poor preservation of sites could be explained by destruction provoked by the 8200 cal BP event (Crotti and Cupillard, 2013).

The latter part of the Early Atlantic, between 8000 and 7000 cal BP, is the second stage of the Late Mesolithic. Sites are well-preserved and several of them are well-dated : this is the case with Villers-le-Lac ‘Roche-aux-Pêcheurs, layer C4’ (Cupillard, 2010), Bretonvillers ‘Gigot, layer C2 pro parte’ (Cupillard, 2008), Saint-Ursanne ‘Les Gripons, layer 3’ (Pousaz, 1991), Saint-Hippolyte ‘Montandon, layer 4’ (Cupillard, 2008), Ruffey-sur-Seille ‘A Daupharde, level R1’ (Séara et al., 2002), Neuville ‘Le Roseau, layer 3’

(Perrin, 2001) and Ambérieu-en-Bugey ‘Gardon cave, layers 57 and 54’ (Voruz, 2009).

From 8000 to 7300 cal BP, the economy of Mesolithic groups seems to have been based only on hunting and gathering. Since 7300 cal BP, few Final Mesolithic industries are contemporary with Early Neolithic industries, as in the Gardon cave where Final Mesolithic levels 54 and 57 are interstratified with Early Neolithic levels 56 and 58 (Voruz, 2009). This Early Neolithic presence is confirmed by palynological results which clearly show agricultural practices in lacustrine or peat-bog sequences at differing altitudes in the Jura range.

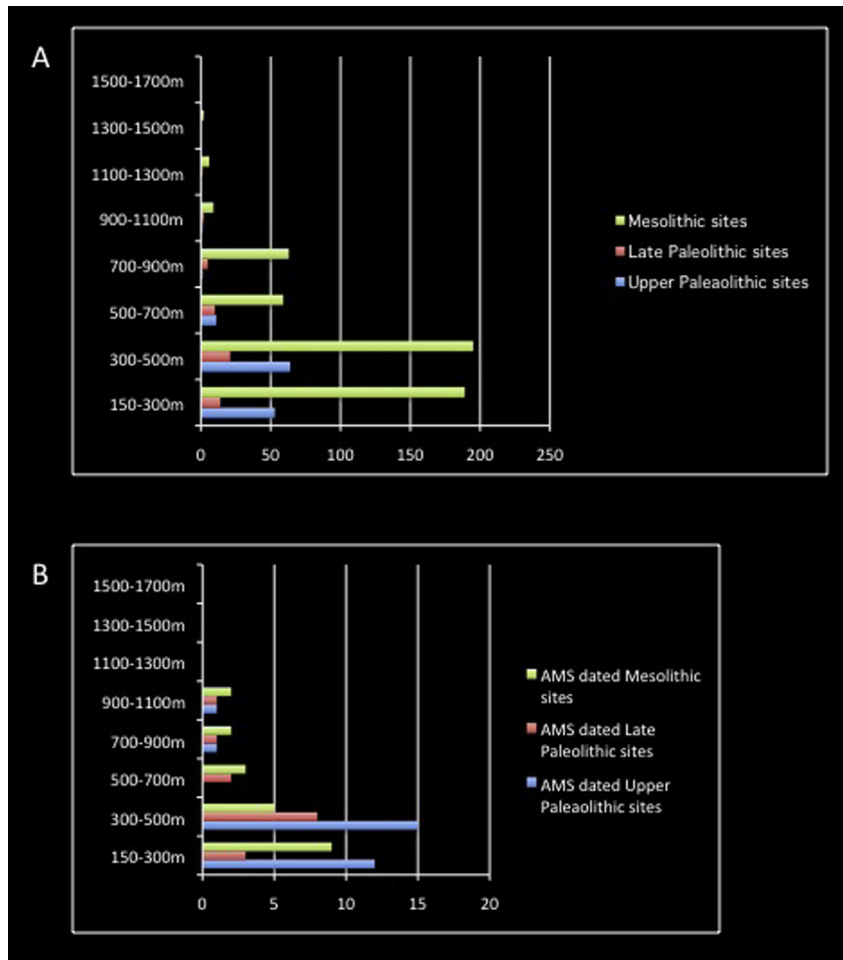

## 4. Discussion and conclusions

The French and Swiss Jura range, between 40 000 and 8000 cal BP, provides an abundance of palaeoclimatic/palaeoenvironmental and archaeological data which have been produced separately for a few decades. In this work, we have attempted to give a general overview of the all this data with a special focus on archaeology. At this point, although it is not yet possible to present a general integrated synthesis, we can nevertheless point out possible correlations between cultural evolution and palaeoclimatic and palaeoenvironmental changes. However, before attempting to compare palaeoclimatic and palaeoenvironmental records with archaeological data for a regional synthesis, it is important to point out some problems in order to reach this integrated view.

The first problem deals with the representativeness of the 48 archaeological sites which have been selected for this study and the 256 available AMS dates used for the reconstruction of the general cultural evolution. In the Jura range and its margins, according to our recent and unpublished archaeological inventories, around 700 Upper/Final Palaeolithic and Mesolithic sites (caves, rockshelters, open air sites and scatter areas) have been found. They compose 130 Upper Paleolithic sites (18%) with 2 Aurignacian sites, 3 Gravettian sites and 7 Badegoulian sites; 53 Final Palaeolithic sites (8%), with 38 Early and Middle Azilian sites, and 15 Late Azilian/Epigravettian sites; and 523 Mesolithic sites (74%), with 78 Early Mesolithic sites, 162 middle Mesolithic sites and 283 Late Mesolithic sites.

Fig. 8a presents the altitudes of these 700 archaeological sites. It shows (i) that Aurignacian, Gravettian and Badegoulian sites are scarce and are located below 500 m a.s.l.; (ii) that Magdalenian sites are relatively abundant and located mainly between 190 and 500 m a.s.l., whereas only rare occupations are located above 900 m a.s.l.; (iii) that Azilian and Epigravettian sites are less numerous than the Upper Magdalenian sites, but with elevated occupations between 700 and 1000 m a.s.l. particularly during the early and middle Azilian. The late Azilian and the late Epigravettian are less numerous and located below ca 500 m a.s.l.; and (iv) that Mesolithic sites are very abundant, located between 190 and 1500 m, but mainly between 190 m and 900 m, with an increasing number of sites from the early to the recent Mesolithic.

Among these 700 sites, only 63 (9%) have been radiocarbon-dated and give 397 dates, with 141 conventional results obtained from 41 sites (5% of the total sites and 36% of the dates), and 256 AMS results from 48 sites (7% of the total of sites and 64% of the dates), with 29 Upper Palaeolithic sites (22% of the Upper Palaeolithic sites), 15 Late Palaeolithic sites (28% of Final Palaeolithic sites) and 21 Mesolithic sites (4% of the Mesolithic sites). Therefore, the Upper and Final Paleolithic are better radiocarbon-dated than the Mesolithic. This situation is illustrated by Fig. 8b which shows the altitude distribution of the 48 AMS radiocarbon-dated sites. This picture mainly reflects the present state of the research and

**Fig. 8.** A. Number and elevation (in m a.s.l.) of all the archaeological sites (radiocarbon-dated or not, i.e. 700 sites): Aurignacian (ca 45 000–34 000 cal BP), Gravettian (ca 34 500–25 000 cal BP), Badegoulian/early Magdalenian (ca 23 000–18 700 cal BP), middle Magdalenian (ca 18 700–17 000 cal BP), late Magdalenian (ca 17 500–14 000 cal BP), early and middle Azilian (ca 14 500–13 000 cal BP), late Azilian and late Epigravettian (ca 13 000–11 700 cal BP), early Mesolithic (ca 11 700–9600 cal BP), middle Mesolithic (ca 9600–9000 cal BP), and late Mesolithic (ca 9000–7000 cal BP). From [Cupillard et al. \(2013\)](#), [Leesch et al. \(2013\)](#), [Crotti and Cupillard \(2013\)](#), Cupillard and Perrenoud-Cupillard (unpublished data). The chronology is in agreement with and refers to cultural phases defined and radiocarbon-dated in neighbouring regions by [Jaubert \(2011\)](#) and [Leesch et al. \(2012\)](#). B. Number and elevation (in m a.s.l.) of the archaeological sites discussed in the paper and dated by the AMS-radiocarbon method (48 sites, 256 AMS dates).

has still to be improved, particularly for the Mesolithic period, by increasing the number of AMS dates.

The second difficulty arises from the chronological and spatial heterogeneity of the sequences used for the reconstruction of palaeoclimatic and paleoenvironmental evolution. Because of the LGM, the Jura mountains do not deliver continuous natural or archaeological sequences covering the period 40 000 to 8000 cal BP. The closest continuous natural ones are located beyond the extent of the LGM, with Les Echets and La Grande Pile, located on the southwestern and northwestern margins of the range. Moreover, continuous karst sequences are absent because of erosion or sedimentation gaps observed in several infillings ([Campy and Chaline, 1993](#)) whereas loessic sequences are incomplete in the northern part of Switzerland. On the other hand, in the extent of LGM, pre-LGM natural sequences are very scarce and truncated, whereas post-LGM sequences from lakes and mires up to 400 m a.s.l. are abundant, and their multi-proxy studies can establish high-resolution palaeoenvironmental and palaeoclimatic records. Unfortunately, only a few provide well-preserved archaeological layers, such as the Magdalenian and Azilian open-air sites of Neuchâtel “Monruz” and Hauterive “Champréveyres”. Between 17 000 and

8000 cal BP, the archaeological sites are included mainly in karst sequences and secondarily in Holocene alluvial sequences. Although they are rarely continuous (but there are exceptions), these sequences give large sets of well-preserved organic materials such as bones, nut shells and charcoal, which facilitate archaeozoological studies, AMS dating and isotope geochemical analyses. These types of data are often the only tools available for reconstructing the palaeoenvironmental and palaeoclimatic context of human settlements. Therefore, defining the palaeoenvironmental and paleoclimatic context of the cultural changes consists of establishing correlations, on the basis of AMS dates, between (i) the data obtained from archaeological sites and (ii) the multi-proxy records provided by lake and mire sediment sequences.

A third difficulty deals with the taphonomy which appears to be particularly evident for archaeological sites as shown by the sites of Hauterive-Champréveyres and of Neuchâtel-Monruz, recently investigated on the shore of Lake Neuchâtel ([Leesch et al., 2012](#)). As noted by [Leesch et al. \(2012\)](#), [Cupillard et al. \(2013\)](#), and [Crotti and Cupillard \(2013\)](#), Palaeolithic and Mesolithic research has long concentrated on caves and rockshelters since they are easier to locate than open air sites. The fortuitous discovery of

Champréveyres and Monruz or Choisey “Les Champins”, Ruffey “A Daupharde” and Dammartin-Marpain “Sur la Prairie”, hints strongly at the possibility of many other well-preserved archaeological sites below the present-day lake water-levels, in alluvial deposits, or even in peat bogs. In contrast, the above compilation of regional lake sediment sequences document the period 40–8 ka. The lack of data for the LGM is due to a local ice cap preventing sediment accumulation in lake basins in elevated areas of the Jura Mountains up to the deglaciation. This points out the need to develop systematic investigations in lower areas (even if geomorphological conditions were not favourable to the formation of lacustrine basins) and/or in more elevated but ice-free areas close to the regional icecap border. This appears to be a pre-requisite to establish a continuous palaeoclimatic-palaeoenvironmental record as well as a solid chronology for the LGM in the Jura range.

A fourth difficulty arises from discrepancies between palaeoclimatic/palaeoenvironmental and archaeological data. Thus, even if several archaeological sites provided key stratigraphic sequences giving evidence of well-dated successive occupations from distinct cultural periods, the available archaeological data most often represent discontinuous cultural sequences from a chronological and spatial point of view. Systematic and extensive investigations are needed and are at work to establish a solid pattern of the regional history of human settlement in terms of changes in culture, spatial extension of occupation in the region, and demography (Leesch et al., 2012; Cupillard et al., 2013; Crotti and Cupillard, 2013). In contrast, strategically selected lake-sediment sequences may relatively easily provide continuous records to identify past changes in climatic and environmental conditions (Wegmüller, 1966; Bégeot, 2006; Magny et al., 2006).

In addition to these first methodological problems dealing with the representativeness of the palaeoenvironmental records and the archaeological data, we have also to consider questions about the economic and social structures of the Upper Palaeolithic and Mesolithic groups (and their possible variations). In this domain, our knowledge has still to be improved: this appears to be particularly evident in comparison with the richness of data collected in the Jurassian range from the Neolithic and Bronze age lake-dwellings sites (Pétrequin et al., 2005). This is a crucial point in evaluating the possible sensitivity of the last hunter-gatherer societies to climatic changes. Nevertheless, during the last decades many improvements have been made which help to define more precisely the subsistence strategies and their variations especially during the Upper Magdalenian and the Mesolithic (Leesch, 2000; Cupillard, 2010; Leesch et al., 2013; Crotti and Cupillard, 2013).

A last difficulty may arise from an estimation of the population density and human dispersal from the number of sites recognised in the region for prehistoric stages characterised by nomadic hunter-gatherer groups (Bocquet-Appel et al., 2005). Studies on lithic raw material and exotic artefacts help to outline exploited territories and exchange networks (Affolter, 2002; Leesch et al., 2013; Séara et al., 2002; Cattin et al., 2009; Cupillard, 2010) and archaeozoological studies coupled with stable isotope analyses provide useful data on the palaeoenvironment and the territories exploited (Drucker et al., 2011a, 2012). However, even if important, these palaeoenvironmental data appear still to be limited to best documented periods, i.e. those after 18 700 cal BP. Similarly, regarding our knowledge about settlements, spatial investigations have been developed only for sites of the Upper Magdalenian and Mesolithic, which give a good data set for a deeper understanding of the organization of hunter-gatherer settlements and help to develop functional models of societies such as those proposed by Leesch and Bullinger (2012) and Séara et al. (2002). In contrast, the data about the habitat appear more deficient for the Upper

Paleolithic before 17 500 cal BP. These types of studies are obviously crucial and need to be developed for a better understanding of the sensitivity of the last hunter-gatherer groups to climatic and environmental changes. As illustrated by Fig. 9, it is clear that the available documentation displays a discontinuity of settlement which supports previous observations (Campy and Richard, 1988). This may reflect a possible impact of the Jurassian LGM ice cap and its consequences on the preservation and the possible discovery of archaeological sites (Cupillard, 2012a; Leesch et al., 2012; Cupillard et al., 2013). According to the apparent timing of the human settlement shown in Fig. 8, three main stages can be distinguished:

- 1) The first stage spans the period 40 000–18 700 cal BP and it is strongly influenced by the LGM. From an archaeological and palaeoclimatological point of view, it is poorly documented because the Jurassian lakes were ice-covered during this phase and because only a few well-dated Aurignacian, Gravettian and Badegoulian occupations have been studied in the western Jurassian lowlands.

Aurignacian and Gravettian settlements, between 40 000 et 30 000 cal BP, predate the LGM. They are very few, and located outside the Jura range. They also seem to be intermittent occupations. The complete absence of Upper Palaeolithic sites before 27 000 cal BP in the Jura mountains as well as on the Swiss Plateau may be explained by their possible destruction by the LGM ice cap. Their regional rareness outside the LGM ice-cap extent is more problematic in comparison with the neighbouring settlement centers recognised in the Swabian Jura (South-western Germany) and in Burgundy in eastern France (Otte, 2010; Floss et al., 2013). This suggests that the western Jura range could have been occasionally frequented by Aurignacian and Gravettian groups. Such a hypothesis has still to be examined on the basis of systematic investigations between the valleys of the Saône and Doubs rivers.

Between 27 000 and 18 700 cal BP, the absence of Solutrean sites and the scarceness of Badegoulian sites in the Jura region may be explained by the presence of an ice cap and unfavourable environmental conditions in its surroundings. Markers of a first re-occupation by Palaeolithic groups appear only at the end of the LGM in the northern and northwestern parts of the Jura region. They suggest only short-term occupations in the vicinity of recently deglaciated zones, marked by presence of reindeers, probably in relation to the existence of refuge areas in margin lowlands around the Jura range (Drucker et al. 2012).

- 2) The second stage from 18 700/18 000 to 11 700 cal BP corresponds to the time window between the end of the ice melt in the Jura Mountains and the end of the Late Glacial. Since ca 17 000 cal BP, climate and paleoenvironment are well revealed by Jurassian lake sediment-sequences, while archaeological sites are numerous and well investigated. Human dispersal suggests different successive sub-stages.

The first one, between 18 700 and 17 000 cal BP, corresponds to the onset of the true Magdalenian settlement (Middle Magdalenian) which is limited to the periphery of the Jura. The absence of Magdalenian sites in the highest parts of the Jura Mountains probably reflects the presence of a residual ice cap. On the less-elevated plateaus, the absence of Magdalenian sites may be explained by particular characteristics of territories exploited by Magdalenian hunters with an apparent preference for raw material originating from lowland areas as suggested by lithic artefacts from Grappin cave in Arlay (Cupillard and Welté, 2009).

**Fig. 9.** Chronology of Upper Palaeolithic, Final Palaeolithic, Mesolithic and Neolithic of the French and Swiss Jura sites AMS dated compared to the Greenland ice sheet climate (NGRIP). The NGRIP oxygen isotopes curve is based on the INTIMATE event stratigraphy (Blockley et al., 2012) for the period 48–0 ka, and the NGRIP Project data (NGRIP Members, 2004) for the period 75–48 ka.

The second phase, corresponding to the Upper Magdalenian and the Early/Middle Azilian between 17 500 and 13 000 cal BP, can be considered as a consolidation phase of settlement. For the first time, settlements are found in the Jura range from 15 000 cal BP. During this phase, after the complete deglaciation of the Jura range at ca 17 000/16 600 cal BP, the Magdalenian sites (ca 17 000–14 000 cal BP) are mainly located below 500 m a.s.l., while only short-term occupations are present in the more elevated areas during the last part of the period, i.e. during the late Oldest Dryas or early Bölling pollen zones at sites of La Chênélaz (900 m a.s.l.) and Mollendruz (1088 m a.s.l.). Available data suggest that Late Magdalenian hunters have preferentially exploited territories

located at low altitude around the Jura range (Swiss Plateau, Rhone Valley, lowland zone to the west of the Jura Mountains, Rhin Valley), with a penetration into the main Jurassian valleys and only short-term occupations in the western plateaus and the high-elevated areas (Leesch et al., 2012). This is supported by studies of the origins of the lithic raw material found in archaeological sites (Leesch et al., 2013; Mével, 2013).

During the Oldest Dryas pollen zone, the preference of Magdalenian groups for lowland areas may have been in relation to a more abundant vegetation cover, which favoured reindeer and horse populations particularly appreciated by the Magdalenian hunters (Leesch et al., 2012). In addition, the extension of forested areas at

the beginning of the Bölling pollen zone favoured the development of new species such as deer and probably provoked changes in cynegetic practices. This led to a diversification of hunting territories which may explain the first Magdalenian occupations in the highest parts of the Jura range, which were followed between 14 000 and 13 000 cal BP by a large altitude range of the Azilian sites.

During the third sub-stage, between 13 000 and 11 700 cal BP (i.e. during the Younger Dryas cold event), Late Palaeolithic sites are rare, and only few well-dated sites are located below 500 m a.s.l. This suggests a contraction of the population density probably linked to cooler climatic conditions during the GS-1 cold event which strongly affected the ecosystems and provoked a decrease in available natural resources. This period is coeval with the apparition of Late Epigravettian groups. It is important to note the synchronicity between changes in climatic/environmental conditions and cultures (northern extension of Epigravettian culture).

3) The third stage between 11 700 and 7000 cal BP corresponds to the early Holocene. An important corpus of palaeoenvironmental and archaeological data record this phase characterised by warmer climatic conditions, an extension of the forest and a recolonisation of the Jura range by Mesolithic groups. Nevertheless, AMS dating shows that this phenomenon was not regular and that the rhythm of these occupations underwent variations during the period.

The first occurrence of the Mesolithic has been radiocarbon dated to ca 11 270–11 190 cal BP. It seems to have been geographically limited to the western lowlands of the Jura range and lithic industries could indicate a northern cultural influence close to the Epi-Ahrensbourgian. This delay of the Mesolithic recolonization, whereas climatic and environmental conditions are quite favourable, could have been explained by a previous strong impact of the more than 1000 year-long Younger Dryas cold event on the Late Azilian/Late Epigravettian groups (strong decrease in natural resources associated with hard climatic and environmental conditions) resulting in a marked decrease in the regional population density.

The true development of the Mesolithic dispersal of the Jura range occurred around 10 400 cal BP during the second part of the Preboreal pollen zone, reinforced during the Boreal pollen zone.

Dating from the second part of the Preboreal, after ca 11 200 cal BP, large Mesolithic open-air sites have been recognized in lowland areas to the west and east of the Jura range, while more elevated areas in the Jura Mountains are characterized by the first Early Mesolithic occupations in the Upper part of the Jura range. The Boreal pollen zone, between ca 10 200 and 9000 cal BP, corresponds to a reinforcement of the Mesolithic settlement in lowland as well in more elevated areas with intensification of occupations to ~1100 m a.s.l. This time interval is also characterised by the possible appearance of a first human impact on the vegetation.

The first part of the Old Atlantic pollen zone before ca 8000 cal BP is characterised by the development of the second phase of the Mesolithic with regular blade debitage and trapezes (Perrin et al., 2010). In the Jura range, this period is marked by a clear decrease in the number of Mesolithic sites which suggests a strong decrease in the population probably affected by unfavourable climatic and environmental conditions (with a reduction in natural resources) characteristic for the 8.2 ka event in the Jura region (Magny et al., 2001). However, the rapid re-expansion of the Mesolithic occupations on the whole Jura range after 8000 cal BP indicates that, in addition to the dynamics of the last Mesolithic societies and the development of the first Neolithic groups, around 7300 cal BP

(Gauthier and Richard, 2008), the impact of the ca 200 years-long 8.2 ka cold event was less strong on both the ecosystems and societies than that of the millennial-scale Younger Dryas cold event.

In conclusion, study of the Jura range has supplied a large data set about climate, paleoenvironment and prehistory for the period 40–8 ka cal BP. Considered as a whole, the data gathered in this synthesis invite further investigations for a better understanding of the response of environment and societies to climate changes as follows:

1. There is a need to develop further systematic exploration of the Jura range to find archaeological sites and sediment sequences containing a record the time window 40 000–17 000 cal BP.
2. Made of calcareous rock, the Jura Mountains have hundreds of caves at different altitudes, inside or outside of the maximal extent of the LGM ice cap. These sites can be ideal for the study of speleothems and fauna (above all bones of bears such as *Ursus spelaeus* and *Ursus arctos*) which will provide highly significant data for the understanding of the regional climatic conditions during the period 40–17 ka cal BP not documented by lake sediment sequences.
3. There is a need to establish a solid chronology for the disappearance of the Jurassian ice cap during the transition between the late Pleniglacial and the early Lateglacial.
4. Another important requirement is to develop systematic extensive archaeological surveys of all the available Upper Paleolithic, Late Paleolithic and Mesolithic sites in order to establish improved chronological, typo-technological and paleoenvironmental records and detailed archaeological maps (Cupillard, 2012a). It is necessary to continue surveys about human impact on environment in pollen profiles (developing studies of anthropogenic pollen indicators and charcoal, and more AMS dates) in order to confirm possible Mesolithic land clearance(s) and to refine the chronology, the intensity and the rhythm of the earliest stages of agriculture.

## Acknowledgements

Financial support for the regional studies synthesized in this paper was provided by (1) the French CNRS (UMR-6249 Chrono-Environment), (2) the CNRS-programme ECLIPSE “*Cervus*” (dir. A. Bridault), (3) the Collective Research Program (PCR-1997–2003) « *The Late Glacial at the North of the Alps and at the South of Jura range* » (dir. G. Pion, 1997–2003), (4) the PCR (2005–2008) « *The Late Glacial and the beginning of Holocene in the Jura range and its margins* » (dir.
