## Abstract

The continuum description of granular flows is still a challenge despite their importance in many geophysical and industrial applications. We extend previous works, which have explored steady flow properties, by focusing on unsteady flows accelerating/decelerating down an inclined plane in the simple shear configuration. We solve the flow kinematics analytically, including predictions of evolving velocity and stress profiles and the duration of the transient stage. The solution shows why and how granular materials reach steady flow on slopes steeper than angle of repose and how they decelerate on shallower slopes. The model might facilitate development of natural hazard assessment, and may be modified in the future to explore unsteady granular flows in different configurations.

# 1 Introduction

Accelerating and decelerating granular materials control many geophysical situations, with notable examples being landslides and geological faults. Understanding their flow would allow us to predict their energy and total deformation, and estimate the risk of natural hazards. While steady granular flows are complex but relatively well understood, unsteady flows, prevailing in nature, still lack a theoretical description. Many fundamental questions regarding unsteady flows are still open. Under what conditions does a granular flow reach steady state and why? How does the velocity profile evolve? What controls the time scale on which the flow accelerate/decelerate? What shear rate and shear stress control the energy dissipation? In this paper, we answer these questions for free surface dry granular flows down a slope.

Our knowledge about granular flows mostly comes from laboratory experiments and computer simulations. As a result, three flow regimes were classified [1]: “solid” in which grains interact via long-lasting frictional contacts and deform slowly, “gaseous” in which grains interact through collision lasting shortly compared to the deformation time scale, and “liquid” which is a transition between the two previous. For a flow down a slope, the three regimes can be attained by changing the slope angle  $\theta$  [2–4]. If  $\theta$  is small, no flow is observed but only an elastic deformation, or the flow decelerates if it was already set in motion previously. Once  $\theta$  exceeds the angle of repose, the flow accelerates. The increasing rate of collisions eventually leads to a steady flow. If, however, the slope is steep enough the flow keeps accelerating because the energy that grains receive during a free fall between collisions exceeds the dissipation. Here we study the liquid regime, in which flow is possible yet not too vigorous.

Steady granular flows have been investigated for more than a half a century, resulting in good knowledge of their rheology [5–8], flow regimes [2,3,33], scaling [9,10] and effects of boundary conditions [11,12]. On the other hand, unsteady flows have been discussed much less and have been described only approximately using depth-averaged models, *a.k.a* “shallow water models”, or computer simulations. Neither of the approaches has established analytical forms of velocity and stress profiles, which are required to access energy dissipation, or the associated destructive potential of the flow. In addition, friction coefficient is known from physics and geophysics to depend on shear rate or relative sliding velocity between two surfaces [6–8,12–14]. Knowledge of shear rate could thus facilitate development of theoretical friction models.

Depth-averaged models for granular flows arise from the depth-averaged mass and momentum conservation equations, originally derived by Savage

and Hutter [15]. The resulting equations for mean velocity neglect spatial variation of velocity inside the moving body. Hence, the depth-averaged models are less accurate if shear rate is large. Flow down a slope or channel flow were studied by [15–21], including analytical solutions for evolution of mean velocity, front position and thickness. These agree with experimental measurements [15,17,18,21] as long as the spatial fluctuations of velocity are small.

Computer simulations allow to examine velocity profile and flow evolution, which are difficult to study experimentally. Acceleration down an inclined plane, sometimes followed by deceleration on a flat plane (landslide geometry), was addressed by [1,22–24] using Discrete element method (DEM). Results reveal that the (top) free surface moves faster than the bottom surface, shearing the mass completely throughout its thickness. Yet, the analytical solutions for velocity and stress profiles are known only for the steady flow [2,3,5,7,9,10]. Also, the duration of the accelerating flow before the steady flow is reached has not been investigated.

The present analytical solution describes granular flows under simple shear induced by gravity (see Fig. 1). The flow is uniform in both lateral and longitudinal directions, and thickness  $h$  is kept constant. As a result, flow properties are functions of depth  $y$  and time  $t$  only. Simple shear geometry is simple enough to allow for an analytical solution, yet describes essential features of many natural flows, such as landslides, avalanches or geophysical faults. These can often be approximated as two-dimensional chute flows, or as flow confined between two walls, with the parallel component of velocity dominating the other components. Note however that elongation and flattening of the flow (observed for landslides) is neglected here.

We first review equations describing rheology of dry granular flows and derive the velocity field for the flow on an inclined plane (Section 2). Then we introduce numerical simulations that serve as a test to our analytical model (Section 3). Finally, we show the analytical model reproducing the kinematics observed in simulations and we explain why, how and in what time scale a flow reaches its final stage, be it steady state for accelerating flows or the rest for decelerating flows (Section 4).

## 2 Theory

Here, we derive analytical forms of velocity, shear rate and stress profiles for a granular flow of constant thickness down an inclined plane. Acceleration

of the flow is a result of the action of gravitational and friction forces

$$\Phi_s \rho \frac{\partial v}{\partial t} = \Phi_s \rho g \sin \theta - \frac{\partial \tau}{\partial y} \quad (1)$$

where  $\theta$  is the inclination angle,  $v(y, t)$  is the velocity along the flow direction,  $\tau(y, t)$  is the shear stress,  $g$  is the gravitational acceleration,  $\rho$  is the grain mass density and  $\Phi_s$  is the solid fraction.  $\Phi_s$  is uniform with depth [2] and constant (a very weak dependence on flow velocity has been found [1,6,7,12]). As a result, the normal stress  $N(y, t)$  is lithostatic:  $N = \Phi_s \rho g \cos \theta y$ .

To form a closed set of equations we need another relation between  $\tau$  and  $v$ , *i.e.* a rheological law. Friction in granular materials has been found to be shear rate dependent [6–8,13]. The only local dimensionless quantity for dry granular flows that contains shear rate is the so-called inertial number  $I(y, t)$

$$I = \frac{\dot{\gamma} d}{\sqrt{N/\rho}}, \quad (2)$$

where  $d$  is the grain size and  $\dot{\gamma}(y, t)$  is the shear rate (the negative sign is because  $y$  axis is pointing downwards)

$$\dot{\gamma} = -\frac{\partial v}{\partial y}. \quad (3)$$

The friction coefficient  $\mu(y, t)$  (also dimensionless) can then be expressed as an expansion in  $I$ . The linearized version of the friction law is

$$\mu \equiv \frac{\tau}{N} = \tan \theta_r + \beta I, \quad (4)$$

where  $\theta_r$  is the dynamic angle of repose and  $\beta$  is another material parameter ( $\tan \theta_r \approx 0.35$  and  $\beta \approx 0.6$  for glass beads [1]). This type of rheology, in which  $\mu$  is a function of  $I$ , has been verified for a variety of systems and boundary conditions [1, 6, 7, 18] and holds as long as plastic processes are negligible. Since  $\beta$  has been found positive, friction increases with shear rate under constant normal stress. The linear approximation, Eq. (4), is valid for the liquid flow regime studied here, which corresponds to inertial number of the order of  $10^{-3} - 10^{-1}$  [1,7]. For larger inertial numbers, the flow is collision dominated and eventually becomes turbulent. In this regime, the linear law breaks down.

The resulting shear stress  $\tau = \mu N$  is

$$\tau = \tan \theta_r \Phi_s \rho g \cos \theta y + \rho \beta d \sqrt{\Phi_s g \cos \theta y} \dot{\gamma}. \quad (5)$$

The first term is rate independent, and is usually of larger magnitude. The second term accounts for the increase of shear stress with shear rate. Consequently, friction force increases as the flow accelerates.

Taking the spatial derivative of Eq. (1) and using the constitutive relation Eq. (5), we arrive at a single equation for  $\dot{\gamma}$

$$\frac{\partial \dot{\gamma}}{\partial t} = \beta d \sqrt{\frac{1}{\Phi_s} g \cos \theta} \frac{\partial^2}{\partial y^2} (\sqrt{y} \dot{\gamma}) . \quad (6)$$

A diffusion equation for shear rate was introduced in Ref. [12] and used to determine transient time to obtain steady Couette flow in a simple shear cell. Note that for a flow under gravity investigated here, the diffusion coefficient is non-uniform.

We will solve Eq. (6) along with the following boundary/initial conditions:

$$\begin{aligned} (a) \quad & \tau(0, t) = 0 , \\ (b) \quad & v(h, t) = 0 , \\ (c) \quad & v(y, 0) = v^0(y) , \end{aligned} \quad (7)$$

where  $h$  is flow thickness. The boundary conditions can be stated as: (a) the top surface of the flow is free of stresses, (b) the velocity at the bottom of the flowing mass is zero (the ground surface is rough), and (c) the initial velocity is  $v^0(y)$ .

The solution is found as a series solution using separation of variables and superposition of all linearly independent solutions [25] (let us suppose for now that the spectrum of solutions is discrete:  $n = 0, 1, \dots$ )

$$\begin{aligned} \dot{\gamma} &= \sum_n p_n(t) q_n(y) , \quad \text{where} \quad (8) \\ \frac{dp_n}{dt} &= K_n p_n , \\ \frac{d^2 (\sqrt{y} q_n)}{dy^2} &= \frac{K_n}{\beta d \sqrt{\frac{1}{\Phi_s} g \cos \theta}} q_n . \end{aligned}$$

The separation constants  $K_n$  are to be determined from the boundary conditions.

The functions  $p_n$  are exponentially growing for  $K_n > 0$ . Because we are looking for a solution that is stable,  $K_n$  are restricted to be non-positive:  $K_0 = 0$  and  $K_n \equiv -1/T_n < 0$  for  $n > 0$ , where  $T_n$  are positive constants with a dimension of time. The spatial functions  $q_n$  have two independent

solutions [26]. For small  $y$ , they behave as  $\sim \sqrt{y}$  or  $\sim 1/\sqrt{y}$ . To satisfy the boundary condition (7a), we have to exclude the divergent solution. This leads to the following expansion for shear rate

$$\dot{\gamma} = \begin{cases} b^* \sqrt{y} + \sqrt{h} \sum_n b_n J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right) e^{-t/T_n} & \theta > \theta_r, \quad (9a) \\ \sqrt{h} \sum_n b_n J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right) e^{-t/T_n} & \theta < \theta_r, \quad (9b) \end{cases}$$

where  $b^*$  and  $b_n$ 's are yet undetermined weights,  $J_{2/3}(z)$  is Bessel function of the first kind [26], and  $\kappa_n$  is a dimensionless constant related to  $T_n$

$$\kappa_n = \frac{4}{3} \left( \frac{\Phi_s h^3}{T_n^2 \beta^2 d^2 g \cos \theta} \right)^{1/4}. \quad (10)$$

Each term in Eq. (9) is a solution of Eq. (6) that satisfies the boundary condition (7a). If the inclination angle is larger than the angle of repose,  $\theta > \theta_r$ , the flow accelerates towards steady state. In that case, we allow for the time-independent solution  $b^* \sqrt{y}$  (the first term), which corresponds to the steady flow shear rate since all other terms vanish after sufficient time. Note that this term is identical to Bagnold shear rate profile, found in numerous studies of steady granular flows on an incline [2, 3, 5]. For  $\theta < \theta_r$  the flow decelerates towards the rest as  $\dot{\gamma}(t \rightarrow \infty) \rightarrow 0$ . Therefore, the time-independent term is discarded.

The spatial integration of  $-\dot{\gamma} = \frac{\partial v}{\partial y}$  yields velocity up to an integration constant, which is allowed to be a function of time. The integration constant is determined from Eq. (1) using the series Eq. (9a) or (9b) in Eq. (5). This leads to the velocity formula

$$v(y, t) = \begin{cases} \frac{2}{3} b^* (h^{3/2} - y^{3/2}) + \frac{16}{9} h^2 \sum_n \frac{b_n}{\kappa_n^2} \frac{d}{dy} \left[ \sqrt{y} J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right) \right] e^{-t/T_n} & \theta > \theta_r, \\ g \cos \theta (\tan \theta_r - \tan \theta) t + \frac{16}{9} h^2 \sum_n \frac{b_n}{\kappa_n^2} \frac{d}{dy} \left[ \sqrt{y} J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right) \right] e^{-t/T_n} & \theta < \theta_r, \end{cases} \quad (11a)$$

$$(11b)$$

where  $b^*$  is

$$b^* = \frac{\sqrt{\Phi_s g \cos \theta} (\tan \theta - \tan \theta_r)}{\beta d}. \quad (12)$$

The solution (11b) is valid as long as  $v(y, t) > 0$ . Once the velocity at given depth  $y$  decays to zero, the layer becomes locked due to static friction and  $v(y) = 0$  afterwards.

To satisfy the boundary condition Eq. (7b),  $v(h, t) = 0$ , for an arbitrary weights  $b_n$ , all terms in Eq. (11) have to vanish for  $y = h$ . This constrains the values of  $\kappa_n$ , and consequently  $T_n$ , so as to satisfy

$$\left. \frac{d}{dy} \left[ \sqrt{y} J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right) \right] \right|_{y=h} = 0 \quad (13)$$

$$T_n = \frac{16\sqrt{\Phi_s}}{9\kappa_n^2} \frac{h^{3/2}}{\beta d \sqrt{g \cos \theta}}, \quad n = 1, 2, \dots, \infty.$$

In other words,  $\kappa_n$  are points where the function  $\sqrt{z} J_{2/3}(z)$  has an extreme value. Since this function oscillates, we have an infinite and discrete number of solutions, and therefore  $n$  is indeed identified with natural numbers. The first few values of  $\kappa_n$  and  $T_n/T_1$  are given in Table 1.

Finally, the constants  $b_n$  are determined from the initial condition (7c) as

$$b_n = \begin{cases} - \frac{\int_0^h (\sqrt{y} dv^0/dy + b^* y) J_{2/3}(\kappa_n (y/h)^{3/4}) dy}{\sqrt{h} \int_0^h J_{2/3}^2(\kappa_n (y/h)^{3/4}) \sqrt{y} dy} & \theta > \theta_r, \quad (14a) \\ - \frac{\int_0^h \sqrt{y} dv^0/dy J_{2/3}(\kappa_n (y/h)^{3/4}) dy}{\sqrt{h} \int_0^h J_{2/3}^2(\kappa_n (y/h)^{3/4}) \sqrt{y} dy} & \theta < \theta_r. \quad (14b) \end{cases}$$

In the last relation we used Eq. (9) and orthogonality of  $q_n$ 's for different  $n$  (see Appendix):  $\int_0^1 \sqrt{z} J_{2/3}(\kappa_n z^{3/4}) J_{2/3}(\kappa_m z^{3/4}) dz \sim \delta_{nm}$ . In Table 1, we give a few values of  $b_n$  corresponding to the initial velocity  $v^0 = 0$  (flow accelerating from the rest) or  $v^0 = 2b^*(h^{3/2} - y^{3/2})/3$  (flow decelerating from steady state).

In general, one needs to calculate  $b_n$ 's for all  $n$  for which the factor  $\exp(-t/T_n)$  is greater than a desired accuracy. Using these  $b_n$ 's in Eqs. (11) and (9) gives the accurate profiles of the velocity and shear rate fields (and also the shear stress field related by Eq. (5)). Nevertheless, for a first order approximation, when we restrict to the  $n = 1$  term only, the velocity field Eq. (11) simplifies to

$$v(y, t) = \begin{cases} \frac{2}{3} b^* (h^{3/2} - y^{3/2}) (1 - e^{-t/T_1}) & \theta > \theta_r, \quad (15a) \\ -g \cos \theta (\tan \theta_r - \tan \theta) t + v^0(y) e^{-t/T_1} & \theta < \theta_r. \quad (15b) \end{cases}$$

The corresponding shear rate and shear stress field can be derived using their definitions Eqs. (3) and (5).

### 3 Simulations

The numerical simulations are used as a benchmark for the theory derived above. They employ the Discrete Element Method (DEM) [27], in which the Newtonian equations of motion for a set of grains are solved in discrete steps.

Grains are modeled as balls with rotational and translational degrees of freedom. They interact via visco-elastic contact forces according to the Hertz-Mindlin contact model [28, 29]

$$\begin{aligned}
 F_{ij}^n &= \frac{\sqrt{2}E}{3(1-\nu^2)} \sqrt{R_{ij}\xi_{ij}} \xi_{ij} - \gamma \sqrt{R_{ij}\xi_{ij}} \dot{\xi}_{ij}, \\
 F_{ij}^t &= \min \left[ \frac{2\sqrt{2}E}{(2-\nu)(1+\nu)} \sqrt{R_{ij}\xi_{ij}} \Delta s, \mu_{gg} F_{ij}^n \right], \quad (16)
 \end{aligned}$$

where  $F_{ij}^n$  and  $F_{ij}^t$  are normal and shear components of the contact force between interacting grains  $i$  and  $j$ .  $R_{ij}$  is the harmonic mean of the grains radii and  $\xi_{ij}$  is the overlap between the two grains. Elastic modulus  $E = 1.31 \times 10^{10}$  Pa and Poisson's ratio  $\nu = 0.235$  were chosen to simulate quartz grains with density  $\rho = 2.5 \times 10^3$  kg m<sup>-3</sup>. Energy dissipation is governed by the normal damping force (the second term in  $F_{ij}^n$ ) with damping coefficient  $\gamma = 0.8$  and by the tangential friction ( $F_{ij}^t$ ). Restitution coefficient is not constant, but depends on velocities of colliding grains [28]. The tangential force is initially elastic, calculated from shear displacement  $\Delta s$  on contacts of the grains from the instant the contact was formed. Once the spring force exceeds the Coulomb friction criterion, the contact starts sliding with a constant shear force,  $F_{ij}^t = \mu_{gg} F_{ij}^n$ , where the grain-grain friction coefficient is  $\mu_{gg} = 0.5$ . Note that the grain-grain friction coefficient is not the same as the macroscopic dynamic friction coefficient [30, 31], which is investigated below and found to be shear rate dependent.

Grain diameters were randomly drawn from a Gaussian distribution with both mean value and standard deviation equal to  $d$ . The distribution is however cut, so that all diameters fall within  $0.8-1.2d$ . Equations of motion were integrated using velocity Verlet algorithm [32] with a time step  $0.1d\sqrt{\rho/E}$  small enough to resolve elastic waves due to grain-grain collisions.

Periodic boundary conditions were applied in the direction of the flow, which is equivalent to constant thickness boundary condition used in the theory. The width of the simulation box along the flow direction was  $96d$  (no size effects due to this scale were observed), while thickness of the flow varied among different simulations between  $h = 12 - 96d$  to test the volumetric scaling.

Granular systems are initiated as layers with random loose packing, standing on a flat horizontal surface made of static grains. Subject to vertical gravitational acceleration the grains sediment. By gradually turning the slope on which material flows, the static angle of repose  $\theta_{\text{sr}} = 17^\circ$  and dynamic angle of repose  $\theta_r = 14^\circ$  were found. To study acceleration we used inclination angles  $\theta = 17 - 25^\circ$ . The selected range of angles can accommodate steady flows, see Ref. [2, 3, 33] for phase diagram of flow regimes. Larger inclination angles lead to unstable acceleration and breakdown of the “liquid” flow regime. To study deceleration we turn the slope down to an angle  $\theta < \theta_r = 14^\circ$ .

## 4 Results

### 4.1 Flow density

The derivation of the flow velocity carried out in the Theory section relies on the presumption that the solid fraction  $\Phi_s$  is constant and uniform throughout the granular layer. In fact,  $\Phi_s$  is a weak function of  $I$  [1, 6, 7, 12], however, its variation can be neglected compared to variations of velocity and shear stress. This point is illustrated in Fig. 2, where we show solid fraction profiles at a number of time instants during a simulation of  $h = 96d = 9.6$  m thick flow. The flow first accelerates on a  $17^\circ$  slope starting from rest. After reaching the steady state, the slope is turned down to  $0^\circ$  and the flow decelerates on a flat plane. The solid fraction at all instants of the simulation remains the same within its fluctuations, while, as we will see later, velocity and shear stress vary significantly.

### 4.2 Stress evolution and flow stability

Here we verify and calibrate the rheological law Eq. (4). Fig. 3(a) shows depth-averaged shear and normal stresses as functions of time. The data were obtained from DEM simulation for  $\theta = 17^\circ > \theta_r$ , *i.e.* the flow accelerates towards steady state. While the normal stress is constant and equal to lithostatic stress,  $N = \Phi_s \rho g \cos \theta y$ , the shear stress increases from its minimum value  $\lim_{\dot{\gamma} \rightarrow 0} \tau = \tan \theta_r \Phi_s \rho g \cos \theta y$  (see Eq. (5)) towards the steady flow value  $\tau = \Phi_s \rho g \sin \theta y$ , which can be derived from Eq. (1). Similarly, the friction coefficient  $\mu = \tau/N$  (not shown) evolves following the evolution of  $\tau$ .

Fig. 3(b) shows the  $\mu(I)$  rheology, *i.e.* the friction coefficient  $\mu$  increases linearly with the inertial number  $I$ , in accordance with Eq. (4). The linear

behavior was found for the whole range of angles leading to a stable flow and for all studied system dimensions:  $d = 0.001 - 0.1$  m,  $h = (12 - 120)d$ , indicating “liquid-like” regime of the flow.

The rheological parameters  $\theta_r$  and  $\beta$  are independent of depth except for close to the ground surface  $y = h$ , so Eq. (4) holds locally. On the other hand, the parameters were found to moderately depend on the thickness for thin layers (with thickness of a few times  $d$ ) due to non-local effects [34]. In addition,  $\beta$  varies with  $\theta$ . In simulations, increasing  $\theta$  from  $17^\circ$  to  $25^\circ$  resulted in the decrease of  $\beta$  by 40%.

Based on Fig. 3 we can understand why a flow can reach a steady state. According to Eq. (1), acceleration of the flow is given by the difference between the driving gravitational force  $g \sin \theta$  and the resisting friction force  $\partial\tau/\partial y$ . This difference is non-negative only if  $\theta > \theta_r$  (if the flow starts from rest, a larger static friction angle  $\theta_{sr}$  needs to be overcome). As the flow accelerates,  $\dot{\gamma}$  increases due to increasing  $v$ . In line with Eq. (5), increasing  $\dot{\gamma}$  leads to increasing  $\tau$  and therefore increasing  $\partial\tau/\partial y$ . Eventually, the friction force  $\partial\tau/\partial y$  balances the gravitational force. At that moment the acceleration vanishes and the flow reaches steady state. From then on, friction and inertial number fluctuate around their constant steady flow values ( $I^\infty = 0.041$  and  $\mu^\infty = 0.31 = \tan 17^\circ$  for the system shown in Fig. 3).

Note that for the Coulomb friction law, *i.e.*  $\beta = 0$ , shear stress is independent of velocity (see Eq. (5)), and thus constant with time. Such system would accelerate unstably with uniform and constant acceleration  $g \cos \theta (\tan \theta - \tan \theta_r) > 0$  and would not reach steady flow apart from the special case  $\theta = \theta_r$ .

### 4.3 Flow velocity

Figs. 4 and 5 show velocity for a flow accelerating from rest (top) and decelerating from steady state (bottom). The theoretical prediction Eq. (11) (dashed lines), in which we neglect all terms with  $n > 3$ , is tested against the DEM simulation results (solid lines).

Fig. 4 shows velocity profiles at discrete time instants. The flow is non-uniform, shearing the mass throughout its thickness. If  $\theta > \theta_r$  the flow accelerates, eventually reaching the steady state. The steady flow profile (magenta line) is given by the first term in Eq. (11a) and is consistent with the Bagnold rheology studied in previous works [2, 3, 5, 9, 10].

If  $\theta < \theta_r$ , the flow decelerates. For the given flow parameters ( $h = 96d = 9.6$  m,  $g = 9.8 \text{ ms}^{-2}$  and  $\theta = 17^\circ$ ), the deceleration rate is approximately

uniform and constant, as the first term in Eq. (11b) dominates the evolution. Once velocity at given depth  $y$  decays to zero, the layer becomes locked due to static friction and  $v(y) = 0$  thereafter. Since deeper layers have lower velocity, they stop first. Consequently, the flow becomes increasingly limited, confined to a gradually thinning layer near the top surface.

Fig. 5 shows complementary plots of velocity evolution at a number of different depths. If  $\theta > \theta_r$ , velocity approaches the steady flow velocity as a series of exponentially decaying functions with characteristic times  $T_n$ . By the time  $T_1$  ( $= 33$  s for the system in the figure) all terms in the series in Eq. (11) with  $n > 1$  vanished (see Table 1 for relative values of  $T_n$ ) and the  $n = 1$  term dominates the time evolution. Acceleration decays as  $\sim \exp(-t/T_1)$  and velocity increases approximately as  $\sim 1 - \exp(-t/T_1)$ .

If  $\theta < \theta_r$ , velocity decays towards zero. For the case  $\theta = 0$  shown here, the deceleration is considerably faster compared to the acceleration down a slope of  $\theta = 17^\circ$  shown above due to the presence of  $-g \tan \theta_r t$  in Eq. (11b). The leading  $n = 1$  term in the series in Eq. (11b) satisfies  $t \ll T_1$ , and can be expanded linearly as  $\sim 1 - t/T_1$ . The remaining terms in the series can be neglected because of small  $\exp(-t/T_n)$  and/or  $b_n$ . As a consequence, the velocity decreases approximately linearly with time.

The overall fit between the theory and the simulations is very good, lending confidence to the new theory. However, there is a noticeable deviation between the simulation and the theoretical curves in Figs. 4 and 5, most pronounced near the bottom surface. This deviation does not result from a time fluctuation or statistical uncertainty, as shown by error bars presenting the variability from different initial configurations. In the acceleration phase (Figs. 4a and 5a) the deviation is due to a difference in boundary conditions. In simulations, the motion of the deepest flowing grains, subject to largest shear and normal stresses, is intermittent and alternates between “stick and slip” stages. This is not perfectly consistent with the no-slip boundary condition used in the theory for brevity of analytical calculations. For the deceleration phase (Figs. 4b and 5b) the simulation velocity profiles have exponentially decaying tails penetrating beyond the stop depth. This feature was explained by Kamrin and Koval [35] to be a non-local effect (not included in the present rheological law), in which the flow above the stop depth induces a limited flow in deeper layers despite shear stress being lower than the yield stress.

Perhaps counter-intuitively, deceleration is not the reversed time evolution of acceleration. The difference between  $\theta > \theta_r$  and  $\theta < \theta_r$  solutions originates from allowing for a time-independent term in the expansion Eq. (8).

For  $\theta > \theta_r$ , the time-independent term is allowed and is identical to the steady shear rate profile  $b^* \sqrt{y}$  reached after the remaining exponentially decaying terms vanish. For  $\theta < \theta_r$ , the time-independent term vanishes as there is not strong enough driving force to maintain steady flow.

#### 4.4 Transient time and its scaling

During acceleration, velocity approaches the steady flow profile as a series of exponentially decaying functions with characteristic times  $T_n$  (see Eq. (11)). According to Eq. (13) the relative magnitudes  $T_n/T_m = \kappa_m^2/\kappa_n^2$  are universal, independent of flow dimensions or inclination angle, since  $\kappa_n$ 's are constants equal to points of extrema of the function  $\sqrt{z}J_{2/3}(z)$ . Because  $T_1$  is sufficiently larger than the other  $T_n$ 's (see Table 1), it dominates the time evolution after the very initial period. Therefore,  $T_1$  is an appropriate scale of the duration of the acceleration stage.

In Fig. 6 (points) we plot the transient time  $T_1$  obtained by fitting  $\sim \exp(-t/T_1)$  to simulation data for  $v(y, t) - v(y, t \rightarrow \infty)$ . The simulations were run for various values of  $h$ ,  $d$  and  $\theta$ . Results are compared to the analytical prediction (solid line) given by Eq. (13), and the expected scaling  $T_1 \sim h^{3/2}/\beta d \sqrt{g \cos \theta}$  is recovered. Thus,  $T_1$  increases with flow thickness as  $\sim h^{3/2}$  and decreases with grain diameter as  $\sim d^{-1}$ , *i.e.* in the same way as the steady flow velocity. The scaling with  $\theta$  is more complex than  $\sim 1/\sqrt{\cos \theta}$  because  $\beta$  also varies with  $\theta$ . The decrease of  $\beta$  by 40% was found on increasing  $\theta$  from  $17^\circ$  to  $25^\circ$  in our simulations.  $T_1$  is not expected to vary significantly with mechanical characteristics of grains, such as restitution coefficient, grain-grain friction coefficient or elastic modulus, as these were shown to have a small influence on the flow rheology [7].

## 5 Conclusions

While a significant progress has been made in continuum description of steady granular flows over the past decade, unsteady flows have been much less discussed, despite their importance in geophysical processes. In this work, we solve kinematics of a granular flow of constant thickness on an inclined plane. We analytically derive velocity and stress fields for both accelerating flows, when the slope angle  $\theta$  is larger than the angle of repose  $\theta_r$  (but still is shallow enough to reach a steady state), or decelerating flows in the opposite case. We compared the analytical derivation to 2D DEM simulations of flow down inclines.

Similarly to steady flows, we find that during acceleration/deceleration friction resistance is an approximately linearly increasing function of shear rate. For  $\theta > \theta_r$  the shear rate increases as the flow accelerates until the resisting friction force balances the originally prevailing gravitational force. At that moment the net force is zero, and the flow reaches steady state. The velocity is found to increase towards the steady flow velocity profile  $v^\infty(y)$  (consistent with the Bagnold scaling) approximately as

$$v(y, t) \approx v^\infty(y) (1 - e^{-t/T_1}) . \quad [\text{accelerating flow}]$$

The transient time  $T_1$ , which characterizes the duration of the acceleration, is found (both analytically and in DEM simulations) to be controlled by granular layer thickness  $h$ , grain size  $d$ , slope angle  $\theta$ , gravitational acceleration  $g$  and rheological parameter  $\beta$

$$T_1 = 0.5\sqrt{\Phi_s} \frac{h^{3/2}}{\beta d \sqrt{g \cos \theta}} .$$

For  $\theta < \theta_r$  the flow decelerates. Deceleration is not a reverse time image of acceleration, since it includes an extra deceleration rate  $-g \cos \theta (\tan \theta_r - \tan \theta)$  that is not present during acceleration. As a result, the deceleration stage is faster than that of acceleration for a given flow. During deceleration, a first order approximation of the velocity, as it decays from the initial velocity  $v^0$ , is shown to be:

$$v(y, t) \approx v^0(y) e^{-t/T_1} - g \cos \theta (\tan \theta_r - \tan \theta) t . \quad [\text{decelerating flow}]$$

DEM simulations show that the first order approximations of the transient velocity fields provide a good fit except for a very initial stage when fast decaying corrections are important. To solve the velocity field (and the related shear rate and shear stress fields) more accurately, Eqs. (11)–(14) are to be used.

Several insights are gained from the present theoretical analysis regarding the transient time to reach steady flow:

1. The transient time increases with flow thickness as  $\sim h^{3/2}$ . This is a weaker dependence compared to  $\sim h^2$  found for Couette flow in a simple shear cell [12].
2. The transient time depends inversely on  $\beta$ . This implies that the less shear strengthening the flow is (*i.e.* smaller  $\beta$ ), the longer it takes the flow to reach steady state. For slopes exceeding  $\theta_r$  the flow will never reach steady-state if stress is independent of shear rate (*i.e.* if  $\beta = 0$ ).

3. It is possible to assess the transient times in natural systems, *e.g.* landslides: assuming  $\theta = 35^\circ$ ,  $d = 1$  cm and  $\Phi_s = 0.6$ , the time scales are expected to be of the order of  $T_1 = 0.7$  s, 23 s, 720 s for flowing layers of thickness of  $h = 0.1$  m, 1 m, 10 m respectively. For this calculation we used  $\beta = 0.6$  from granular experiments with glass beads [1]. Clearly, the transient time is sensitive to the thickness of the flow. For the 10 m thick flow the transient time is several minutes, which exceeds duration of flows on natural slopes. It is thus predicted that thick landslides do not reach steady flow.
4. Acceleration and deceleration are not symmetrical, acceleration to steady flow takes longer than it takes to stop the same flow. In addition, the geometry of acceleration and deceleration is not symmetrical: while flow accelerates eventually through the depth of the layer, stopping occurs from the bottom upwards, so that flow becomes confined to an increasingly thinning layer near the top, while the bottom grains have already stopped.

These results will hopefully prove useful for understanding and predicting natural and industrial flows.

## 6 Acknowledgements

We acknowledge fruitful discussions with D. Ertas and L. Goren. The research leading to these results has received funding from the People Programme (Marie Curie Actions) of the European Union's Seventh Framework Programme FP7/2007-2013/ under REA grant agreement No. 316889.

## APPENDIX: ORTHOGONALITY RELATIONS

Here we show that the functions

$$q_n(y) = J_{2/3} \left( \kappa_n \left( \frac{y}{h} \right)^{3/4} \right), \quad n = 1, \dots, \infty \quad (\text{A1})$$

form an orthogonal system relative to the scalar product  $(a, b) = \int_0^h ab\sqrt{y} dy$ . This, in turn, allows us to derive Eq. (14).

The functions  $q_n$  are solutions of Eq. (8)

$$\frac{d^2 (\sqrt{y} q_n)}{dy^2} = -\frac{9\kappa_n^2}{16h^{3/2}} q_n, \quad (\text{A2})$$

which satisfy the following boundary conditions, corresponding to the boundary conditions (7a) and (7b),

$$\begin{aligned}\lim_{y \rightarrow 0} \sqrt{y} q_n(y) &= 0, \\ \frac{d(\sqrt{y} q_n)}{dy}(h) &= 0.\end{aligned}\tag{A3}$$

In the following we evaluate the integral  $\int_0^h \frac{d^2(\sqrt{y} q_i)}{dy^2} q_j \sqrt{y} dy$  in two ways. First, we use Eq. (A2)

$$\int_0^h \frac{d^2(\sqrt{y} q_i)}{dy^2} q_j \sqrt{y} dy = -\frac{9\kappa_i^2}{16h^{3/2}} \int_0^h q_i q_j \sqrt{y} dy.\tag{A4}$$

Second, we apply a double integration by parts

$$\int_0^h \frac{d^2(\sqrt{y} q_i)}{dy^2} q_j \sqrt{y} dy = \int_0^h \sqrt{y} q_i \frac{d^2(\sqrt{y} q_j)}{dy^2} dy = -\frac{9\kappa_j^2}{16h^{3/2}} \int_0^h q_i q_j \sqrt{y} dy,\tag{A5}$$

where the surface terms vanish because of the boundary conditions Eq. (A3).

Since  $\kappa_i \neq \kappa_j$  for  $i \neq j$ , comparison of Eqs. (A4) and (A5) implies the orthogonality of the functions  $q_n$

$$\int_0^h q_i q_j \sqrt{y} dy = \delta_{ij} \int_0^h q_j^2 \sqrt{y} dy,\tag{A6}$$

where  $\delta_{ij}$  is the Kronecker delta.

## Initial condition for shear rate

The solution for shear rate  $\dot{\gamma}$ , Eq. (9), is a linear combination of  $q_n$  functions with weights  $b_n$  that need to be determined from the initial condition

$$\dot{\gamma}(y, t = 0) = -\frac{dv^0}{dy},\tag{A7}$$

corresponding to Eq. (7c).

Multiplying Eq. (9) for  $t = 0$  by  $b_i \sqrt{y}$  and integrating over the range of  $y \in (0, h)$  leads after some rearrangements to

$$b_i = \begin{cases} -\frac{\int_0^h (\sqrt{y} dv^0/dy + b^* y) q_i dy}{\sqrt{h} \int_0^h q_i^2 \sqrt{y} dy} & \theta > \theta_r, & \text{(A8a)} \\ -\frac{\int_0^h \sqrt{y} dv^0/dy q_i dy}{\sqrt{h} \int_0^h q_i^2 \sqrt{y} dy} & \theta < \theta_r. & \text{(A8b)} \end{cases}$$

where the sum was reduced to a single term thanks to Eq. (A6). The last equation is identical to Eq. (14).

**Table 1.** Parameters  $\kappa_n$ ,  $T_n$  and  $b_n$  used in the expansions in Eqs. (9) and (11).  $b_n^a$  and  $b_n^d$  given here correspond to the initial velocity  $v^0 = 0$  (for a flow accelerating from the rest) and  $v^0 = 2b^*(h^{3/2} - y^{3/2})/3$  (for a flow decelerating from steady state) respectively. While the absolute values of  $T_n$  and  $b_n$  depend on the system dimensions, material properties and inclination angle, their relative values given below are universal.

$n$	$\kappa_n$	$T_n/T_1$	$b_n^a/b^*$	$b_n^d/b^*$
1	1.87	1	-1.30	1.30
2	4.99	0.14	0.30	-0.30
3	8.12	0.053	-0.14	0.14

**Figure 1.** (color online). Geometry of the studied system depicted on a snapshot from a DEM simulation. An infinite granular layer accelerates down a slope inclined at an angle  $\theta$ . The red envelope for the velocity vectors  $v(y, t)$  denotes the velocity profile predicted by Eq. (11). The shades of the grains indicate contact stress: the dark grains are most stressed.

**Figure 2.** Solid fraction profiles recorded in a simulation of a  $h = 96 d = 9.6$  m thick flow accelerating on a  $\theta = 17^\circ$  slope and decelerating on a flat plane thereafter. The profiles were taken at times when the system starts flowing (—), in the middle of the acceleration stage ( $\cdots$ ), on reaching the steady flow (— — —) and in the middle of the deceleration stage ( $-\cdots-$ ). The shown 2D solid fraction of 0.80 can be mapped to 3D solid fraction of 0.54 [23].

**Figure 3.** (a) Depth averaged shear and normal stresses evolution observed in DEM simulation of the flow with  $h = 96d = 9.6$  m and  $\theta = 17^\circ$ . The normal stress is multiplied by the steady state friction coefficient  $\tan 17^\circ = 0.31$  to match the steady state shear stress value. (b) Friction coefficient  $\tau/N$  as a function of inertial number  $I$  for the same system. Points are simulation data at a series of time instants during the acceleration. The course of time is indicated by the arrow. The solid line is a fit to Eq. (4), resulting in  $\tan \theta_r = 0.26 \pm 0.01$  and  $\beta = 1.35 \pm 0.08$ , where the uncertainty of the fit was calculated based on the deviation among values for different  $y$ .

**Figure 4.** (color online). Velocity profiles at various time instants during (a) acceleration down a slope of  $\theta = 17^\circ$  and (b) deceleration on a flat plane  $\theta = 0^\circ$ . The times, at which profiles were recorded, increase with the line thickness (from left to right in (a) and from right to left in (b)). The solid lines are simulation results while the dashed lines are analytical predictions of Eq. (11) for the granular flow with  $h = 96d = 9.6$  m and the angle of repose  $\theta_r = 14^\circ$ . In the case of the accelerating flow (a), the time  $T_1$  characterizes the time required to reach the steady flow. The error bars indicate uncertainties of velocity profiles associated with different initial configurations.

**Figure 5.** (color online). Velocity evolution during (a) acceleration down a slope of  $\theta = 17^\circ$  and (b) deceleration on a flat plane  $\theta = 0^\circ$ . Each line is velocity at a depth  $y = 0.3$  m – 9.3 m, where the depth increases from the upper line towards the lower line, inside the  $h = 96d = 9.6$  m thick flow. The solid lines are simulation results while the dashed lines are analytical predictions of Eq. (11). Note that deceleration (b) is not the reversed evolution of acceleration (a). The error bars indicate uncertainties of velocity associated with different initial configurations.

**Figure 6.** Scaling of  $T_1$ , the characteristic acceleration time scale, with flow thickness  $h$ , average grain size  $d$  and inclination angle  $\theta$ . Points are simulation results for systems with  $h = 12 - 96 d$ ,  $d = 0.1$  m,  $\theta = 17^\circ$  (squares);  $h = 48, 70$  or  $96 d$ ,  $d = 0.1 - 1$  m,  $\theta = 17^\circ$  (circles);  $h = 48 d$ ,  $d = 0.1$  or  $1$  m,  $\theta = 18 - 25^\circ$  (triangles). The solid line is the analytical prediction, Eq. (13).
