ABSTRACT: Motivated by a class of flux compactifications of type IIA strings on rigid Calabi-Yau manifolds, preserving $N = 2$ local supersymmetry in four dimensions, we derive a non-perturbative potential of all scalar fields from the exact D-instanton corrected metric on the hypermultiplet moduli space. Applying this potential to moduli stabilization, we find a discrete set of exact vacua for axions. At these critical points, the stability problem is decoupled into two subspaces spanned by the axions and the other fields (dilaton and Kähler moduli), respectively. Whereas the stability of the axions is easily achieved, numerical analysis shows instabilities in the second subspace.

1 Introduction

One of the outstanding issues in string theory is the problem of finding realistic string compactifications and connecting them to cosmological observations. It requires several steps such as (i) choosing an appropriate setup for moduli stabilization, (ii) obtaining a meta-stable vacuum with a positive cosmological constant, and (iii) producing an inflationary model. Each of these steps is highly non-trivial and has its own obstructions. Despite

of many years of research and the extensive literature on the subject, meta-stable de Sitter (dS) vacua still appear to be very difficult to get in string theory. There are no robust predictions about inflation, and no nice inflationary model from string theory was found yet. And both, dS vacua and inflation, are usually obtained in string theory at the price of adding effects which can spoil moduli stabilization (see [1] for a recent review).

Furthermore, most of the scenarios in string theory cannot be considered as those derived from the first principles, because of at least one of the following reasons:

- the lack of precise knowledge about quantum corrections,
- splitting the procedure of moduli stabilization into several steps which may result in ignorance of tachyonic directions spoiling meta-stability,
- the necessity to introduce additional uplifting mechanisms,
- disregarding back reaction effects.

The first of these issues is particularly important. While it is possible to stabilize all moduli at the classical level [2], several no-go theorems forbid dS vacua in such simplest supergravity compactifications [3, 4]. To avoid them, it is necessary to include either quantum corrections, both perturbative and non-perturbative, or non-geometric fluxes (see, for instance, [5–13]).

The significance of explicit examples of truly “quantum” calculations in string theory goes well beyond the problem of the cosmological constant. It is just about the string theory based computations of quantum gravity corrections that are usually put “out of brackets” in modern phenomenologically based theoretical cosmology. Taking into account non-perturbative corrections is necessary to stabilise all moduli, provide resolution of unphysical singularities in moduli spaces, and ensure string dualities. The very possibility of explicit (or exact) non-perturbative calculations is highly non-trivial in string theory, and the known examples are very rare.

One example, where such calculations have become possible, is the case of type II string compactifications on Calabi-Yau (CY) threefolds. In this case the low energy effective action (LEEA) in four dimensions preserves $N = 2$ local supersymmetry (8 supercharges) and is completely determined by the geometry of its moduli space spanned by the scalar fields of $N = 2$ vector and hypermultiplets. While the vector multiplet moduli space was described in full detail using mirror symmetry long ago (see, e.g., [14] for a review), understanding of the quantum corrected hypermultiplet moduli space was very limited until recently. The advance of twistorial techniques drastically changed the situation and allowed us to get an *exact* description of the most of quantum effects — at present, amongst all quantum corrections, only the so-called NS5-brane instantons remain out of control (see [15, 16] and references therein).

Thus, it is natural to apply these exact results in a more general context of moduli stabilization. Of course, this requires extending them beyond the class of compactifications where they were initially derived. In particular, the phenomenologically interesting compactifications include fluxes, localized sources such as D-branes and orientifold planes, and

preserve only $N = 1$ local supersymmetry (4 supercharges) in four dimensions. However, at present, quantum corrections are beyond control in such cases.

On the other hand, it is possible to generate a non-trivial scalar potential for moduli stabilization in a unique way already in $N = 2$ supergravity. This can be achieved by adding NS- and RR-fluxes leading to the gauging of some of the isometries of the moduli space of the original fluxless compactification. In fact, the integrated Bianchi identities give rise to certain tadpole cancellation conditions, which in the presence of fluxes generically can be satisfied only by adding orientifolds reducing supersymmetry to $N = 1$ [17]. However, in type IIA string theory it is possible to choose such fluxes that the tadpole cancellation condition holds automatically.

This motivates us to consider $N = 2$ gauge supergravity, which results from the type IIA CY compactifications with the NS H -fluxes and the RR F_4 - and F_6 -fluxes provided one ignores their back reaction. Such setup was already studied in [18]. We go beyond the earlier studies, and compute the quantum corrected scalar potential in the gauged supergravity including the non-perturbative terms, which come from the instanton corrections to the geometry of the moduli space known exactly in the absence of fluxes. The idea beyond this computation is that the preserved $N = 2$ supersymmetry protects the quantum corrections so that the exact non-perturbative potential, where the back reaction effects are taken into account, should not differ too much from the one obtained here.

In this paper we restrict ourselves to the case of a *rigid* CY threefold \mathfrak{Y} . Such manifold has the vanishing Hodge number $h^{2,1}(\mathfrak{Y}) = 0$, so that the LEAA is described by $N = 2$ supergravity interacting with a single hypermultiplet, called the *universal hypermultiplet* (UH), and some number $h^{1,1}(\mathfrak{Y}) > 0$ of vector multiplets. This leads to various simplifications, such as the absence of complex structure moduli, which allow to make our analysis very explicit. Actually, one of our original motivations was to find a setup for flux compactifications which takes into account quantum corrections and, at the same time, can be treated as explicitly as possible.

It should be mentioned that several attempts to take into account instanton corrections in compactifications on rigid CY already appeared in the literature, most notably, in [19]. However, the analysis of [19] did not include contributions of vector multiplets and, as it turned out later, was based on a misleading ansatz for D-instantons. In contrast, we consider here the full scalar potential including all moduli. Moreover, we do not assume that there exists a hierarchy allowing us to perform moduli stabilization in a step-by-step procedure, but analyze all equations on critical points on the same footing.

One of our results is a simple condition on the flux parameters (see (3.1)) which allows us to find a set of *exact* solutions to the quantum corrected equations for all axion fields, i.e. the periods of the B -field and the RR 3-form potential along 2 and 3-cycles of \mathfrak{Y} , respectively. The role of the worldsheet and D-instanton corrections for the existence of these solutions is pivotal.

Unfortunately, the equations we get on the remaining scalars, namely, dilaton and Kähler moduli, are too complicated to be treated in full generality. Therefore, in the beginning we restrict our attention to the perturbative approximation where all instanton contributions are neglected, but perturbative α' and g_s -corrections, controlled by the Euler

characteristic of \mathfrak{M} , are retained. We obtain bounds on the values of the dilaton and the CY volume, which admit the existence of critical points. In particular, we find that this class of compactifications does not allow critical points with both large volume and small string coupling, i.e. in the only region where all quantum corrections can be neglected. This can be contrasted with the result of [2] that a more general choice of fluxes provides the moduli stabilization at classical level, but this choice must be supplemented by an orientifold projection to satisfy the tadpole cancellation condition mentioned above and leads to AdS vacua.

To further analyze the critical points, we first restrict ourselves to the case with one Kähler modulus, i.e. to a CY with $h^{1,1} = 1$. Since up to now no CY was found with such Hodge numbers, this case should only be viewed as a model convenient to test the moduli stabilization, but not having a string theory realization. In this special case we find two critical points, which both lead to a positive potential, but both turn out to be unstable. Then we turn to the general case, where we directly address the problem of stability of critical points, without trying to find them explicitly. To this end, we analyse the matrix of the second derivatives and show that it cannot be positive definite, which means that there are no meta-stable vacua. Thus, in the perturbative approximation, these simple models cannot provide stabilization of all moduli.

Finally, we attempt to take into account the contributions of worldsheet and D-instantons in the simplest case of $h^{1,1} = 1$. As before, we perform a numerical analysis of the second derivative matrix, which shows us again that in the physical region the matrix is never positive definite on mass shell. This result appears to be extremely non-trivial, given a very complicated analytical form of the second derivatives. The effect of instantons on the perturbative analysis for $h^{1,1} > 1$ will be investigated elsewhere.

The paper is organized as follows. In the next section we review some basic information about CY string compactifications, their moduli spaces, the effect of fluxes, and provide a formula for the scalar potential induced by the gauging in $N = 2$ supergravity. We also compute this potential explicitly, including perturbative and non-perturbative quantum corrections, in the gauged supergravity inspired by the class of compactifications we concentrate on. In section 3 we discuss equations on critical points and find a solution for all axion fields. In section 4 we study the perturbative approximation. First, we derive general bounds on critical points, then analyze in detail the case with one Kähler modulus, and finally perform a stability analysis in a generic case with arbitrary number of moduli. In section 5 we present the results of our numerical analysis of the one-modulus case in the presence of instantons. Section 6 is devoted to a discussion of our results. Several appendices contain details about special and quaternionic geometries, the metrics on $N = 2$ vector and hypermultiplet moduli spaces, and our stability analysis of critical points.

2 Scalar potential from gauging

2.1 $N = 2$ gauged supergravity and its scalar potential

The four-dimensional LEEA of type II strings compactified on a Calabi-Yau threefold \mathfrak{M} is given by $N = 2$ supergravity coupled to $N = 2$ vector and hypermultiplets. In the

two-derivative approximation, where one ignores the higher curvature terms appearing as α' -corrections, the bosonic part of the action comprises only kinetic terms for the metric, vector and scalar fields arising after compactification. The couplings of these kinetic terms are, however, non-trivial, being restricted by $N = 2$ supersymmetry in terms of the metrics on the vector and hypermultiplet moduli spaces, \mathcal{M}_V and \mathcal{M}_H , parametrized by the scalars of the corresponding multiplets. Furthermore, $N = 2$ supersymmetry restricts \mathcal{M}_V to be a special Kähler manifold, with a Kähler potential $\mathcal{K}(z^i, \bar{z}^{\bar{i}})$ (with $i = 1, \dots, h^{1,1}$ in type IIA) determined by a holomorphic prepotential $F(X^I)$ (with $I = (0, i) = 0, \dots, h^{1,1}$ and $z^i = X^i/X^0$), a homogeneous function of degree 2. Similarly, \mathcal{M}_H must be a quaternion-Kähler (QK) manifold of dimension $4(h^{2,1} + 1)$ [20]. We denote the metrics on the two moduli spaces by $\mathcal{K}_{i\bar{j}}$ and g_{uv} , respectively.

The resulting theory is, however, not appropriate from the phenomenological point of view since it does not have a scalar potential, so that all moduli remain unspecified. This gives rise to the problem of *moduli stabilization*, i.e. generating a potential for the moduli with a local minimum and no flat directions. Local $N = 2$ supersymmetry does allow a non-trivial scalar potential, but this requires to consider $N = 2$ *gauged* supergravity. The latter can be constructed from the usual ungauged supergravity when the moduli space $\mathcal{M}_V \times \mathcal{M}_H$ has some isometries, which are to be gauged with respect to the vector fields A^I comprising, besides those of vector multiplets, the gravi-photon A^0 of the gravitational multiplet. Physically, this means that the scalar fields affected by the isometries acquire charges under the vector fields used in the gauging. The charges are proportional to the components of the Killing vectors k_α corresponding to the gauged isometries. In general, the gauge group must be a subgroup of the isometry group, but in this paper we deal only with abelian gaugings of isometries of the hypermultiplet moduli space \mathcal{M}_H . Then the charges are characterized by the vectors $\mathbf{k}_I = \Theta_I^\alpha k_\alpha \in T\mathcal{M}_H$ where Θ_I^α is known as the *embedding tensor*.

It is remarkable that in $N = 2$ gauged supergravity the geometry of the moduli space together with the charge vectors *completely* fix the scalar potential. Explicitly, it is given by [21–23]¹

$$V = 4e^{\mathcal{K}} \mathbf{k}_I^u \mathbf{k}_J^v g_{uv} X^I \bar{X}^J + e^{\mathcal{K}} (\mathcal{K}^{i\bar{j}} D_i X^I D_{\bar{j}} \bar{X}^J - 3X^I \bar{X}^J) (\vec{\mu}_I \cdot \vec{\mu}_J), \quad (2.1)$$

where $D_i X^I = (\partial_i + \partial_i \mathcal{K}) X^I$ and $\vec{\mu}_I$ is the triplet of moment maps which quaternionic geometry of \mathcal{M}_H assigns to each isometry \mathbf{k}_I [24]. This result gives us an opportunity to search for the potentials ensuring moduli stabilization, using the geometric data from the ungauged theory as an input. In particular, here we employ the exact results about the non-perturbative description of \mathcal{M}_V and \mathcal{M}_H in type II CY compactifications, described below in subsection 2.3, to infer the impact of quantum corrections on the potential (2.1) and stabilization of moduli.

¹Our conventions and normalizations are explained in appendix A. Note that the potential appears in the literature in the two possible forms, which are both given in (A.13) and are simply related by eq. (A.8b). In the presence of non-abelian gaugings the potential acquires additional terms which we, however, omit.

2.2 Flux compactifications

In string theory, $N = 2$ gauge supergravity can be obtained by adding closed string fluxes to a CY compactification (see [25] for a review). In fact, fluxes back react on the background geometry so that the simple direct product $M_4 \times \mathfrak{Y}$ is not a solution of the (classical) equations of motion anymore. To get a solution, one has to add a warp factor and to consider internal manifolds with torsion [26–28]. Although such backgrounds are nicely described in the framework of generalized geometry [29], the corresponding effective actions are poorly understood. Due to this reason, we accept the common strategy (see, for instance, [2, 18, 30, 31]) and ignore the back reaction, assuming that the compactification manifold is still a Calabi-Yau.²

The LEEA for flux compactifications on CY was found in [30], and was shown to perfectly fit the framework of $N = 2$ gauged supergravity.³ In particular, given the LEEA, one can read off the embedding tensor Θ_I^α providing a map between the fluxes and the gauged isometries. Let us briefly review these results.

First, we recall the field content of the moduli spaces. In type IIA, the vector multiplet moduli space \mathcal{M}_V describes the complexified Kähler moduli of \mathfrak{Y} parametrizing deformations of the Kähler structure and the periods of the B -field along two-dimensional cycles, $z^i = b^i + it^i$. The hypermultiplet moduli space \mathcal{M}_H consists of

- u^a — complex structure moduli of \mathfrak{Y} ($a = 1, \dots, h^{2,1}$),
- $\zeta^\Lambda, \tilde{\zeta}_\Lambda$ — RR-scalars given by periods of the RR 3-form potential along three-dimensional cycles of \mathfrak{Y} ($\Lambda = (0, a) = 0, \dots, h^{2,1}$),
- σ — NS-axion, dual to the 2-form B -field in four dimensions,
- ϕ — dilaton, determining the value of the four-dimensional string coupling, $g_s^{-2} = e^\phi \equiv r$.

The Kaluza-Klein reduction from ten dimensions, performed in [30], leads to the classical metrics on \mathcal{M}_V and \mathcal{M}_H . The former is the special Kähler metric $\mathcal{K}_{i\bar{j}}$ given by the derivatives of the Kähler potential

$$\mathcal{K} = -\log \left[i \left(\bar{X}^I F_I^{\text{cl}} - X^I \bar{F}_I^{\text{cl}} \right) \right], \tag{2.2}$$

where $F_I^{\text{cl}} = \partial_{X^I} F^{\text{cl}}$ are the derivatives of the classical holomorphic prepotential

$$F^{\text{cl}}(X) = -\kappa_{ijk} \frac{X^i X^j X^k}{6X^0}, \tag{2.3}$$

²It should be mentioned that in the type IIA theory under consideration in this paper, it is the less justified assumption than in type IIB. In the latter case, some choices of fluxes allow the vacua where the internal manifold is a *conformal* Calabi-Yau space, which is not too much different from the usual Calabi-Yau manifolds. In contrast, in the type IIA case the equations of motion require the compactification manifold to be either non-Kähler, or even non-complex.

³More precisely, in the presence of the so-called magnetic fluxes, it should be generalized to incorporate massive tensors. In the absence of fluxes, these tensor fields are massless and can be dualized to the scalars contributing to the hypermultiplet moduli space. After receiving a mass, they are rather dual to massive vector fields.

which is determined by the triple intersection numbers κ_{ijk} of \mathfrak{Y} . The hypermultiplet metric is given by the so-called *c-map* [32] which produces a QK metric out of another holomorphic prepotential characterizing the complex structure moduli. We omit its explicit expression, but mention the crucial fact that it carries a Heisenberg group of continuous isometries acting by shifts on the RR-scalars and the NS-axion. The corresponding Killing vectors are

$$k^\Lambda = \partial_{\tilde{\zeta}_\Lambda} - \zeta^\Lambda \partial_\sigma, \quad \tilde{k}_\Lambda = \partial_{\zeta_\Lambda} + \tilde{\zeta}_\Lambda \partial_\sigma, \quad k_\sigma = 2\partial_\sigma. \quad (2.4)$$

It is these isometries that are gauged by adding fluxes.

In general, type IIA strings on CY admit NS-fluxes incorporated by the following field strength of the *B*-field:

$$H_3^{\text{flux}} = h^\Lambda \tilde{\alpha}_\Lambda - \tilde{h}_\Lambda \alpha^\Lambda, \quad (2.5)$$

where $(\alpha^\Lambda, \tilde{\alpha}_\Lambda)$ is a symplectic basis of harmonic 3-forms, and RR-fluxes given by the 2- and 4-form field strengths

$$F_2^{\text{flux}} = -m^i \tilde{\omega}_i, \quad F_4^{\text{flux}} = e_i \omega^i, \quad (2.6)$$

where $\tilde{\omega}_i$ and ω^i are bases of $H^2(\mathfrak{Y})$ and $H^4(\mathfrak{Y})$, respectively. Besides, there are two additional parameters, m^0 and e_0 . The first one is Romans mass which gives a consistent deformation of ten-dimensional type IIA supergravity [33], and the second one is a constant arising after dualization of the 3-form RR potential [30]. They can be viewed as the fluxes F_0^{flux} and F_6^{flux} , and also lead to a gauging in the effective action.

Although the effective action was found in [30] in the presence of all these flux parameters, we set the “magnetic” fluxes m^I to zero in what follows. The reason is twofold. First, this allows to avoid complications with the simultaneous appearance of electric and magnetic charges of the NS-axion as well as massive vector fields (see footnote 3). Second, the vanishing of Romans mass m^0 allows to avoid adding orientifold planes, otherwise, needed to satisfy the D6-brane tadpole cancellation condition [18]. This also allows us to keep $N = 2$ supersymmetry unbroken, which partially justifies our use of the results obtained for fluxless CY compactifications.

With this restriction, the gauging induced by the fluxes is characterized by the following charges [30]:

$$\mathbf{k}_0 = h^\Lambda \tilde{k}_\Lambda + \tilde{h}_\Lambda k^\Lambda + e_0 k_\sigma, \quad \mathbf{k}_i = e_i k_\sigma, \quad (2.7)$$

written down here as linear combinations of the Killing vectors (2.4).

2.3 Quantum corrections

The scalar potential obtained in [30] was found by the Kaluza-Klein reduction and, therefore, resulted from gauging of the isometries of the *classical* moduli space. However, both \mathcal{M}_V and \mathcal{M}_H are known to receive *quantum* corrections. Unfortunately, one has a very limited understanding of the impact of fluxes on these corrections. On the other hand, for fluxless CY compactifications the situation is much better, as we now describe.

We have full control over the metric on \mathcal{M}_V : it receives the α' -corrections which are all captured by a modification of the holomorphic prepotential (2.3) [34, 35]

$$F(X) = F^{\text{cl}}(X) + \chi_{\mathfrak{Y}} \frac{i\zeta(3)(X^0)^2}{16\pi^3} - \frac{i(X^0)^2}{8\pi^3} \sum_{k_i \gamma^i \in H_2^+(\mathfrak{Y})} n_k^{(0)} \text{Li}_3 \left(e^{2\pi i k_i X^i / X^0} \right), \quad (2.8)$$

where $\chi_{\mathfrak{Y}} = 2(h^{1,1} - h^{2,1})$ is Euler characteristic of CY, $n_k^{(0)}$ are the genus-zero Gopakumar-Vafa invariants, and the sum goes over the effective homology classes, i.e. $k_i \geq 0$ for all i , with not all of them vanishing simultaneously. The two additional terms correspond to a perturbative correction and a contribution of worldsheet instantons, respectively.

As regards \mathcal{M}_H , though its complete non-perturbative description is still beyond reach, a significant progress in this direction was recently achieved by using twistorial methods (see [15, 16] for reviews). In contrast to \mathcal{M}_V , the hypermultiplet metric is exact in α' , but receives g_s -corrections. At the perturbative level, it is known explicitly [36] and is given by a one-parameter deformation of the classical c-map metric, whose deformation parameter is controlled by $\chi_{\mathfrak{Y}}$ [37–39]. At the non-perturbative level, the metric gets the instanton contributions coming from D2-branes wrapping 3-cycles (and, hence, parametrized by a charge $\gamma = (p^\Lambda, q_\Lambda)$) and NS5-branes wrapping the whole CY. The D-instantons were incorporated to all orders using the twistor description of QK manifolds [40–43], so that only NS5-instanton contributions still remain unknown (see, however, [44–46] for a recent progress on the type IIB side). Though the twistor description is rather implicit via encoding the metric into the holomorphic data on the twistor space of \mathcal{M}_H , in the case when only the D-instantons with “mutually local charges” $\langle \gamma, \gamma' \rangle = 0$,⁴ are taken into account, the metric was explicitly computed in [47].

Thus, it is natural to use these exact results for analyzing the scalar potential (2.1). Of course, it would be naive to expect that they are not going to be affected by fluxes and, eventually, their back reaction via torsion, and it is an open question whether in such situation one can trust the quantum corrections computed before the fluxes were switched on. However, the presence of $N = 2$ supersymmetry allows us to think that the back reaction effects should not be too strong. Indeed, most of the results mentioned above were obtained by using only requirements of supersymmetry and a few discrete symmetries expected to survive at the non-perturbative level. Besides, this expectation is supported by the recent results about perturbative α' and g_s -corrections for compactifications on manifolds with the $SU(3)$ structure [48]. In the worst case, if our expectation does turn out to be wrong, the gauged supergravity obtained in this approximation and studied in this paper should only be considered as inspired by string theory.

It should be noticed that instanton corrections break the continuous isometries of the classical hypermultiplet moduli space: a D-instanton of charge γ comes with a factor $e^{2\pi i(p^\Lambda \tilde{\zeta}_\Lambda - q_\Lambda \zeta^\Lambda)}$ and, therefore, breaks a linear combination of k^Λ and \tilde{k}_Λ , whereas NS-brane instantons break all isometries of (2.4). This raises the question, how such instantons can be consistent with the gauging induced by fluxes, since the latter can be only performed in

⁴We use the skew symmetric product defined by $\langle \gamma, \gamma' \rangle = q_\Lambda p'^\Lambda - q'_\Lambda p^\Lambda$. The mutual locality is equivalent to the condition that there is a symplectic frame where all charges are purely electric, i.e. $p^\Lambda = 0$.

the presence of continuous isometries? This problem was solved in [49] where it was shown that fluxes protect from the instanton corrections precisely those isometries that are to be gauged. Applying this result to type IIA string theory on CY with H_3 , F_4 and F_6 fluxes, one concludes from (2.7) that it excludes NS5-instantons and allows only D-instantons with charges satisfying $h^\Lambda q_\Lambda - \tilde{h}_\Lambda p^\Lambda = 0$.

2.4 Scalar potential from fluxes on rigid CY

In this paper we restrict our attention to the flux compactifications on a *rigid* Calabi-Yau manifold, i.e. when \mathfrak{Y} has vanishing $h^{2,1}$ and thus does not have complex structure deformations. As a result, the capital Greek indices Λ, Σ, \dots take only one value and, therefore, can be safely dropped.

In the case of rigid CY, \mathcal{M}_H has the lowest possible dimension and thus this case represents a nice laboratory to study quantum corrections, gaugings, fluxes, etc. (see, for instance, [18, 38, 50–55]). Moreover, the metric on four-dimensional QK spaces allows an explicit parametrization [56, 57], which reduces it to a solution of an integrable system. In particular, in the presence of one continuous isometry, it is encoded in a solution of the integrable *Toda* equation. This fact was extensively used in several studies of instantons and their impact on moduli stabilization [19, 58–62].

Here we use the explicit results of [47] providing the *exact* metric on \mathcal{M}_H corrected by D-instantons with mutually local charges, which was shown to be consistent with the description based on the Toda equation. As explained in the end of the previous subsection, the H -fluxes protect one linear combination of the isometries k and \tilde{k} . Since in the rigid case the D-instanton charge is a two-dimensional vector, $\gamma = (p, q)$, the charges of the allowed D-instantons are necessarily mutually local. Thus, the metric computed in [47] contains *all* instantons allowed by the fluxes.

Explicitly, this metric is given by

$$ds^2 = \frac{2}{r^2} \left[\left(1 - \frac{2r}{\mathcal{R}^2 \mathbf{U}} \right) \left((dr)^2 + \frac{\mathcal{R}^2}{4} |\mathcal{Y}|^2 \right) + \frac{1}{64} \left(1 - \frac{2r}{\mathcal{R}^2 \mathbf{U}} \right)^{-1} \left(d\sigma + \tilde{\zeta} d\zeta - \zeta d\tilde{\zeta} + \mathcal{V}_{(\sigma)} \right)^2 \right], \tag{2.9}$$

where all notations, such as \mathcal{R} , \mathbf{U} , \mathcal{Y} , $\mathcal{V}_{(\sigma)}$, are explained in appendix C.1. The charge vectors (2.7) corresponding to our choice of fluxes are given by

$$\begin{aligned} \mathbf{k}_0 &= \tilde{h} \partial_{\tilde{\zeta}} + h \partial_{\zeta} + \left(2e_0 + h\tilde{\zeta} - \tilde{h}\zeta \right) \partial_{\sigma}, \\ \mathbf{k}_i &= 2e_i \partial_{\sigma}. \end{aligned} \tag{2.10}$$

They generate isometries of the metric (2.9) provided that the D-instanton charges are restricted to satisfy $hq = \tilde{h}p$. The associated moment maps $\vec{\mu}_I$ are computed in appendix C.2 with the following result:

$$\begin{aligned} \mu_i^+ &= 0, & \mu_i^3 &= \frac{e_i}{2r}, \\ \mu_0^+ &= \frac{i\mathcal{R}}{2r} \left(\tilde{h} - \lambda h \right), & \mu_0^3 &= \frac{1}{2r} \left(e_0 + h\tilde{\zeta} - \tilde{h}\zeta \right). \end{aligned} \tag{2.11}$$

Thus, the only effect of instantons on the moment maps is contained in the function \mathcal{R} determined by the equation (C.12).

Now we use all these data to compute the scalar potential (2.1). A simple calculation gives

$$V = \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{2|E+\mathcal{E}|^2}{1-\frac{2r}{\mathcal{R}^2\mathbf{U}}} + \mathcal{K}^{i\bar{j}} (e_i + E\mathcal{K}_i)(e_j + \bar{E}\mathcal{K}_{\bar{j}}) - 3|E|^2 + 4\mathcal{R}^2|\tilde{h} - \lambda h|^2 \left(\mathcal{K}^{i\bar{j}}\mathcal{K}_i\mathcal{K}_{\bar{j}} - 1 - \frac{4r}{\mathcal{R}^2\mathbf{U}} \right) \right], \quad (2.12)$$

where $\mathcal{K}_i = \partial_i\mathcal{K}$ and we have denoted

$$\begin{aligned} E &= e_0 + h\tilde{\zeta} - \tilde{h}\zeta + e_i z^i, \\ \mathcal{E} &= \frac{1}{2} \left(h\nu_{\partial_\zeta} + \tilde{h}\nu_{\partial_{\tilde{\zeta}}} \right) \mathcal{V}_{(\sigma)}. \end{aligned} \quad (2.13)$$

Note that both the metric and the potential are invariant under the symplectic transformations induced by a change of basis of 3-cycles on \mathfrak{Y} . This invariance can be used to put h -flux to zero, which we assume from now on. In this symplectic frame, only electrically charged instantons contribute to the potential. Using this simplification, one can show that

$$\mathcal{E} = \frac{4\tilde{h}r\bar{v}}{\mathcal{R}(|M|^2 + |v|^2)}, \quad (2.14)$$

where the quantities appearing on the r.h.s., initially introduced in appendix C.1, can now be computed explicitly as

$$\begin{aligned} v &= 384c \sum_{q>0} s(q)q^2 \sin(2\pi q\zeta) K_1(4\pi q\mathcal{R}), \\ M &= 2\lambda_2 + 384c \sum_{q>0} s(q)q^2 \cos(2\pi q\zeta) K_0(4\pi q\mathcal{R}), \\ r &= \frac{\lambda_2\mathcal{R}^2}{2} - c - \frac{24c\mathcal{R}}{\pi} \sum_{q>0} s(q)q \cos(2\pi q\zeta) K_1(4\pi q\mathcal{R}), \end{aligned} \quad (2.15)$$

whereas \mathbf{U} , also appearing in the potential (2.12), is still given by (C.9). Here we have introduced the divisor function

$$s(q) \equiv \sigma_{-2}(q) = \sum_{d|n} d^{-2}, \quad (2.16)$$

and, using (C.3) and (C.1), expressed the DT invariants, counting the D-instantons, via the parameter c . As a result, all g_s -corrections affecting the scalar potential are controlled by just one topological number! It is in contrast to the α' -corrections which require knowledge of an infinite set of genus-zero Gopakumar-Vafa invariants.

3 Moduli stabilization

Given the scalar potential (2.12), we can investigate whether it has local minima where all moduli are stabilized. If such minima exist, the sign of the potential evaluated at these points indicates whether they correspond to a de Sitter or an anti-de Sitter vacuum.

At $h = 0$ the potential explicitly depends on dilaton r , Kähler moduli t^i , periods b^i of the B -field, and the RR scalar ζ , and is independent of another RR scalar $\tilde{\zeta}$ and the NS-axion σ . This fact, however, is not a problem for moduli stabilization since these are the scalars which are used for the gauging. In the effective action, one can redefine some of the gauge fields to absorb these scalars. In such frame the scalars are “eaten up” and thus disappear from the spectrum, whereas the corresponding gauge fields become massive.

It is also important to note that in the perturbative approximation the potential depends on the fields b^i and ζ , known as *axions*,⁵ only through the combination $e_i b^i - \tilde{h}\zeta$ appearing in (2.13). Thus, the other $h^{2,1}$ independent combinations of these fields enter the potential only via instanton corrections: b^i and ζ appear in the imaginary part of the worldsheet and the D-instanton actions, respectively. This shows that the instanton corrections are indispensable for stabilization of all moduli.⁶

The instanton corrected potential (2.12) leads to a very complicated system of equations on its extrema. However, if one assumes that the fluxes satisfy the relation

$$e_0 = (n\tilde{h} - \ell^i e_i)/2, \quad n, \ell^i \in \mathbb{Z}, \quad (3.1)$$

there exists a very simple solution for the axions,

$$\zeta = n/2, \quad b^i = \ell^i/2. \quad (3.2)$$

Indeed, using the expressions for the inverse metric $\mathcal{K}^{i\bar{j}}$ (A.5c) and the first derivative of the Kähler potential \mathcal{K}_i (A.4a), the scalar potential can be rewritten as

$$V = \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{2|E+\mathcal{E}|^2}{1-\frac{2r}{\mathcal{R}^2\mathbf{U}}} - 2|E|^2 - e^{-\mathcal{K}} \hat{N}^{ij} e_i e_j + \frac{\left[\text{Re} \left(E + e^{-\mathcal{K}} \hat{N}^{kl} \mathcal{K}_k e_l \right) \right]^2 + 4\tilde{h}^2 \mathcal{R}^2}{e^{-\mathcal{K}} \hat{N}^{ij} \mathcal{K}_i \mathcal{K}_j - 1} - \frac{16\tilde{h}^2 r}{\mathbf{U}} \right], \quad (3.3)$$

where \hat{N}^{ij} is the inverse of $N_{ij} = -2 \text{Im} F_{ij}$. Besides, it is straightforward to verify by using the explicit formulae (2.15) and (B.1) that at the point (3.2) all the following quantities vanish:

$$\text{Re}(E), \quad v, \quad \mathcal{E}, \quad \text{Re} \mathcal{K}_i, \quad \partial_{\zeta} \mathcal{R}, \quad \partial_{\zeta} M, \quad \partial_{\zeta} \mathbf{U}, \quad \partial_{b^i} N_{jk}, \quad \partial_{b^i} \mathcal{K}. \quad (3.4)$$

Taking also into account that $\hat{N}^{j\bar{k}} \mathcal{K}_j \mathcal{K}_{\bar{k}} = \hat{N}^{jk} \text{Re} \mathcal{K}_j \text{Re} \mathcal{K}_k + e^{2\mathcal{K}} N_{ij} t^i t^j$, these results imply that the potential (3.3) satisfies

$$\partial_{\zeta} V \Big|_{\substack{\zeta=n/2 \\ b^i=\ell^i/2}} = 0, \quad \partial_{b^i} V \Big|_{\substack{\zeta=n/2 \\ b^i=\ell^i/2}} = 0. \quad (3.5)$$

Thus, given the fluxes satisfying (3.1), half-integer axions are always a solution of (at least, half of) the equations on critical points.

⁵The axions also include the “eaten up” fields $\tilde{\zeta}$ and σ .

⁶In the given case of rigid CY, this argument does not allow us to conclude that D-instantons are truly necessary, since worldsheet instantons together with the combination $e_i b^i - \tilde{h}\zeta$ lead to a dependence on all axions. However, when $h^{2,1} > 0$, it is still true that only one combination of RR-scalars appears in the perturbative potential [30], so that D-instantons must be taken into account to stabilize all moduli.

Of course, there is no guarantee that sticking to this solution would allow to stabilize the remaining moduli and to get a local minimum, not a saddle point of the potential. Note, however, that the above properties also imply that the mixed second derivatives vanish,

$$\partial_{\varphi^I} \partial_{\psi^J} V \Big|_{\substack{\zeta=n/2 \\ b^i=\ell^i/2}} = 0, \quad (3.6)$$

where we have introduced the collective notation for the axions, $\psi^I = (\zeta, b^i)$, and for the remaining fields, $\varphi^I = (r, t^i)$. This result means that the matrix of the second derivatives has a block-diagonal form,

$$\partial\partial V = \begin{pmatrix} \partial_{\varphi^I} \partial_{\varphi^J} V & 0 \\ 0 & \partial_{\psi^I} \partial_{\psi^J} V \end{pmatrix}, \quad (3.7)$$

so that the condition of having a local minimum gives rise to the two independent conditions on the positive definiteness of $\partial_{\varphi^I} \partial_{\varphi^J} V$ and $\partial_{\psi^I} \partial_{\psi^J} V$. Furthermore, the integers n and ℓ^i control the signs of instanton contributions. One may expect that changing these integers, it may be possible to adjust the signs in such a way that the matrix $\partial_{\psi^I} \partial_{\psi^J} V$ becomes positive definite, thus providing a local minimum in the subspace spanned by the axions, whereas the positive definiteness of $\partial_{\varphi^I} \partial_{\varphi^J} V$ would impose certain restrictions on the critical points in the remaining subspace.

Thus, in the following, we choose to work with the solution (3.2). Having restricted ourselves to this solution, we can significantly simplify the potential. Using the vanishing of (3.4), we find

$$V^{(\varphi)}(r, t^i) \equiv V \Big|_{\substack{\zeta=n/2 \\ b^i=\ell^i/2}} = \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{4r(et)^2}{\mathcal{R}^2 M - 2r} - e^{-\mathcal{K}} \hat{N}^{ij} e_i e_j + \frac{4\tilde{h}^2 \mathcal{R}^2}{e^{\mathcal{K}} N_{ij} t^i t^j - 1} - \frac{16\tilde{h}^2 r}{M} \right]. \quad (3.8)$$

Having fixed the axions, we still have to stabilize the four-dimensional dilaton r and the Kähler moduli t^i . To this end, we need to solve the equations obtained by variation of the potential (3.8) with respect to these moduli. However, we find it more natural to consider the potential as a function of \mathcal{R} rather than of the dilaton r because $\mathcal{R}(r)$ is defined only implicitly: see the last equation in (2.15) where $\cos(2\pi q\zeta)$ should now be replaced by $(-1)^{nq}$. Proceeding this way and using that

$$\partial_{\mathcal{R}} r = \frac{\mathcal{R}}{4} (M + 2\lambda_2), \quad (3.9)$$

we obtain the following equations:

$$\begin{aligned} \partial_{\mathcal{R}} V^{(\varphi)} = & \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{\mathcal{R}}{2r} (M + 2\lambda_2) e^{-\mathcal{K}} \hat{N}^{ij} e_i e_j \right. \\ & - \frac{(et)^2 \mathcal{R}}{(\mathcal{R}^2 M - 2r)^2} (\mathcal{R}^2 M^2 + 2\lambda_2 (\mathcal{R}^2 M - 4r) + 4r (M + \mathcal{R} \partial_{\mathcal{R}} M)) \\ & \left. + \frac{2\tilde{h}^2 \mathcal{R} (4r - \mathcal{R}^2 (M + 2\lambda_2))}{r (e^{\mathcal{K}} N_{ij} t^i t^j - 1)} + \frac{4\tilde{h}^2}{M^2} (\mathcal{R} M (M + 2\lambda_2) + 4r \partial_{\mathcal{R}} M) \right] = 0, \quad (3.10a) \end{aligned}$$

$$\begin{aligned} \partial_{t^i} V^{(\varphi)} = & -\frac{1}{2r^2} \left[4r e^{2\mathcal{K}} \left(\frac{(et)}{\mathcal{R}^2 M - 2r} ((et) N_{ij} t^j - e^{-\mathcal{K}} e_i) - \frac{4\tilde{h}^2}{M} N_{ij} t^j \right) \right. \\ & \left. + \text{Re } F_{ijk} \left(\hat{N}^{jm} e_m \hat{N}^{kn} e_n - \frac{4e^{2\mathcal{K}} \tilde{h}^2 \mathcal{R}^2 t^j t^k}{(e^{\mathcal{K}} N_{ij} t^i t^j - 1)^2} \right) \right] = 0. \quad (3.10b) \end{aligned}$$

Unfortunately, in their full generality, these equations are too complicated for an analytic treatment. Therefore, they should be studied either numerically or perturbatively. For instance, we can first analyze them by neglecting all non-perturbative corrections, and then add the terms with worldsheet and D-brane instantons. In the next section, we perform the first step, and then in section 5 attempt the second step in the special case $h^{1,1} = 1$.

It is important to note that the fields to be stabilized cannot take arbitrary values, being restricted to certain physical domains. These restrictions typically appear due to various approximations used to get the scalar potential, while approaching a boundary of a physical domain corresponds to a failure of one of such approximations. The physical domains are defined by the following conditions:

- The Kähler moduli t^i must belong to the Kähler cone of \mathfrak{M} and be such that the Kähler potential is well defined, which implies that $e^{-\mathcal{K}} > 0$. This quantity is explicitly computed in (B.1d). Typically, its positivity is ensured by the instanton contributions, but in the perturbative approximation with t^i sufficiently small, one can reach a point where the negative perturbative correction becomes dominant over the classical volume term. This indicates the breakdown of the perturbative approximation and puts a bound on the domain of the Kähler moduli.
- Similarly, the Kähler moduli must be such that $\text{Im}\mathcal{N}_{IJ}$, defined in (A.2) and determining the kinetic terms of the gauge fields, and its inverse computed in (A.5b), are negative definite.
- The four-dimensional dilaton $r = e^\phi$, besides being positive, should satisfy an additional bound. In [47] it was shown that the metric (2.9) has a curvature singularity at the hypersurface determined by the equation $r = \frac{1}{2}\mathcal{R}^2\mathbf{U}$. However, the metric on the physical moduli space must be regular. Thus, the curvature singularity is an artefact of an approximation: in the case of fluxless CY compactifications, it is believed that it should be resolved by NS5-brane instantons [63], whereas in our case it should probably disappear after taking into account the back reaction of fluxes. This implies that close to the singularity the metric (2.9) and, hence, the corresponding scalar potential cannot be trusted. In other words, we should require that $r > r_{\text{cr}}$. In the perturbative approximation one has $r_{\text{cr}} = -2c$.

4 Perturbative approximation

After dropping all instanton corrections, the scalar potential (3.8) takes the following form:

$$V^{(\varphi)} \approx \frac{e^{\mathcal{K}}}{8r^2} \left[\frac{16\tilde{h}^2}{\lambda_2} \frac{(1-\gamma)r+2c}{1+\gamma} + \frac{4r(et)^2}{r+2c} - e^{-\mathcal{K}} \kappa^{ij} e_i e_j \right], \quad (4.1)$$

where the sign \approx means that the equation holds in the perturbative approximation, κ^{ij} is the inverse of $\kappa_{ij} \equiv \kappa_{ijk} t^k$, and we have introduced

$$\gamma = 3C e^{\mathcal{K}} = \frac{3\chi\eta}{4\pi^3} \zeta(3) e^{\mathcal{K}} \quad (4.2)$$

as the variable encoding the volume \mathcal{V} of the Calabi-Yau space since $e^{-\mathcal{K}} \approx 8\mathcal{V} - C$ due to (B.1d). Note that both κ^{ij} and γ are functions of the Kähler moduli.

The equations on critical points (3.10) simplify as

$$e^{-\mathcal{K}} \kappa^{ij} e_i e_j \approx \frac{4(et)^2 r(r+c)}{(r+2c)^2} + \frac{8\tilde{h}^2}{\lambda_2} \frac{(1-\gamma)r+4c}{1+\gamma}, \tag{4.3a}$$

$$\kappa_{ijk} \kappa^{jm} e_m \kappa^{kn} e_n \approx \frac{8re^{\mathcal{K}}(et)}{r+2c} (2e^{\mathcal{K}}(et)\kappa_{ij}t^j - e_i) + \frac{64\tilde{h}^2}{\lambda_2} e^{2\mathcal{K}} \kappa_{ij} t^j \left(\frac{2(r+c)}{(1+\gamma)^2} - r \right). \tag{4.3b}$$

The main complication here comes from the presence of the inverse matrix κ^{ij} that introduces a non-polynomial dependence on the Kähler moduli. It is, however, possible to get at least one equation without such dependence. To this end, let us contract (4.3b) with t^i . This gives

$$e^{-\mathcal{K}} \kappa^{ij} e_i e_j \approx \frac{4r(et)^2(1+\gamma)}{r+2c} + \frac{16\tilde{h}^2}{\lambda_2} (3+\gamma) \left(\frac{2(r+c)}{(1+\gamma)^2} - r \right). \tag{4.4}$$

Combining this equation with (4.3a) leads to

$$\frac{r(et)^2}{(r+2c)^2} \approx \frac{2\tilde{h}^2}{\lambda_2} \frac{(2\gamma^3 + 9\gamma^2 + 10\gamma - 5)r - 8c}{(1+\gamma)^2(\gamma(r+2c)+c)}, \tag{4.5}$$

which is a cubic equation on the dilaton r . Furthermore, substituting (4.3a) and (4.5) into the perturbative potential (4.1), we find the following result for its value at critical points:

$$\begin{aligned} V_{\text{cr}}^{(\varphi)} &\approx \frac{e^{\mathcal{K}}}{r} \left[\frac{\tilde{h}^2}{\lambda_2} \frac{1-\gamma}{1+\gamma} + \frac{c(et)^2}{2(r+2c)^2} \right] \\ &\approx \frac{e^{\mathcal{K}} \tilde{h}^2}{\lambda_2 r^2} \frac{\gamma(1-\gamma^2)r^2 - 4c(1-3\gamma-2\gamma^2)r - 8c^2}{(1+\gamma)^2(\gamma(r+2c)+c)}. \end{aligned} \tag{4.6}$$

In principle, one can solve the cubic equation (4.5) to express r in terms of the combination $e_i t^i$ and the Calabi-Yau volume encoded in γ . The solution $r(t)$ is to be substituted into (4.3b), which leads to a complicated system of equations on the Kähler moduli. But even without explicitly solving this system, it turns out to be possible to derive some bounds on its solution.

4.1 Bounds on perturbative solutions

As we noticed in the end of section 3, the possible values of the scalar fields are restricted to satisfy certain conditions. In the perturbative approximation, two of them put simple bounds on the lowest values of the dilaton (inversely proportional to the string coupling) and the volume of CY,

$$r > 2|c|, \quad \mathcal{V} > C/8, \tag{4.7}$$

whereas the third one demands that $\text{Im}\mathcal{N}_{IJ}$ is negative definite. The last condition is equivalent to $\text{Im}\mathcal{N}^{IJ} v_I v_J < 0$ for any real vector v_I . Let us take $v_I = (-eb, e_i)$. Then, using the perturbative result (B.3f), we arrive at the following condition:

$$\frac{e^{-\mathcal{K}} \kappa^{ij} e_i e_j}{(et)^2} < 4. \tag{4.8}$$

Figure 1. The plane γ - $(r/|c|)$ and its regions where various conditions are satisfied: the condition (4.8) corresponds to the dark grey region with the blue boundary, positivity of (4.5) holds in the pink region with the purple boundary, and the potential at the extremum (4.6) is positive in the light grey region with the brown boundary. The right picture magnifies the region close to the bifurcation point corresponding to $\left(\gamma_* = \frac{1}{4}(\sqrt{17} - 3), r_* = \frac{|c|}{2}(\sqrt{17} + 7)\right)$. All three conditions are satisfied only in the very narrow region which ends at this point. If one drops the positivity of the potential, the region of large γ and r is also allowed.

Let us now apply this condition to the extrema of the potential. Using equations (4.3a) and (4.5), we find that

$$\begin{aligned}
 & e^{-\mathcal{K}} \kappa^{ij} e_i e_j - 4(et)^2 \tag{4.9} \\
 & \approx \frac{8\tilde{h}^2}{\lambda_2 r} \frac{\gamma(1 - \gamma^2)r^3 + 8c(2 - 3\gamma - 3\gamma^2 - \gamma^3)r^2 + 4c^2(12 - 7\gamma - 7\gamma^2 - 2\gamma^3)r + 32c^3}{(1 + \gamma)^2(\gamma(r + 2c) + c)}.
 \end{aligned}$$

Then (4.8) implies that the r.h.s. of (4.9) must be negative. This severely restricts the regions in the γ - r plane where the potential can have critical points. Furthermore, the positivity of (4.5) gives another condition of the same kind. Figure 1 shows the regions allowed by the two conditions, as well as those where the potential (4.6) is positive. We observe that there is a narrow region where all conditions are satisfied so that they do not exclude the existence of meta-stable dS vacua, although they put a strong upper bound on the dilaton.

It is the important feature of our results presented in figure 1 that the above conditions do *not* allow solutions which have *both* large r (small string coupling) and small γ (large volume). Such conclusion can actually be derived analytically. Indeed, it is enough to get a milder consequence of (4.8) than the negativity of (4.9). For instance, one can note that the first term in (4.3a) is larger than $4(et)^2$. Then (4.8) implies that the second term must

be negative, which is equivalent to

$$\gamma > 1 + \frac{4c}{r} \quad \Rightarrow \quad \left(1 + \frac{c}{r}\right) \left(1 - \frac{C}{8\mathcal{V}}\right) < \frac{3}{4}. \quad (4.10)$$

When both r and \mathcal{V} are large, which corresponds to the classical limit, this condition is clearly violated. This shows that for the set of fluxes under consideration, it is impossible to stabilize the string coupling and the volume in the region where all quantum corrections become irrelevant. Note also that the bound does not depend on the values of fluxes, which means that it is impossible to tune them in order to get arbitrarily large r and \mathcal{V} .

4.2 One-modulus case

Given a complicated structure of the equations on critical points of the scalar potential even in the perturbative approximation, it is natural to consider some particular cases with a low number of moduli. First, we concentrate on the simplest case with a single Kähler modulus, corresponding to CY with Hodge numbers $(h^{1,1}, h^{2,1}) = (1, 0)$. To the best of our knowledge, no CY manifolds with such topological characteristics have been constructed so far, so that this case represents a fictional geometry and the corresponding gauged supergravity has no direct connection to string theory. Nevertheless, it is instructive to study it because the resulting equations allow an analytic treatment.

In the one modulus case, we find an additional relation,

$$\frac{e^{-\mathcal{K}} \kappa^{ij} e_i e_j}{(et)^2} \approx \frac{4}{3 + \gamma}, \quad (4.11)$$

where $\kappa^{ij} e_i e_j = \frac{e_1^2}{\kappa_{111} t^1}$. It allows to rewrite the cubic equation on the dilaton in the form where the coefficients are functions of γ only. Namely, combining (4.3a), (4.5) and (4.11), we find

$$(5 + \gamma)(2 - 4\gamma - 5\gamma^2 - \gamma^3)r^3 + 4(2 + \gamma - 4\gamma^2 - \gamma^3)cr^2 - 8(5 - \gamma)c^2r - 32c^3 = 0. \quad (4.12)$$

Remarkably, this equation can be factorized so that all three roots can be found explicitly as

$$r_0 = \frac{4|c|}{5 + \gamma}, \quad r_{\pm} = \frac{2|c| \left(\gamma \pm \sqrt{(2 + \gamma)(2 - 5\gamma - 2\gamma^2)} \right)}{2 - \gamma(1 + \gamma)(4 + \gamma)}. \quad (4.13)$$

However, not all of them are relevant to us. First, we observe that $r_0 < |c|$ and, hence, this root violates the bound (4.7). The other two roots are real only when

$$\gamma < \gamma_{(1)} = \frac{1}{4} \left(\sqrt{41} - 5 \right) \approx 0.3508. \quad (4.14)$$

However, in this region we have $r_- < 0$. Thus, only r_+ should be considered, whose positivity puts a stronger bound than (4.14), namely,⁷

$$\gamma < \gamma_{(2)} \approx 0.3429. \quad (4.15)$$

⁷ $\gamma_{(2)}$ is one of the roots of the denominator in (4.13).

Figure 2. The graphs represent the same quantity $\frac{\lambda_2}{|c|\hbar^2}(et)^2|_{r=r_+(\gamma)}$ evaluated in the one-modulus case as a function of the parameter γ in the two ways: the blue curve represents the function (4.5) and the red curve represents the function $f^{-1}(1 + 3\gamma^{-1})^{2/3} \sim t^2$ obtained by using (4.17). The parameter f controls the height of the second curve. For large f the curves intersect at two points (the left picture with $f = 26$) corresponding to two extrema of the potential, whereas for small f there are no intersections (the right picture with $f = 6.5$).

We should also check the two conditions mentioned in the previous subsection: (4.8) and positivity of (4.5). The first one is automatically satisfied due to (4.11), whereas the second one leads to an even stronger bound,⁸

$$\gamma < \gamma_* \approx 0.2808, \tag{4.16}$$

where γ_* was defined in the caption to figure 1.

Having verified all our conditions, it remains to solve the equation fixing the modulus γ . The easiest way to obtain such equation is to take (4.5), where one should substitute $r = r_+(\gamma)$ and

$$t^1 = \left(\frac{3C}{4\kappa_{111}} (1 + 3\gamma^{-1}) \right)^{1/3}. \tag{4.17}$$

Unfortunately, a solution can be found only numerically, and it is controlled by the parameter

$$f = \frac{|c|\tilde{h}^2}{\lambda_2 e_1^2} \left(\frac{4\kappa_{111}}{3C} \right)^{2/3} = \frac{\pi\tilde{h}^2}{24\lambda_2 e_1^2} \left(\frac{\kappa_{111}}{3\zeta(3)} \right)^{2/3}, \tag{4.18}$$

where we have used that we are considering the case with $\chi_{\mathcal{M}} = 2$. One can show that for

$$f > f_{\text{crit}} \approx 9.8 \tag{4.19}$$

the equation always has two solutions, and does not have any in the opposite case. The situation is demonstrated in figure 2 which represents the two sides of eq. (4.5) as functions of γ . For the parameters satisfying (4.19), the two curves have two intersection points, but once f decreases and reaches the critical value, they do not intersect anymore.

⁸ γ_* is one of the roots of the denominator in (4.5) after substitution $r = r_+$, namely, it solves $\gamma(r_+(\gamma) + 2c) + c = 0$. It coincides with the bifurcation point in figure 1, which is independent of the number of moduli. Note also that for $\gamma_* < \gamma < \gamma_{(2)}$, the r.h.s. of (4.9) is positive, which seems to contradict to (4.8). In fact, there is no contradiction because in this domain one already violates the bound (4.16).

Figure 3. The profile of the potential on the plane γ - $(r/|c|)$. There is a local maximum at $\gamma \approx 0.27$, $r \approx 5.18|c|$ and a saddle point at $\gamma \approx 0.14$, $r \approx 2.66|c|$. The profile corresponds to the choice $f = 26$, and the potential is rescaled by the factor $\frac{3\lambda_2|c|C}{\hbar^2}$.

Thus, if the H -flux is sufficiently large compared to the F_4 -flux, the potential has two critical points. Remarkably, for both of them the potential turns out to be positive (the curve $r_+(\gamma)$ drawn on the γ - r plane precisely fits the narrow region identified in figure 1). Unfortunately, both critical points do not correspond to local minima. As can be seen in figure 3, the solution with larger γ and r corresponds to a local maximum, whereas the one with smaller parameters corresponds to a saddle point. This is also confirmed by our analysis of the matrix of the second derivatives of the potential performed in appendix D. As a result, we conclude that in the one-modulus case the perturbative potential does not have meta-stable vacua.

4.3 Generic case: stability analysis

Next, it is natural to analyze the case with two Kähler moduli. Remarkably, a Calabi-Yau manifold with Hodge numbers $(h^{1,1}, h^{2,1}) = (2, 0)$ was constructed a few years ago in [64]. Thus, in contrast to the one-modulus case, this one does have a mathematical realization. The intersection numbers of this CY were recently calculated in [65], and are given by⁹

$$\kappa_{111} = 344, \quad \kappa_{112} = 492 \quad \kappa_{122} = 600, \quad \kappa_{222} = 440. \quad (4.20)$$

Unfortunately, these numbers do not have any particular symmetry which could help us in solving our equations. Furthermore, although it is possible to explicitly invert the 2×2 matrix κ_{ij} entering these equations, they still remain unsuitable to an analytic treatment.

Due to these reasons, instead of solving the equations on critical points, we directly proceed to the analysis of meta-stability. Remarkably, it turns out that this analysis can be carried out for the general case with *any* number of Kähler moduli.

⁹We are very grateful to Eberhard Freitag for informing us about his calculations.

The meta-stability of a vacuum requires that the matrix of the second derivatives $\partial_{\varphi^I} \partial_{\varphi^J} V^{(\varphi)}$ at the corresponding critical point is positive definite. To understand whether this can be the case for our potential, we apply the following trick. First, we note that the signature of any linear operator does not depend on the choice of a basis in the space where it acts. Therefore, we can rotate the derivatives ∂_{t^i} by an invertible matrix \mathbf{m}_i^j . We choose

$$\mathbf{m}_1^j = t^j, \quad \mathbf{m}_2^j = n^j \equiv \frac{\kappa^{jk} e_k}{e^{\mathcal{K}}(et)}, \quad (4.21)$$

and \mathbf{m}_i^j with $i > 2$ such that together with t^j and n^j they form a set of linearly independent vectors. Thus, instead of $\partial_{\varphi^I} \partial_{\varphi^J} V^{(\varphi)}$, we are going to analyze a matrix of the following form:

$$\mathbf{M} = \begin{pmatrix} \partial_r^2 V^{(\varphi)} & t^i \partial_{t^i} \partial_r V^{(\varphi)} & n^i \partial_{t^i} \partial_r V^{(\varphi)} & & \\ t^i \partial_{t^i} \partial_r V^{(\varphi)} & t^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} & n^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} & \dots & \\ n^i \partial_{t^i} \partial_r V^{(\varphi)} & n^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} & n^i n^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} & \dots & \\ & & \dots & & \dots \end{pmatrix}. \quad (4.22)$$

Since \mathbf{M} is a Hermitian matrix, we can apply Sylvester's criterion which tells us that \mathbf{M} is positive definite *if and only if* all its leading principal minors are positive. In other words, all matrices $\mathbf{M}^{(k)}$ given by the upper left k -by- k corner of \mathbf{M} must have a positive determinant, i.e. $\Delta_k \equiv \det \mathbf{M}^{(k)} > 0$. In particular, a *necessary* condition for \mathbf{M} to be positive definite is the positivity of Δ_k , $k = 1, 2, 3$.¹⁰

The crucial fact is that it is possible to express all elements of the matrix $\mathbf{M}^{(3)}$, and hence Δ_k , in terms of γ and r only. Indeed, contracting the vector-like equation (4.3b) with n^i , we obtain

$$\begin{aligned} \kappa_{ijk} \kappa^{il} e_l \kappa^{jm} e_m \kappa^{kn} e_n &\approx \frac{8r e^{2\mathcal{K}}(et)}{r+2c} (2(et)^2 - e^{-\mathcal{K}} \kappa^{ij} e_i e_j) + \frac{64\tilde{h}^2}{\lambda_2} e^{2\mathcal{K}}(et) \left(\frac{2(r+c)}{(1+\gamma)^2} - r \right) \\ &\approx \frac{32\tilde{h}^2}{\lambda_2} \frac{(et)e^{2\mathcal{K}}}{r+2c} \frac{(5-10\gamma-13\gamma^2-2\gamma^3)r^3 - 2c(1-8\gamma+3\gamma^2)r^2 - 4c^2(9-8\gamma)r - 8c^3(3-2\gamma)}{(1+\gamma)^2(c+\gamma(r+2c))}, \end{aligned} \quad (4.23)$$

where we have used (4.4) and (4.5) to get the second line. Then, as shown in appendix D, using the equations (4.4), (4.5) and (4.23), we can express all independent structures appearing in the entries of $\mathbf{M}^{(3)}$ in terms of only two variables γ and r . As a result, it becomes possible to search for regions in the γ - r plane where Δ_k are all positive. It is important to emphasize that, due to the use of the equations on critical points, all the parameters λ_2 , κ_{ijk} , the fluxes e_i and \tilde{h} conspire into the same positive multiplicative factor in all entries of the matrix $\mathbf{M}^{(3)}$, and, hence, in all minors Δ_k , so that the stability analysis does *not* depend on particular values of these parameters.

The details of this analysis are presented in appendix D. We find that there are no regions in the γ - r plane where all three minors Δ_k are positive. This implies that the matrix \mathbf{M} (4.22) *cannot* be positive definite and, hence, the perturbative potential *cannot* have local minima for any number of Kähler moduli.

¹⁰In the following, whenever Δ_k is mentioned, the condition $k = 1, 2, 3$ is implied.

5 Instanton contributions in the one-modulus case

Given the results of the previous section about the absence of meta-stable vacua in the perturbative approximation, it is natural to ask whether such vacua exist after taking into account the non-perturbative corrections generated by worldsheet and D-brane instantons. In this section we study this question in the simplest case of a fictional CY with $h^{1,1} = 1$. Thus, given all our approximations, the potential analyzed here should be viewed only as inspired by string theory, rather than realizing one of its compactifications. Nevertheless, we expect that it captures the main features of the cases which do have such realization.

In the presence of the non-perturbative corrections it seems to be impossible to solve our equations analytically, and we have to rely on numerical calculations. Our basic idea is to evaluate the matrix of the second derivatives of the non-perturbative scalar potential on-shell, so that the dependence on the flux parameters is completely factorized, and then look for regions in the $t\mathcal{R}$ plane¹¹ such that (i) they contain the curve of possible critical points, and (ii) the resulting matrix is positive definite. More precisely, we perform the following steps:

1. Solve (3.10b), which in this case is a single equation, with respect to $(et)^2$. The solution can be represented as

$$(et)^2 = \tilde{h}^2 \mathcal{E}(t, \mathcal{R}) \tag{5.1}$$

with some function $\mathcal{E}(t, \mathcal{R})$. Note that this function, as well as all other functions below, also depend on the signs $(-1)^n$ and $(-1)^l$ determined by the values of the axion fields. Thus, each function appears in four different copies corresponding to four different choices of these signs. It is enough to get a local minimum with one of these copies.

2. Substitute (5.1) into (3.10a) so that the dependence on \tilde{h}^2 is factored out and the equation reduces to

$$\mathcal{Q}(t, \mathcal{R}) = 0, \tag{5.2}$$

where the function $\mathcal{Q}(t, \mathcal{R})$ is independent on the flux parameters.

3. Calculate the matrix (3.7)¹² and substitute (5.1), so that the dependence on \tilde{h}^2 is also factored out and the matrix takes the form

$$\partial\partial V = \tilde{h}^2 \begin{pmatrix} \Phi_{IJ}(t, \mathcal{R}) & 0 \\ 0 & \Psi_{IJ}(t, \mathcal{R}) \end{pmatrix}. \tag{5.3}$$

4. All the steps above can be done analytically. To proceed further, we have to stick to a numerical analysis. To this end, we fix a finite number of instantons N_{inst} to be taken into account, and choose some values for λ_2 , κ and Gopakumar-Vafa invariants $n_k^{(0)}$, $k \leq N_{\text{inst}}$. We recall that we take a fictional CY, so that all these numbers can be chosen at will.

¹¹In this section we drop the index i at the quantities like Kähler moduli since it takes only one value.

¹²More precisely, in the upper left entry we evaluate the derivatives with respect to $(\mathcal{R}, \log t)$ instead of (r, t) .

5. Find the low bounds \mathcal{R}_{cr} and t_{cr} by demanding

$$r(\mathcal{R}) > -2c, \quad e^{-\mathcal{K}(t)} > 0, \quad \text{Im}\mathcal{N}_{IJ}(t) \text{ is negative definite.} \quad (5.4)$$

Under the second condition, the last one can be shown to be equivalent to (see appendix E)

$$Nt^2 > e^{-\mathcal{K}} \quad \text{or} \quad N < 0, \quad (5.5)$$

where $N \equiv N_{11}(t)$. The subsequent analysis is concentrated on the region ($\mathcal{R} > \mathcal{R}_{\text{cr}}$, $t > t_{\text{cr}}$).

6. Draw the curve $\mathcal{Q}(t, \mathcal{R}) = 0$ on the t - \mathcal{R} plane, and identify the parts of this curve belonging to the regions where

- $\mathcal{E}(t, \mathcal{R}) > 0$,
- the matrix $\Psi_{IJ}(t, \mathcal{R})$ is positive definite,
- the matrix $\Phi_{IJ}(t, \mathcal{R})$ is positive definite.

7. Should such parts exist, it means that there is a range of the flux parameters that allows the existence of a local minimum of the scalar potential. This range corresponds to those values of e and \tilde{h} when the two equations, (5.1) and (5.2), have a common solution. The fact that such values exist is ensured by positivity of $\mathcal{E}(t, \mathcal{R})$.

For practical purposes, it is convenient to split the step 6 into two steps: first, impose the positivity of \mathcal{E} and the positive definiteness of Ψ_{IJ} , and only afterwards analyze Φ_{IJ} . Then, typically, at the first stage we can exclude $(-1)^l = 1$ and identify a finite part of the curve $\mathcal{Q}(t, \mathcal{R}) = 0$, not too far from the critical values, as a candidate for the position of the minima. However, for all choices of the parameters we considered, it turns out that the matrix Φ_{IJ} is *not* positive definite in the region around the candidate part. A typical situation is demonstrated in figure 4. It is striking that in all our examples the regions of the positive trace and the positive determinant of Φ_{IJ} approach each other, with their boundaries going almost parallel, but *never* intersect. Given a highly non-trivial dependence of these functions on t , \mathcal{R} and all the parameters, this observation begs for a deeper analytical explanation.¹³ We conclude that in the one-modulus case the instanton corrections do not lead to meta-stable vacua.

6 Conclusions

In this paper we considered a simple class of flux compactifications which preserve $N = 2$ local supersymmetry in the four-dimensional low energy effective action. Ignoring the back reaction of fluxes and using the recent results on the non-perturbative description of fluxless CY compactifications, we derived a scalar potential which takes into account not only perturbative corrections, but also worldsheet and D-brane instantons. Extremizing this potential, we found that the axion fields are fixed to half-integer values, provided the fluxes satisfy the simple constraint (3.1). The axion stabilization greatly simplifies the

¹³Actually, we found that in the deep quantum region (with small \mathcal{R} and t) it is possible to have Φ_{IJ} positive definite and the non-perturbative scalar potential does have local minima. However, these minima spoil at least one of the conditions (5.4) and, therefore, are non-physical.

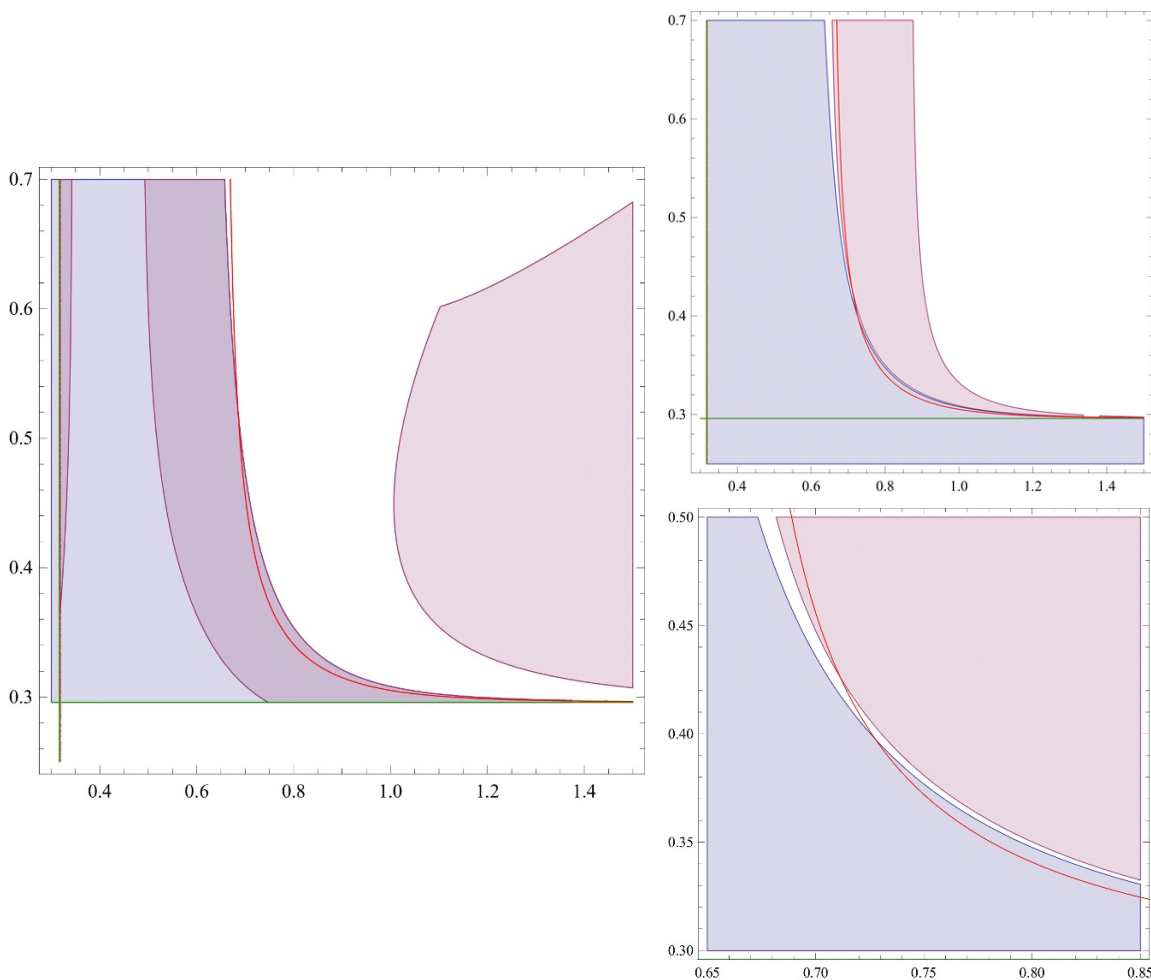

Figure 4. The left picture displays the t - \mathcal{R} plane and its regions where $\mathcal{E}(t, \mathcal{R}) > 0$ (blue) and $\Psi_{IJ}(t, \mathcal{R})$ is positive definite (pink). The red curve is a curve of solutions of $\mathcal{Q}(t, \mathcal{R}) = 0$, while the horizontal and vertical green lines correspond to $\mathcal{R} = \mathcal{R}_{\text{cr}}$ and $t = t_{\text{cr}}$, respectively. One can see that a part of the red curve belongs to the region where both conditions are satisfied. The right pictures display the same plane and the curve of solutions together with the regions of the positive trace (blue) and the determinant (pink) of $\Phi_{IJ}(t, \mathcal{R})$. The lower picture magnifies the part where the two regions are close to each other, in order to make clear that they do not intersect indeed. Thus, Φ_{IJ} is not positive definite near the red curve. The parameters are chosen as $N_{\text{inst}} = 4$, $\lambda_2 = 0.1$, $\kappa = 10$, $n_k^{(0)} = 100k$.

scalar potential and the equations on its critical points, and also leads to a factorization of the matrix of its second derivatives, which allows to disentangle the issue of stability into two independent problems in the subspaces spanned by the axions and the remaining moduli, respectively.

Whereas the stability in the axion subspace is easy to achieve, our results on the stabilization of the dilaton and the Kähler moduli are largely negative. First, we found the bound (4.10) on the critical values of the CY volume and the dilaton, which shows that the scalar potential does not have critical points in the large volume, weak coupling region of the moduli space where both α' and g_s -corrections can be neglected. Second,

we investigated these critical points in the perturbative approximation, but found that all of them are *not* stable (i.e. not local minima). Furthermore, in the case with one Kähler modulus, corresponding to the non-physical case of rigid CY with $h^{1,1} = 1$, we extended this result to the non-perturbative level by taking into account all instanton contributions. Thus, in all these cases not all of the moduli are stabilized by the chosen set of fluxes. The direction of instability lies in the subspace spanned by the dilaton and the Kähler moduli. This shows the existence of a non-trivial mixture between different moduli, and a failure of the approximation where they are supposed to be stabilized in a step-by-step procedure.

Our results can be compared to the no-go theorems in the literature that forbid the existence of dS vacua. For instance, [66] proves such a theorem in the approximation where the coupling of hypermultiplets is ignored, i.e. when *only* abelian $N = 2$ vector multiplets are taken into account, whereas [67] has a similar statement in the opposite case where *only* hypermultiplets are present. The main differences to these papers are: (i) we take into account *both* types of $N = 2$ matter multiplets, and (ii) obtain the stronger result that not only dS, but *any* vacua are unstable. At the same time, our results only apply either to the perturbative level or to CY's with Hodge numbers $(h^{1,1}, h^{2,1}) = (1, 0)$.

It was argued in [55] that meta-stable dS vacua can be obtained in N=2 gauged supergravity with a single hypermultiplet and a single vector multiplet, by gauging an abelian isometry of the hypermultiplet moduli space. It was based on the observation that the bound of [67] on (scalar) sGoldstini masses is relaxed in such case. Our results in the one-modulus case are not in tension with these findings because [55] studied the most general metrics on \mathcal{M}_V and \mathcal{M}_H , which are consistent with the special Kähler and quaternion-Kähler properties, respectively, whereas we restricted them to those resulting from the fluxless CY compactifications. Rather, our results imply that the vacua of [55] are not expected to arise in string theory, at least, if the back reaction does not change the situation drastically.

It is also worth mentioning that dS vacua are known to arise after the gauging of *non-abelian* isometries [68–70]. The non-abelian isometries do exist in the *classical* supergravity where the hypermultiplet moduli space can be taken to be a quaternionic homogeneous space¹⁴ G/H with a semi-simple stability group H , which allows to introduce the so-called Roo-Wagemans angles playing a crucial role in the construction of the classical dS vacua. However, any *quantum* correction, either perturbative or non-perturbative, breaks the non-abelian symmetries of the hypermultiplet moduli space, so that the non-abelian gaugings do not apply in quantum theory.¹⁵ Thus, the vacua constructed in [68–70] do not appear to be relevant in the context of full string theory where quantum corrections are not ignored.

Returning to our results, we note that they do not fully exclude the class of flux compactifications which inspired our potential: it remains to understand what happens at the full non-perturbative level for CY's with $h^{1,1} > 1$ (i.e. in all non-fictional cases), and whether the picture we found still persists. In fact, there is a serious obstacle on this way

¹⁴For instance, the universal hypermultiplet moduli space, appearing in CY compactifications in the classical approximation, is given by the symmetric coset space $SU(2, 1)/SU(2) \times U(1)$.

¹⁵That is why we omitted the non-abelian contributions in the basic equation (2.1) of the scalar potential in $N = 2$ gauged supergravity.

due to the absence of any knowledge about Gopakumar-Vafa invariants for rigid CY manifolds. Usually, these invariants are calculated by using mirror symmetry [34, 35]. However, rigid CY's do not have mirror duals ($h^{1,1}$ cannot be zero). It is the outstanding mathematical problem to find the non-perturbative holomorphic prepotential for such manifolds. Because of this problem, it might be reasonable to drop the assumption of rigidness and consider more general CY threefolds. Since the D-instanton corrected metric on the hypermultiplet moduli space is known for any CY [47], it may not be difficult to generalize the derivation of the non-perturbative potential (2.12) to a generic case. However, then both the metric and the scalar potential would become even more complicated by acquiring extra dependence on the complex structure moduli which also have to be stabilized.

Finally, it should be emphasized that we considered the very restricted set of fluxes, with all magnetic fluxes, including Romans mass, being set to zero. It was chosen to preserve $N = 2$ local supersymmetry that, in turn, was needed to take into account non-perturbative contributions, which are known only under very special circumstances. Of course, from both phenomenological and pure theoretical viewpoints, it would be desirable to extend our analysis to more general flux compactifications when $N = 2$ local supersymmetry is broken to $N = 1$. This, however, would require a much better understanding of quantum effects in $N = 1$ flux compactifications, beyond the current level. Whereas their direct calculation from the first principles is hardly possible, one may hope that a combination of string dualities with geometry of the moduli spaces will become as powerful in the $N = 1$ case as it turned out to be in the $N = 2$ case.

Acknowledgments

It is our pleasure to thank Sibasish Banerjee, Eric Bergshoeff, Renata Kallosh, Amir-Kian Kashani-Poor, Ruben Minasian, Ulrich Theis and Stefan Vandoren for valuable discussions and correspondence. We are particularly grateful to Eberhard Freitag for sharing with us his results about the intersection numbers of a rigid Calabi-Yau manifold with Picard number two. SVK is also grateful to the University of Montpellier for kind hospitality extended to him during part of this investigation.

SVK was supported by a Grant-in-Aid of the Japanese Society for Promotion of Science (JSPS) under No. 26400252, the World Premier International Research Centre Initiative (WPI Initiative), MEXT, Japan, and the Competitiveness Enhancement Program of Tomsk Polytechnic University in Russia.

A Conventions and normalizations

A.1 Special geometry relations

A special Kähler manifold \mathcal{M}_{sk} is determined by a holomorphic prepotential $F(X^I)$, a homogeneous function of degree 2. The homogeneous coordinates X^I are related to the coordinates on the manifold z^i by $z^i = X^I/X^0$ and, for simplicity, we choose the gauge where $X^0 = 1$. Given the prepotential, it is convenient to define the matrix

$$N_{IJ} = -2\text{Im} F_{IJ}. \tag{A.1}$$

It is invertible, but has a split signature $(b_2, 1)$. A related invertible matrix with a definite signature can be constructed as follows. Let us define

$$\mathcal{N}_{IJ} = \bar{F}_{IJ} - \frac{i N_{IK} X^K N_{JL} X^L}{N_{MN} X^M X^N}. \quad (\text{A.2})$$

\mathcal{N}_{IJ} appears as the coupling matrix of the gauge fields in the low-energy effective action and its imaginary part is negative definite.

In terms of the matrix (A.1), the Kähler potential on \mathcal{M}_{sk} is given by

$$\mathcal{K} = -\log(X^I N_{IJ} \bar{X}^J). \quad (\text{A.3})$$

For reader's convenience, we give here its derivatives with respect to z^i and $\bar{z}^{\bar{i}}$,

$$\mathcal{K}_i = -e^{\mathcal{K}} N_{iI} \bar{X}^I, \quad (\text{A.4a})$$

$$\mathcal{K}_{i\bar{j}} = -e^{\mathcal{K}} N_{ij} + \mathcal{K}_i \mathcal{K}_{\bar{j}}, \quad (\text{A.4b})$$

$$\mathcal{K}_{ij} = -2e^{\mathcal{K}} F_{ijk} t^k + \mathcal{K}_i \mathcal{K}_j, \quad (\text{A.4c})$$

$$\mathcal{K}_{i\bar{j}\bar{k}} = -ie^{\mathcal{K}} F_{ijk} + \mathcal{K}_i \mathcal{K}_{\bar{j}\bar{k}} + \mathcal{K}_j \mathcal{K}_{i\bar{k}} + \mathcal{K}_{\bar{k}} \mathcal{K}_{ij} - \mathcal{K}_i \mathcal{K}_j \mathcal{K}_{\bar{k}}, \quad (\text{A.4d})$$

where we have used homogeneity of the holomorphic prepotential and $z^i = b^i + it^i$. In particular, (A.4b) provides the metric on \mathcal{M}_{sk} .

The inverse matrices of N_{IJ} , $\text{Im}\mathcal{N}_{IJ}$ and $\mathcal{K}_{i\bar{j}}$ are explicitly given by

$$N^{IJ} = \Delta^{-1} \begin{pmatrix} 1 & -\hat{N}^{jk} N_{0k} \\ -\hat{N}^{ik} N_{0k} & \hat{N}^{ij} \Delta + \hat{N}^{ik} N_{0k} \hat{N}^{jl} N_{0l} \end{pmatrix}, \quad (\text{A.5a})$$

$$\frac{1}{2} \text{Im}\mathcal{N}^{IJ} = N^{IJ} - e^{\mathcal{K}} (X^I \bar{X}^J + \bar{X}^I X^J), \quad (\text{A.5b})$$

$$\mathcal{K}^{i\bar{j}} = -e^{-\mathcal{K}} \left(\hat{N}^{ij} + \frac{e^{-\mathcal{K}} \hat{N}^{ik} \mathcal{K}_{\bar{k}} \hat{N}^{jl} \mathcal{K}_l}{1 - e^{-\mathcal{K}} \hat{N}^{kl} \mathcal{K}_{\bar{k}} \mathcal{K}_l} \right), \quad (\text{A.5c})$$

where \hat{N}^{ij} denotes the inverse of N_{ij} and $\Delta = N_{00} - \hat{N}^{ij} N_{0i} N_{0j}$. It follows from (A.5c) that

$$\mathcal{K}^{i\bar{j}} \mathcal{K}_{\bar{j}} = \frac{e^{-\mathcal{K}} \hat{N}^{ij} \mathcal{K}_{\bar{j}}}{e^{-\mathcal{K}} \hat{N}^{m\bar{n}} \mathcal{K}_m \mathcal{K}_{\bar{n}} - 1}, \quad (\text{A.6a})$$

$$\mathcal{K}_i \mathcal{K}^{i\bar{j}} \mathcal{K}_{\bar{j}} - 1 = \frac{1}{e^{-\mathcal{K}} \hat{N}^{m\bar{n}} \mathcal{K}_m \mathcal{K}_{\bar{n}} - 1}. \quad (\text{A.6b})$$

Finally, using the covariant derivatives

$$D_i X^I = (\partial_i + \partial_i \mathcal{K}) X^I, \quad (\text{A.7})$$

we can rewrite (A.5a) and (A.5b) as

$$N^{IJ} = -e^{\mathcal{K}} (\mathcal{K}^{i\bar{j}} D_i X^I D_{\bar{j}} \bar{X}^J - X^I \bar{X}^J), \quad (\text{A.8a})$$

$$\frac{1}{2} \text{Im}\mathcal{N}^{IJ} = -e^{\mathcal{K}} (\mathcal{K}^{i\bar{j}} D_i X^I D_{\bar{j}} \bar{X}^J + \bar{X}^I X^J). \quad (\text{A.8b})$$

A.2 Quaternionic geometry and scalar potential

There is the extensive literature about the scalar potential in the gauged $N = 2$ supergravity, although one should be careful of the relative normalization of various contributions to the scalar potential in explicit calculations. There are two sources of different normalizations: (i) the gravitational coupling constant κ^2 , and (ii) the relation between the quaternionic 2-forms and the metric tensor on the hypermultiplet moduli space. Here we explain this numerical ambiguity, provide the scalar potential with a generic choice of the parameters, fix our conventions and compare them to the literature.

We recall that a QK space is a $4n$ -real-dimensional manifold with a holonomy group $\text{Sp}(n) \times \text{SU}(2)$ [71]. It is characterized by the existence of a quaternionic structure encoded in a triplet of 2-forms $\vec{\omega}$. Let us choose the local complex structure such that ω^+ is holomorphic.¹⁶ Denoting by π^X a basis of $(1,0)$ -forms in this complex structure, the metric is related to ω^3 as

$$ds^2 = 2g_{X\bar{Y}}\pi^X \otimes \bar{\pi}^{\bar{Y}}, \quad \omega^3 = ia g_{X\bar{Y}}\pi^X \otimes \bar{\pi}^{\bar{Y}}, \quad (\text{A.9})$$

where we have parametrized the ambiguity in the normalization of the quaternionic forms by a real parameter a .

The triplet of 2-forms $\vec{\omega}$ is, in fact, proportional to the $\text{SU}(2)$ part of the curvature. Denoting by \vec{p} the $\text{SU}(2)$ part of the spin connection, we have

$$d\vec{p} + \frac{1}{2}\vec{p} \times \vec{p} = \frac{\nu}{a}\vec{\omega}, \quad (\text{A.10})$$

where ν is the constant of proportionality. It is related to the scalar curvature and the quaternionic dimension n as $R = 4n(n+2)\nu$ and, hence, fixes the scale of the metric. When $n = 1$, we find $R = 12\nu$ and, consequently, $\nu = \Lambda/3$, where Λ is a ‘‘cosmological constant’’. Furthermore, given the conventional normalization of the kinetic terms of graviton and scalars,

$$L_{\text{kin}} = -\frac{1}{2\kappa^2}R(e) - \frac{1}{2}g_{uv}\partial_\mu\phi^u\partial^\mu\phi^v, \quad (\text{A.11})$$

the local $N = 2$ supersymmetry fixes the parameter ν in terms of the gravitational coupling as $\nu = -\kappa^2$.

Finally, when the QK metric has a Killing vector $k \in T\mathcal{M}$, one can define a triplet of moment maps $\vec{\mu}$ [24] by the equation

$$\partial_u\vec{\mu} + \vec{p}_u \times \vec{\mu} = \vec{\omega}_{uv}k^v \Rightarrow \vec{\mu} = -\frac{1}{2\nu}\vec{\omega}_v^u D_u k^v, \quad (\text{A.12})$$

where we have used (A.10) and the fact that $\vec{\omega}$ are covariantly constant with respect to the $\text{SU}(2)$ connection, $d\vec{\omega} + \vec{p} \times \vec{\omega} = 0$.

Given these conventions with arbitrary κ^2 and a , the scalar potential resulting from gauging a set of isometries on the hypermultiplet moduli space is given by

$$\begin{aligned} V &= 2\kappa^{-2}e^{\mathcal{K}}\mathbf{k}_I^u\mathbf{k}_J^vg_{uv}X^I\bar{X}^J - a^{-2}\left(\frac{1}{2}\text{Im}\mathcal{N}^{IJ} + 4e^{\mathcal{K}}X^I\bar{X}^J\right)(\vec{\mu}_I \cdot \vec{\mu}_J) \\ &= 2\kappa^{-2}e^{\mathcal{K}}\mathbf{k}_I^u\mathbf{k}_J^vg_{uv}X^I\bar{X}^J + a^{-2}e^{\mathcal{K}}(\mathcal{K}^{i\bar{j}}D_iX^ID_{\bar{j}}\bar{X}^J - 3X^I\bar{X}^J)(\vec{\mu}_I \cdot \vec{\mu}_J), \end{aligned} \quad (\text{A.13})$$

¹⁶We define the chiral basis as $x^\pm = -\frac{1}{2}(x^1 \mp ix^2)$, so that $\vec{x} \cdot \vec{y} = x^3y^3 + 2x^+y^- + 2x^-y^+$.

where $\mathbf{k}_I \in T\mathcal{M}_H$ are the charge vectors characterizing the gauging and given by linear combinations of the Killing vectors, and $\vec{\mu}_I$ are the triplets of moment maps defined by \mathbf{k}_I . In going from the first representation to the second one, we have used the relation (A.8b). Note that the definition (A.12) implies $\vec{\mu} \sim a\kappa^{-2}$, whereas a combination of (A.9) and (A.10) yields $g_{uv} \sim \kappa^{-2}$. As a result, using all these facts in the potential (A.13), we find that the dependence on all normalization constants is factorized as $V \sim \kappa^{-4}$ so that different normalizations do not affect physics.

In the literature, one can find two natural choices for the parameter a and two choices for κ^2 :

	$a = 1$	$a = 2$
$\kappa^2 = 2$	[23]	[70]
$\kappa^2 = a/2$	[19, 47]	[15]

Substituting the corresponding values of κ^2 and a , one can check that the scalar potential (A.13) agrees with the one given in [19], but differs by the factor of 1/4 from those in [23, 70]. In this paper, we choose $a = 1$ and $\kappa^2 = 1/2$ so that the scalar potential takes the form (2.1).

B The worldsheet instanton corrected metric on \mathcal{M}_V

Here we apply the general special geometry relations given in appendix A.1 to the case of the holomorphic prepotential (2.8) defining the geometry of $N = 2$ vector multiplets in the type IIA compactifications. A straightforward calculation yields

$$N_{ij} = 2\kappa_{ijk}t^k + \frac{1}{2\pi} \sum_{k_l\gamma^l \in H_2^+(\mathfrak{Q})} n_k^{(0)} k_i k_j \log \left| 1 - e^{2\pi i k_l z^l} \right|^2, \tag{B.1a}$$

$$N_{0i} = -2\kappa_{ijk}b^j t^k - \frac{1}{2\pi^2} \sum_{k_l\gamma^l \in H_2^+(\mathfrak{Q})} n_k^{(0)} k_i \operatorname{Im} \left[\operatorname{Li}_2 \left(e^{2\pi i k_l z^l} \right) + 2\pi i k_j z^j \log \left(1 - e^{2\pi i k_l z^l} \right) \right] \tag{B.1b}$$

$$N_{iI} \bar{X}^I = -e^{-\mathcal{K}} \mathcal{K}_i = -2i\kappa_{ijk}t^j t^k \tag{B.1c}$$

$$+ \frac{i}{4\pi^2} \sum_{k_l\gamma^l \in H_2^+(\mathfrak{Q})} n_k^{(0)} k_i \left[\operatorname{Li}_2 \left(e^{2\pi i k_l z^l} \right) - \operatorname{Li}_2 \left(e^{-2\pi i k_l \bar{z}^l} \right) - 4\pi k_j t^j \log \left(1 - e^{2\pi i k_l z^l} \right) \right],$$

$$e^{-\mathcal{K}} = 8\mathcal{V} - C + \frac{1}{2\pi^3} \sum_{k_l\gamma^l \in H_2^+(\mathfrak{Q})} n_k^{(0)} \operatorname{Re} \left[\operatorname{Li}_3 \left(e^{2\pi i k_l z^l} \right) + 2\pi k_j t^j \operatorname{Li}_2 \left(e^{2\pi i k_l z^l} \right) \right], \tag{B.1d}$$

where we have introduced the CY volume, $\mathcal{V} = \frac{1}{6} \kappa_{ijk} t^i t^j t^k$, and the parameter controlling the perturbative α' -correction

$$C = \frac{\zeta(3)\chi_{\mathfrak{Q}}}{4\pi^3}. \tag{B.2}$$

The metric in question is obtained by plugging these results into (A.4b).

The inverse metric and other related matrices cannot be explicitly computed in the presence of worldsheet instantons. If, however, we restrict ourselves to the perturbative approximation, then they can be expressed in terms of the inverse of $\kappa_{ij} \equiv \kappa_{ijk} t^k$ which we denote by κ^{ij} . In particular, we find

$$\mathcal{K}_i \approx \frac{2i\kappa_{ij}t^j}{8\mathcal{V} - C}, \tag{B.3a}$$

$$\mathcal{K}_{i\bar{j}} \approx -\frac{2\kappa_{ij}}{8\mathcal{V} - C} + \frac{4\kappa_{ik}t^k\kappa_{jl}t^l}{(8\mathcal{V} - C)^2} \tag{B.3b}$$

$$\mathcal{K}^{i\bar{j}} \approx -\frac{1}{2}(8\mathcal{V} - C) \left(\kappa^{ij} - \frac{2t^i t^j}{4\mathcal{V} + C} \right), \tag{B.3c}$$

$$N_{IJ} \approx \begin{pmatrix} 2\kappa_{ij}b^i b^j - 4\mathcal{V} - C & -2\kappa_{ij}b^j \\ -2\kappa_{ij}b^j & 2\kappa_{ij} \end{pmatrix}, \tag{B.3d}$$

$$N^{IJ} \approx -\frac{1}{4\mathcal{V} + c} \begin{pmatrix} 1 & b^i \\ b^i & b^i b^j - \frac{1}{2}(4\mathcal{V} + C)\kappa^{ij} \end{pmatrix}, \tag{B.3e}$$

$$-\frac{1}{2} \text{Im}\mathcal{N}^{IJ} \approx \left(\frac{1}{4\mathcal{V} + C} + \frac{2}{8\mathcal{V} - C} \right) \begin{pmatrix} 1 & b^i \\ b^i & b^i b^j \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & \frac{2t^i t^j}{8\mathcal{V} - C} - \frac{1}{2}\kappa^{ij} \end{pmatrix}. \tag{B.3f}$$

C The D-instanton corrected metric of the universal hypermultiplet

C.1 The metric

To write down the metric computed in [47], we have to introduce several important objects. First, let us summarize the data characterizing a rigid Calabi-Yau manifold:

- The intersection numbers κ_{ijk} , which specify the classical holomorphic prepotential (2.3) on the Kähler moduli space.
- The Euler characteristic $\chi_{\mathfrak{Y}} = 2h^{1,1} > 0$, which appears in the α' -corrected prepotential (2.8), and is always positive for rigid \mathfrak{Y} . We also use the following parameter:

$$c = -\frac{\chi_{\mathfrak{Y}}}{192\pi} = -\frac{\pi^2}{48\zeta(3)} C. \tag{C.1}$$

- The complex number

$$\lambda \equiv \lambda_1 - i\lambda_2 = \frac{\int_{\mathcal{B}} \Omega}{\int_{\mathcal{A}} \Omega} \tag{C.2}$$

given by the ratio of periods of the holomorphic 3-form $\Omega \in H^{3,0}(\mathfrak{Y})$ over an integral symplectic basis $(\mathcal{A}, \mathcal{B})$ of $H_3(\mathfrak{Y}, \mathbb{Z})$. The geometry requires that $\lambda_2 > 0$, which explains the minus sign in (C.2).

- The generalized Donaldson-Thomas (DT) invariants Ω_{γ} , which are integers counting, roughly, the number of BPS instantons of charge $\gamma = (p, q)$. In the case of the vanishing magnetic charge p and arbitrary electric charge q , they coincide with the Euler characteristic,

$$\Omega_{(0,q)} = \chi_{\mathfrak{Y}}. \tag{C.3}$$

Next, we introduce the central charge

$$Z_\gamma = q - \lambda p \tag{C.4}$$

which characterizes a D-instanton of charge γ . It is used to define the function

$$\mathcal{X}_\gamma(t) = (-1)^{qp} \exp \left[-2\pi i \left(q\zeta - p\tilde{\zeta} + \mathcal{R} \left(t^{-1}Z_\gamma - t\bar{Z}_\gamma \right) \right) \right], \tag{C.5}$$

where \mathcal{R} is a function on the moduli space, which is fixed below. Geometrically, t parametrizes the fiber of the twistor space \mathcal{Z} , a $\mathbb{C}P^1$ bundle over \mathcal{M}_H , whereas \mathcal{X}_γ are Fourier modes of holomorphic Darboux coordinates on \mathcal{Z} [41, 42]. Using (C.5), we define

$$\begin{aligned} \mathcal{J}_\gamma^{(1)} &= \int_{\ell_\gamma} \frac{dt}{t} \log(1 - \mathcal{X}_\gamma), & \mathcal{J}_\gamma^{(2)} &= \int_{\ell_\gamma} \frac{dt}{t} \frac{\mathcal{X}_\gamma}{1 - \mathcal{X}_\gamma}, \\ \mathcal{J}_\gamma^{(1,\pm)} &= \pm \int_{\ell_\gamma} \frac{dt}{t^{1\pm 1}} \log(1 - \mathcal{X}_\gamma), & \mathcal{J}_\gamma^{(2,\pm)} &= \pm \int_{\ell_\gamma} \frac{dt}{t^{1\pm 1}} \frac{\mathcal{X}_\gamma}{1 - \mathcal{X}_\gamma}, \end{aligned} \tag{C.6}$$

where ℓ_γ is a contour on $\mathbb{C}P^1$ joining $t = 0$ and $t = \infty$ along the direction fixed by the phase of the central charge, $\ell_\gamma = iZ_\gamma\mathbb{R}^+$. These functions satisfy the reality properties

$$\overline{\mathcal{J}_\gamma^{(n)}} = \mathcal{J}_{-\gamma}^{(n)}, \quad \overline{\mathcal{J}_\gamma^{(n,+)}} = \mathcal{J}_{-\gamma}^{(n,-)}, \tag{C.7}$$

and the following identities:

$$Z_\gamma \mathcal{J}_\gamma^{(n,+)} = \bar{Z}_\gamma \mathcal{J}_\gamma^{(n,-)}, \tag{C.8}$$

which can be verified by partial integration. Expanding the integrands in powers of \mathcal{X}_γ , they can be expressed as series of the modified Bessel functions of the second kind K_n .

The set of functions (C.6) encodes the D-instanton corrections to the moduli space. It is, however, convenient to introduce a few more quantities, which explicitly appear in the metric:

- the functions

$$\begin{aligned} v &= \frac{1}{2\pi} \sum_\gamma \Omega_\gamma |Z_\gamma|^2 \mathcal{J}_\gamma^{(2,-)}, & M &= 2\lambda_2 - \frac{1}{2\pi} \sum_\gamma \Omega_\gamma |Z_\gamma|^2 \mathcal{J}_\gamma^{(2)}, \\ \mathbf{U} &= M + M^{-1}|v|^2, \end{aligned} \tag{C.9}$$

- the one-forms

$$\mathcal{Y} = d\tilde{\zeta} - \lambda d\zeta - \frac{i}{4\pi} \sum_\gamma \Omega_\gamma Z_\gamma \left(\mathcal{J}_\gamma^{(2)} - v M^{-1} \mathcal{J}_\gamma^{(2,+)} \right) \left(q d\zeta - p d\tilde{\zeta} \right) - \frac{2iv}{\mathcal{R}M} dr, \tag{C.10}$$

$$\mathcal{V}_{(\sigma)} = \frac{2r}{\pi \lambda_2 \mathcal{R} \mathbf{U}} \sum_\gamma \Omega_\gamma Z_\gamma \left(\mathcal{J}_\gamma^{(2,+)} + \bar{v} M^{-1} \mathcal{J}_\gamma^{(2)} \right) \left[(q - \lambda_1 p) \left(d\tilde{\zeta} - \lambda_1 d\zeta \right) + \lambda_2^2 p d\zeta \right]. \tag{C.11}$$

Finally, the function \mathcal{R} entering (C.5) is implicitly determined as a solution to the following equation:

$$r = \frac{\lambda_2 \mathcal{R}^2}{2} - c - \frac{i\mathcal{R}}{32\pi^2} \sum_{\gamma} \Omega_{\gamma} \left(Z_{\gamma} \mathcal{J}_{\gamma}^{(1,+)} + \bar{Z}_{\gamma} \mathcal{J}_{\gamma}^{(1,-)} \right), \quad (\text{C.12})$$

where $r = e^{\phi}$ is the four-dimensional dilaton.

With all the notations above, the D-instanton corrected metric on the four-dimensional hypermultiplet moduli space is given by

$$ds^2 = \frac{2}{r^2} \left[\left(1 - \frac{2r}{\mathcal{R}^2 \mathbf{U}} \right) \left((dr)^2 + \frac{\mathcal{R}^2}{4} |\mathcal{Y}|^2 \right) + \frac{1}{64} \left(1 - \frac{2r}{\mathcal{R}^2 \mathbf{U}} \right)^{-1} \left(d\sigma + \tilde{\zeta} d\zeta - \zeta d\tilde{\zeta} + \mathcal{V}_{(\sigma)} \right)^2 \right]. \quad (\text{C.13})$$

There are two regimes of validity of this result:

- One includes D-instantons of all charges $\gamma = (p, q)$, but in this case the metric is not valid beyond the one-instanton approximation, i.e. only the terms *linear* in the DT invariants Ω_{γ} can be trusted. In particular, such metric is merely *approximately* quaternion-Kähler. In this approximation it can be further simplified by expanding all the coefficients to the first order in Ω_{γ} .
- One includes only “half” of D-instantons by restricting them to a set of charges satisfying the condition of mutual locality, $\langle \gamma, \gamma' \rangle = 0$. In this case, all charge vectors are proportional to each other, $\gamma = n\gamma_0$ with a fixed γ_0 . This restriction should be imposed in all sums over γ in (C.9)–(C.12). Then the metric is *exactly* quaternion-Kähler.

As was proven in [47] in the latter case, the metric (C.13) agrees with the Tod ansatz [57] where the role of the Tod potential satisfying the Toda equation is played by the function $T = 2 \log(\mathcal{R}/2)$. Unfortunately, this function and the coordinates adapted to the Tod ansatz are defined only implicitly in terms of the physical fields, so that we do not use this representation here.

C.2 The moment maps

In this appendix we evaluate the quaternionic moment maps for the Killing vectors (2.10) of the metric (C.13). They are defined by equation (A.12) and can be found using the following trick. Let us contract (A.10) with \mathbf{k}_I . In our normalization $\nu a^{-1} = -\frac{1}{2}$, so that the resulting equation can be written down as

$$\iota_{\mathbf{k}_I} \vec{\omega} = 2d(\iota_{\mathbf{k}_I} \vec{p}) + 2\vec{p} \times (\iota_{\mathbf{k}_I} \vec{p}) - 2\mathcal{L}_{\mathbf{k}_I} \vec{p}. \quad (\text{C.14})$$

Thus, if the following condition holds

$$\mathcal{L}_{\mathbf{k}_I} \vec{p} = \iota_{\mathbf{k}_I} d\vec{p} + d(\iota_{\mathbf{k}_I} \vec{p}) = 0, \quad (\text{C.15})$$

comparing (C.14) and (A.12), we conclude that the moment maps are given by a very simple expression,

$$\vec{\mu}_I = 2\iota_{\mathbf{k}_I} \vec{p}. \quad (\text{C.16})$$

To proceed further, we have to know the explicit expressions of the components of the SU(2) connection \vec{p} . They were computed in [47] and, after restricting them to four dimensions, the result reads

$$\begin{aligned}
 p^+ &= \frac{i\mathcal{R}}{4r} \left(d\tilde{\zeta} - \lambda d\zeta - \frac{1}{8\pi^2} \sum_{\gamma} \Omega_{\gamma} Z_{\gamma} d\mathcal{J}_{\gamma}^{(1)} \right), \\
 p^3 &= \frac{1}{8r} \left(d\sigma + \tilde{\zeta} d\zeta - \zeta d\tilde{\zeta} \right).
 \end{aligned}
 \tag{C.17}$$

First, we need to check the vanishing of Lie derivatives (C.15) along the Killing vectors (2.10). It is a trivial exercise for p^3 , whereas for p^+ we find

$$\mathcal{L}_{\mathbf{k}_I} p^+ = \frac{i}{4r} (\iota_{\mathbf{k}_I} d\mathcal{R}) \left(d\tilde{\zeta} - \lambda d\zeta - \frac{1}{8\pi^2} \sum_{\gamma} \Omega_{\gamma} Z_{\gamma} d\mathcal{J}_{\gamma}^{(1)} \right) - \frac{i\mathcal{R}}{32\pi^2 r} \sum_{\gamma} \Omega_{\gamma} Z_{\gamma} d(\iota_{\mathbf{k}_I} d\mathcal{J}_{\gamma}^{(1)}).
 \tag{C.18}$$

Let us now take into account that the presence of the H -flux only admits D-instantons of the charges satisfying $hq = \tilde{h}p$. This implies that $\iota_{\mathbf{k}_I} d\mathcal{X}_{\gamma} = 0$ and, as a result, both terms in (C.18) vanish. Due to the same reason, the instanton term in (C.17) does not contribute to the moment maps (C.16). Then it is easy to check that they coincide with the expressions given in (2.11).

D The second derivatives of the perturbative potential

A straightforward calculation gives the following results for the second derivatives of the scalar potential (4.1):

$$\partial_r^2 V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^4} \left[\frac{16\tilde{h}^2}{\lambda_2} \frac{(1-\gamma)r+6c}{1+\gamma} + \frac{4(et)^2 r}{(r+2c)^3} (3(r+c)^2 + c^2) - 3e^{-\mathcal{K}} \kappa^{ij} e_i e_j \right],
 \tag{D.1a}$$

$$\begin{aligned}
 \partial_{ti} \partial_r V^{(\varphi)} &= \frac{e^{\mathcal{K}}}{4r^3} \left[16e^{\mathcal{K}} \kappa_{ij} t^j \left(\frac{2\tilde{h}^2}{\lambda_2} \left(\frac{2(r+2c)}{(1+\gamma)^2} - r \right) + \frac{(et)^2 r(r+c)}{(r+2c)^2} \right) - \frac{8(et)e_i r(r+c)}{(r+2c)^2} \right. \\
 &\quad \left. - e^{-\mathcal{K}} \kappa_{ijk} \kappa^{jm} e_m \kappa^{kn} e_n \right],
 \end{aligned}
 \tag{D.1b}$$

$$\begin{aligned}
 \partial_{ti} \partial_{tj} V^{(\varphi)} &= \frac{e^{\mathcal{K}}}{4r^2} \left[64e^{2\mathcal{K}} \kappa_{ik} t^k \kappa_{jl} t^l \left(\frac{4\tilde{h}^2}{\lambda_2} \left(\frac{2(r+c)}{(1+\gamma)^3} - r \right) + \frac{r(et)^2}{r+2c} \right) \right. \\
 &\quad \left. - 16e^{\mathcal{K}} \kappa_{ij} \left(\frac{4\tilde{h}^2}{\lambda_2} \left(\frac{2(r+c)}{(1+\gamma)^2} - r \right) + \frac{r(et)^2}{r+2c} \right) - \frac{16r(et)e^{\mathcal{K}}}{r+2c} (e_i \kappa_{jk} + e_j \kappa_{ikl}) t^k \right. \\
 &\quad \left. + \frac{4re_i e_j}{r+2c} - e^{-\mathcal{K}} \kappa_{ikl} \kappa^{kp} e_p \kappa^{lm} \kappa_{jmn} \kappa^{nq} e_q \right].
 \end{aligned}
 \tag{D.1c}$$

Contracting the last two quantities with t^i and $n^i \equiv \frac{\kappa^{ij} e_j}{e^{\mathcal{K}}(et)}$, we find

$$t^i \partial_{t^i} \partial_r V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^3} \left[\frac{8\tilde{h}^2(3+\gamma)}{\lambda_2} \left(\frac{2(r+2c)}{(1+\gamma)^2} - r \right) + \frac{4(et)^2 r(r+c)(1+\gamma)}{(r+2c)^2} - e^{-\mathcal{K}} \kappa^{ij} e_i e_j \right], \quad (\text{D.2a})$$

$$n^i \partial_{t^i} \partial_r V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^3} \left[\frac{32\tilde{h}^2}{\lambda_2} \left(\frac{2(r+2c)}{(1+\gamma)^2} - r \right) + \frac{8r(r+c)}{(r+2c)^2} (2(et)^2 - e^{-\mathcal{K}} \kappa^{ij} e_i e_j) - \frac{e^{-2\mathcal{K}}}{(et)} \kappa_{ijk} \kappa^{il} e_l \kappa^{jm} e_m \kappa^{kn} e_n \right], \quad (\text{D.2b})$$

$$t^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{16\tilde{h}^2(3+\gamma)}{\lambda_2} \left(\frac{4(r+c)}{(1+\gamma)^3} - (2+\gamma)r \right) + \frac{4(et)^2 r(1+3\gamma+\gamma^2)}{r+2c} - e^{-\mathcal{K}} \kappa^{ij} e_i e_j \right], \quad (\text{D.2c})$$

$$n^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^2} \left[\frac{64\tilde{h}^2}{\lambda_2} \left(\frac{4(r+c)}{(1+\gamma)^3} - (2+\gamma)r \right) + \frac{4r}{r+2c} (4(1+\gamma)(et)^2 - e^{-\mathcal{K}} (2+\gamma) \kappa^{ij} e_i e_j) - \frac{e^{-2\mathcal{K}}}{(et)} \kappa_{ijk} \kappa^{il} e_l \kappa^{jm} e_m \kappa^{kn} e_n \right], \quad (\text{D.2d})$$

$$n^i n^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} = \frac{e^{\mathcal{K}}}{4r^2 (et)^2} \left[16 (4(et)^2 - e^{-\mathcal{K}} \kappa^{ij} e_i e_j) \left(\frac{4\tilde{h}^2}{\lambda_2} \left(\frac{2(r+c)}{(1+\gamma)^2} - r \right) + \frac{(et)^2 r}{r+2c} \right) - \frac{512\tilde{h}^2 (et)^2 \gamma (r+c)}{\lambda_2 (1+\gamma)^3} - \frac{4r e^{-\mathcal{K}}}{r+2c} \kappa^{ij} e_i e_j (8(et)^2 - e^{-\mathcal{K}} \kappa^{ij} e_i e_j) - e^{-3\mathcal{K}} \kappa^{ij} \kappa_{ikl} \kappa^{kp} e_p \kappa^{lq} e_q \kappa_{jmn} \kappa^{mr} e_r \kappa^{ns} e_s \right]. \quad (\text{D.2e})$$

Using (4.4), (4.5) and (4.23), all terms with the intersection numbers and/or flux parameters e_i , and, hence, all the second derivatives also, can be written down as functions of γ and r only. Explicitly, they are

$$\partial_r^2 V^{(\varphi)} = -\frac{2\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^4} \frac{\gamma(1-\gamma^2)r^3 - 2(7-17\gamma-13\gamma^2-\gamma^3)cr^2 - 8(4-3\gamma-2\gamma^2)c^2r - 16c^3}{(1+\gamma)^2(r+2c)(\gamma r + c(1+2\gamma))}, \quad (\text{D.3a})$$

$$t^i \partial_{t^i} \partial_r V^{(\varphi)} = -\frac{2\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^3} \frac{\gamma(3-5\gamma-5\gamma^2-\gamma^3)r^2 - 2(1-3\gamma-2\gamma^2)cr - 8(1+\gamma)c^2}{(1+\gamma)^2(\gamma r + c(1+2\gamma))}, \quad (\text{D.3b})$$

$$n^i \partial_{t^i} \partial_r V^{(\varphi)} = -\frac{8\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^3 (1+\gamma)^2 (r+2c)^2 (\gamma r + c(1+2\gamma))} (\gamma(1-2\gamma-\gamma^2)r^4 + 2(3-4\gamma-11\gamma^2-3\gamma^3)cr^3 + 4\gamma(3-4\gamma-\gamma^2)c^2r^2 - 8(5-2\gamma)c^3r - 32c^4), \quad (\text{D.3c})$$

$$t^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} = -\frac{2\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^2 (1+\gamma)^3 (\gamma r + c(1+2\gamma))} (\gamma(4+29\gamma+5\gamma^2-5\gamma^3-\gamma^4)r^2 - 2(3-23\gamma-69\gamma^2-29\gamma^3-2\gamma^4)cr - 4(3-4\gamma-17\gamma^2-6\gamma^3)c^2), \quad (\text{D.3d})$$

Figure 5. The functions $\Delta_1(\gamma, r = r_+(\gamma))$ (blue) and $\Delta_2(\gamma, r = r_+(\gamma))$ (red) rescaled by $a \equiv \frac{3\lambda_2|c|C}{\tilde{h}^2}$ and a^2 , respectively. (Δ_2 was also multiplied by 10 to make it more visible.) The vertical line indicates the bound $\gamma < \gamma_*$ in (4.16). The right picture magnifies the region near the critical value. Both pictures demonstrate that, in the allowed range of γ , the two functions are never simultaneously positive.

$$\begin{aligned}
 n^i t^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} &= \frac{8\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^2 (1 + \gamma)^3 (r + 2c)(\gamma r + c(1 + 2\gamma))} (\gamma(2 - 13\gamma - 13\gamma^2 - 7\gamma^3 - \gamma^4)r^3 \\
 &\quad + 2(1 - 8\gamma - 28\gamma^2 - 4\gamma^3 - \gamma^4)cr^2 + 4(2 - 13\gamma - 27\gamma^2 - 2\gamma^3)c^2r \\
 &\quad + 8(1 - 3\gamma - 6\gamma^2)c^3), \tag{D.3e}
 \end{aligned}$$

$$\begin{aligned}
 n^i n^j \partial_{t^i} \partial_{t^j} V^{(\varphi)} &= \frac{32\tilde{h}^2 e^{\mathcal{K}}}{\lambda_2 r^2 (1 + \gamma)^3 (r + 2c)^3 (\gamma r + c(1 + 2\gamma))((5 - 10\gamma - 9\gamma^2 - 2\gamma^3)r + 8c)} \\
 &\quad \times ((100 - 320\gamma - 377\gamma^2 + 831\gamma^3 + 1246\gamma^4 + 614\gamma^5 + 135\gamma^6 + 11\gamma^7)r^6 \\
 &\quad + 2(275 - 643\gamma - 1180\gamma^2 + 1232\gamma^3 + 2193\gamma^4 + 1043\gamma^5 + 216\gamma^6 + 16\gamma^7)cr^5 \\
 &\quad + 4(168 - 233\gamma - 903\gamma^2 + 482\gamma^3 + 1087\gamma^4 + 439\gamma^5 + 76\gamma^6 + 4\gamma^7)c^2r^4 \\
 &\quad + 8(-158 + 139\gamma + 127\gamma^2 + 340\gamma^3 + 313\gamma^4 + 61\gamma^5 + 6\gamma^6)c^3r^3 \\
 &\quad + 16(-232 + 21\gamma + 232\gamma^2 + 195\gamma^3 + 88\gamma^4 + 4\gamma^5)c^4r^2 \\
 &\quad + 32(-93 - 36\gamma + 41\gamma^2 + 32\gamma^3 + 12\gamma^4)c^5r - 256(3 + 2\gamma)c^6). \tag{D.3f}
 \end{aligned}$$

We are interested in whether the first three principle minors Δ_k of the matrix \mathbf{M} (4.22), which are constructed from the quantities (D.3), can be simultaneously positive. Verifying this condition on Mathematica shows that it is *never* satisfied (we employed the function RegionPlot with the argument $\{\Delta_1 > 0 \ \&\& \ \Delta_2 > 0 \ \&\& \ \Delta_3 > 0\}$). This implies that there are *no* local minima of the perturbative potential with at least two Kähler moduli.

The same method can be used to show that the same conclusion remains true in the one-modulus case. In this case, one should consider only two functions, Δ_1 and Δ_2 . Plotting the regions where they are positive shows that they have a non-trivial intersection. Hence, this simple analysis does not exclude meta-stable vacua yet. However, in the one-modulus case we know that critical points must belong to the curve $r = r_+(\gamma)$ (4.13). Substituting this into Δ_1 and Δ_2 , and plotting the resulting functions of γ , we arrive at figure 5. It shows that these two functions are *never* simultaneously positive and, hence, both critical points of the perturbative potential are unstable.

E The matrix $\text{Im } \mathcal{N}_{IJ}$

In this appendix we elaborate the condition of negative definiteness of the matrix $\text{Im } \mathcal{N}_{IJ}$ defined in (A.2). Since any change of basis does not change the signature of a matrix, we can equivalently consider the matrix $\mathcal{N} = U^T(\text{Im } \mathcal{N})U$. Choosing $U = \begin{pmatrix} 1 & 0 \\ b^i & \delta^i_j \end{pmatrix}$ and using

$$N_{iI}X^I = -e^{-\mathcal{K}}\mathcal{K}_{\bar{i}}, \quad N_{IJ}X^IX^J = e^{-\mathcal{K}}(1 - 2it^i\mathcal{K}_{\bar{i}}), \quad (\text{E.1})$$

we find

$$\mathcal{N} = \begin{pmatrix} \frac{1}{2}(e^{-\mathcal{K}} - N_{ij}t^it^j) - e^{-\mathcal{K}}\text{Re}\frac{(1-it^i\mathcal{K}_{\bar{i}})^2}{1-2it^i\mathcal{K}_{\bar{i}}} & -\frac{1}{2}\text{Re}\mathcal{K}_{\bar{i}} + e^{-\mathcal{K}}\text{Re}\frac{(1-it^i\mathcal{K}_{\bar{i}})\mathcal{K}_{\bar{i}}}{1-2it^i\mathcal{K}_{\bar{i}}} \\ -\frac{1}{2}\text{Re}\mathcal{K}_{\bar{i}} + e^{-\mathcal{K}}\text{Re}\frac{(1-it^i\mathcal{K}_{\bar{i}})\mathcal{K}_{\bar{i}}}{1-2it^i\mathcal{K}_{\bar{i}}} & \frac{1}{2}N_{ij} - e^{-\mathcal{K}}\text{Re}\frac{\mathcal{K}_{\bar{i}}\mathcal{K}_{\bar{j}}}{1-2it^i\mathcal{K}_{\bar{i}}} \end{pmatrix}. \quad (\text{E.2})$$

Let us now take half-integer b^i -moduli as in (3.2). Then $\mathcal{K}_{\bar{i}} = -ie^{\mathcal{K}}N_{ij}t^j$ (see (B.1)) and the matrix (E.2) simplifies to

$$\mathcal{N} = \begin{pmatrix} -\frac{1}{2}e^{-\mathcal{K}}\frac{e^{-\mathcal{K}} - N_{ij}t^it^j}{e^{-\mathcal{K}} - 2N_{ij}t^it^j} & 0 \\ 0 & \frac{1}{2}N_{ij} + \frac{N_{ik}t^k N_{jl}t^l}{e^{-\mathcal{K}} - 2N_{ij}t^it^j} \end{pmatrix}. \quad (\text{E.3})$$

Thus, the negative definiteness of $\text{Im } \mathcal{N}_{IJ}$ requires

$$\frac{N_{ij}t^it^j - e^{-\mathcal{K}}}{2N_{ij}t^it^j - e^{-\mathcal{K}}} > 0 \quad \text{and} \quad \frac{2N_{ik}t^k N_{jl}t^l}{2N_{ij}t^it^j - e^{-\mathcal{K}}} - N_{ij} \quad \text{is positive definite.} \quad (\text{E.4})$$

Let us further restrict ourselves to the one-modulus case and drop the indices i, j taking a single value. Then the two conditions (E.4) simplify as

$$\frac{Nt^2 - e^{-\mathcal{K}}}{2Nt^2 - e^{-\mathcal{K}}} > 0 \quad \text{and} \quad \frac{Ne^{-\mathcal{K}}}{2Nt^2 - e^{-\mathcal{K}}} > 0. \quad (\text{E.5})$$

Given positivity of $e^{-\mathcal{K}}$, it is easy to see that these conditions are equivalent to (5.5).
