Abstract

In this paper we propose an updated bulk chemical composition of the Earth based on new estimates for the composition of the Earth's core. We present the different cosmochemical constraints that allow us to search for the Earth's building blocks. Chemical equilibrium calculations of gas – solid equilibria in solar composition gas show that at first approximation the Earth is chondritic for the refractory lithophile (rock-loving) elements. Elemental and isotopic compositions are then used to discuss the different possible types of meteoritic material (exemplified by the meteorites in our collections) that may represent the bulk Earth composition.

Introduction

Consideration of Earth's building blocks requires knowledge of its bulk composition today, chemistry in the solar nebula, and of chemical effects during accretion of the Earth (e.g., see pp. 35-38 of Lewis & Prinn 1984). The Earth is a differentiated planet consisting of five (physically distinct) geochemical reservoirs (atmosphere,

1 biosphere, hydrosphere, lithosphere, and core) with different chemical
2 compositions. (In this paper we *geochemically* define lithosphere as the crust plus
3 the entire mantle so it encompasses the entire silicate portion of the Earth. This is
4 distinct from the geophysical definition of lithosphere, which is based on mechanical
5 properties of rock.) Thus, the lithosphere is similar, but not identical to the bulk
6 silicate Earth, which also includes the atmosphere, biosphere, and hydrosphere (see
7 below). All accessible terrestrial samples have been modified to a greater or lesser
8 extent from Earth's original composition. For example, the atmosphere, biosphere,
9 hydrosphere, and lithosphere originated from Earth's primordial silicate portion
10 after it was depleted in siderophile (metal-loving) and chalcophile (sulfur-loving)
11 elements by core formation but before it differentiated into crust plus mantle and
12 outgassed volatiles to form the atmosphere and oceans. Thus the mass-weighted
13 chemical composition of the atmosphere, biosphere, hydrosphere, and lithosphere is
14 that of the bulk silicate Earth (BSE), also known as Earth's primitive mantle (PM).
15 We use the term BSE throughout this chapter. Two major processes shaped the
16 composition of the BSE: (1) gas – solid (and/or gas – melt) volatility fractionation of
17 Earth – forming materials in the solar nebula (including volatility effects on
18 planetesimals), and during accretion of the Earth, and (2) silicate, metal, and sulfide
19 elemental partitioning during core formation on the early Earth and its planetesimal
20 precursors.

21 We could also divide the Earth into geochemically different reservoirs such
22 as undepleted primitive mantle (UPM) and depleted MORB mantle (DMM), but we
23 did not take this approach for two reasons. First, the size of the undepleted and

1 depleted reservoirs may vary for each element and isotope under consideration, e.g.,
 2 different size reservoirs for a lithophile and a noble gas. Second, the depleted and
 3 undepleted reservoirs are model constructs that do not necessarily correspond to
 4 physically different reservoirs such as upper and lower mantle. For example the
 5 entire mantle may be a mixture of more and less depleted regions like raisins in a
 6 cake (Figure 6 of Helffrich & Wood 2001).

7 It is more convenient for us to consider the five physically distinct reservoirs
 8 mentioned above. In principle, Earth's bulk composition can be reconstructed from
 9 chemical analyses of elements in each of these five reservoirs combined together in
 10 their relative mass fractions. Thus the concentration C of an element E in the bulk
 11 Earth (Bulk) is given by

$$C_E^{Bulk} = F_A C_E^A + F_B C_E^B + F_H C_E^H + F_L C_E^L + F_C C_E^C$$

12 The mass fraction of each reservoir R is F_R and the subscripts denote the
 13 atmospheric (A), biospheric (B), hydrospheric (H), lithospheric (L), and core (C)
 14 reservoirs. Table 1 lists the mass and mass fraction of each of these reservoirs and
 15 shows the further subdivision of the lithospheric and core reservoirs. The
 16 concentration of an element E in each reservoir is C_E^R . For example, the bulk earth
 17 concentration of Mg is given by

$$C_{Mg}^{Bulk} = F_A C_{Mg}^A + F_B C_{Mg}^B + F_H C_{Mg}^H + F_L C_{Mg}^L + F_C C_{Mg}^C$$

$$C_{Mg}^{Bulk} = (8.6 \times 10^{-7})(0\%) + (1.9 \times 10^{-9})(0.098\%) + (2.79 \times 10^{-4})(0.128\%)$$

$$+ (0.6748)(22.17\%) + (0.3249)(0\%)$$

$$C_{Mg}^{Bulk} = 14.96\%$$

1 In comparison, Morgan & Anders (1980), Kargel & Lewis (1993), and McDonough
2 (2003) give 13.90%, 14.86%, and 15.4% Mg, respectively, in the bulk Earth. The
3 variations are due to the different values selected for the Mg percentage in Earth's
4 mantle. The amounts of Mg in the atmosphere (none), biosphere (0.098% in
5 phytomass), hydrosphere (0.128% in seawater) (Lodders & Fegley 1998, 2011),
6 lithosphere (22.17%, Table 4 of Palme & O'Neill 2014), and core (none, McDonough
7 2003) are very small. Thus, the Mg concentration in the bulk Earth is effectively just
8 the mass-weighted Mg concentration in the lithosphere.

9 We can simply write the mass balance equations by using elemental
10 concentrations in the BSE; then a two-term equation results, e.g., the equation for
11 Mg becomes:

$$C_{Mg}^{Bulk} = F_{BSE} C_{Mg}^{BSE} + F_C C_{Mg}^C$$
$$C_{Mg}^{Bulk} = (0.6751)(22.17\%) + (0.3249)(0\%) = 14.96\%$$

12 Other lithophile elements that are insoluble in water and do not behave as
13 siderophiles or chalcophiles at core-forming conditions (e.g., Al, Ba, Be, Ca, F, Li, REE,
14 Sc, Sr, Th, Ti, U, Y, Zr) have similar mass balance equations comprised of only the
15 lithospheric reservoir term. (We defer discussion of Na, K, Rb, and Cs to later.)

16 Several other elements are concentrated in one reservoir, but not to the same
17 extent as the lithophiles mentioned above. For example, most of the iodine in the
18 bulk silicate Earth is primarily found in organic-rich marine sediments and marine
19 organisms (i.e., biospheric reservoir) with ~ 11% residing in the lithosphere.

20 However, the core may contain up to 82% of Earth's total iodine inventory if

1 metal/silicate partition coefficients measured at high pressures and temperatures
2 are relevant to core formation on Earth (Armytage et al. 2013).

3 About 75% of Cl and Br in the BSE are in the oceans (hydrospheric reservoir)
4 with the remaining 25% in the lithosphere. Neglecting any nitrogen that may be
5 dissolved in the molten outer core, 73.1% of Earth's nitrogen is in the atmosphere,
6 26.5% is in the crust, and 0.4% in the oceans (Lodders & Fegley 2011). Geochemical
7 modeling (Allegre et al. 1995; Albarede 1998; Ballentine & Holland 2008) shows
8 only 45-50% of Earth's ^{40}Ar is in the atmosphere. This modeling depends on the
9 amount of K in the BSE, which is fairly well constrained at 230 – 280 ppm by mass
10 (260 ppm, Jagoutz et al 1979; 240 ppm, McDonough & Sun 1995; 232 ppm, Kargel &
11 Lewis 1993; 258 ppm, Hofmann 1988; 231 ppm, Wänke et al 1984; 258 ppm, Hart &
12 Zindler 1986; 280 ppm, Allègre et al. 1995; and 260 ppm, Palme & O'Neill 2014). If
13 the degassing efficiency is similar for other noble gases, the atmosphere contains ~
14 50% of Earth's $^{36+38}\text{Ar}$, Kr, and Xe (Fegley & Schaefer 2014). Helium is not
15 considered in this comparison because it is continually escaping to space with an
16 atmospheric lifetime of 0.9–1.8Ma for ^4He and 0.4–0.8Ma for ^3He (Torgersen, 1989).
17 Neon is not considered because the different isotopic compositions of atmospheric
18 and mantle Ne suggest atmospheric Ne is probably a mixture of Ne degassed from
19 the mantle and from chondritic bolides by impact degassing (Marty 2012; Moreira
20 2013; Zhang 2014). An alternative scenario is the Ne has been lost by hydrodynamic
21 escape to space associated with an isotopic mass-fractionation (Pepin 2006).

22 The atmospheric inventory of Xe is lower than it should be by analogy with
23 Ne, Ar, and Kr – the missing Xe problem. Various solutions to the missing Xe

1 problem have been suggested over the past 50 years, which generally involve
2 sequestering the “missing” Xe inside the Earth, e.g., in glacial ice, sediments, or
3 clathrate hydrates (e.g., see Ozima & Podosek 2001). More recently Sanloup et al.
4 (2005, 2011) suggested that significant amounts of Xe are in the lower mantle or in
5 the crust as XeO₂ in quartz and olivine, which is supported by the synthesis of XeO₂
6 (Brock & Schrobilgen 2011). A last scenario is that Xe has been lost to space through
7 an unknown process associated with an isotopic fractionation (Pujol et al. 2011).
8 Over the past 30 years geoscientists have speculated that the “missing” Xe is in
9 Earth’s core (Ozima & Podosek 2001). Their reasoning is that Xe becomes a metal
10 with hexagonal close packed (hcp) structure above 120 GPa and it may alloy with, or
11 dissolve into Fe, which is also a hcp metal at core conditions. However the
12 experimental study of Nishio-Hamane et al. (2010) finds no evidence for Xe alloy
13 formation with or dissolution into Fe at P, T conditions similar to those in the core. A
14 more detailed discussion of noble gas geochemistry is beyond our scope, but is
15 given by Zhang (2014).

16 As evident from our discussion above, this simple mass balance approach is
17 difficult in practice because of our incomplete knowledge of reservoir compositions,
18 e.g., the core, which is ~ 32.5% by mass, and the mantle, which is ~ 67.5% by mass,
19 of the Earth. For example, recent metal/silicate partitioning experiments indicate
20 that Earth’s core may be a significant reservoir of helium (Bouhifd et al. 2013a),
21 iodine (Armytage et al. 2013), and lead (Bouhifd et al. 2013b). The measured
22 partition coefficients depend upon several variables (e.g., P, T, oxygen fugacity,
23 sulfur content of the molten metal) and the “true” concentrations of these and many

1 other elements in Earth's core will be incredibly difficult to constrain. Likewise, the
2 concentrations of several elements in the mantle are not well known, e.g., As, Bi, Cd,
3 H, In, S, Sb, Se, Te, Tl. The estimate of H in the mantle varies from 1 – 2 oceans of
4 water (e.g., Saal et al. 2002, Hirschmann & Dasgupta 2009; Zhang 2014). Even the
5 crustal concentrations of some elements such as As, Bi, Hg, Sb, and Tl are poorly
6 known (Palme & O'Neill 2014).

7 Our knowledge of the compositions of the five major geochemical reservoirs
8 comes from four principal types of data: (1) seismological observations, (2)
9 chemical and isotopic analyses of the atmosphere, biosphere, hydrosphere, and
10 lithosphere, (3) experimental studies of elemental partitioning between coexisting
11 phases (e.g., metal, silicate, sulfide, melt) as a function of temperature, pressure,
12 oxygen and/or sulfur fugacity, (4) ratios of elements with very similar geochemical
13 behavior (e.g., Sm/Sn, K/U, K/La, W/Th, P/Nd, Rb/Ba, Nb/Ta) combined with
14 analysis of one element in the pair, and (5) cosmochemical constraints, e.g.,
15 elemental and isotopic abundances in meteorites and solar composition material.

16 Palme & O'Neill (2014) describe in more detail several of these approaches
17 that they use to determine the composition of the bulk silicate Earth. Thus we do not
18 repeat their discussion here but refer the reader to their chapter. Published values
19 for composition of the BSE are in good agreement. For example, Table 3 of Palme &
20 O'Neill (2014) compares BSE major element compositions from Ringwood (1979),
21 Jagoutz et al (1979), Wänke et al (1984), Palme & Nickel (1985), Hart & Zindler
22 (1986), McDonough & Sun (1995), and Allègre et al. (1995). The range for SiO₂ – the
23 most abundant oxide in the BSE – is only from 45.0% (McDonough & Sun 1995) to

1 46.2% (Palme & Nickel 1985) – and the unweighted mean value of all seven
2 compilations is $45.6 \pm 0.5\%$ (1 sigma error), identical within error to the value of
3 $45.40 \pm 0.30\%$ recommended by Palme & O'Neill (2014). Likewise the concentration
4 range for MgO – the 2nd most abundant oxide in the BSE – is from 35.5% (Palme &
5 Nickel 1985) to 38.3% (Jagoutz et al. 1979). The unweighted mean MgO
6 concentration from all seven compilations is $37.4 \pm 0.9\%$ (1 sigma error), identical
7 within error to the value of $36.77 \pm 0.44\%$ given by Palme & O'Neill (2014). Table
8 6.9 of Lodders & Fegley (1998) compares ten BSE compositions, and the same
9 conclusion is reached – that the major element composition of the BSE is well
10 constrained. As we discuss later these BSE compositions assume that the mantle is
11 compositionally uniform. There is good evidence for this summarized by Palme and
12 O'Neill (2014).

13 More than one line of evidence is often used to constrain the composition of
14 the lithospheric and core reservoirs. For example, seismological observations show
15 the Earth is physically divided (to 1st order) into crust, upper mantle, lower mantle,
16 and core, and that Earth's core is divided into a molten outer core and a solid inner
17 core. Seismic data and analyses of Fe-Ni meteorite metal show that most of the core
18 is Fe-Ni alloy (Fe/Ni ~ 16.5 by weight = Fe 94.3%, Ni 5.7% – this is the solar
19 composition value which is found in most iron meteorites). However, the molten
20 outer core is ~ 5-10% less dense and the inner core is ~ 2-3% less dense than this
21 alloy (Badro et al. 2014). One or more light elements are present in the core (Birch
22 1952, 1964). The identity of the light element(s) in the molten outer core and in the
23 solid inner core is not uniquely constrained by the seismic data alone but also

1 depends upon observed elemental abundances in Fe-Ni alloy in meteorites, Fe –
2 element binary phase diagrams, metal/silicate partition coefficients, and solar
3 elemental abundances; the plausible light elements include C, S, Si, O, N, P, and H.
4 Molecular dynamics simulations of density and sound speed at plausible P & T for
5 the core by Badro et al. (2014) show oxygen is the most abundant light element in
6 the core with their best fit model containing 3.7% O and 1.9% Si by weight. The
7 maximum light element contents permitted by their modeling are 5.4% O, 4.5% Si,
8 and 2.4% S.

9 Seismic tomography shows the penetration of down-welling slabs into the
10 lower mantle, which requires mass exchange between upper and lower mantle. This
11 evidence is important because it implies a generally well-mixed, compositionally
12 uniform mantle (Palme & O'Neill 2014). Bina & Helffrich (2014) computed density
13 and sound velocity profiles along plausible lower mantle adiabats for a variety of
14 compositions and concluded that lower mantle physical properties are consistent
15 with a pyrolite, i.e., upper mantle, composition. Palme & O'Neill (2014) review other
16 lines of evidence supporting a homogenous mantle composition.

17 Thus most geoscientists accept that analyses of relatively unaltered upper
18 mantle xenoliths (fertile peridotites, spinel lherzolites, garnet lherzolites),
19 petrological models of peridotite – basalt melting (e.g., Ringwood's pyrolite model),
20 and concentration ratios of geochemically similar elements in basalts, can be used to
21 determine the composition of the entire mantle – not just the upper mantle. But see
22 Anderson (2002) and Javoy et al. (2010) for arguments that the upper and lower

1 mantle has different compositions. The latter group requires this in order for their
2 enstatite chondrite model to match the BSE.

3 In this review we focus on three lines of evidence– cosmochemical
4 constraints and geochemical and isotopic analyses– that provide information about
5 the bulk composition of the Earth and its building blocks.

6

7 **Cosmochemical constraints**

8 We discuss meteoritic constraints on Earth’s composition and origin in a
9 subsequent section. Here we discuss constraints from solar nebula chemistry, but
10 before doing so we briefly summarize the different stages of solar nebula evolution,
11 and planetary accretion based on Cameron (1995), Lodders & Fegley (2011), and
12 Chamber (2014).

13 *1st Stage: Molecular cloud collapse.* During this stage, the solar nebula disk is
14 built up of infalling material from a collapsing molecular cloud core. This stage lasts
15 for a few times 10^5 years. Most (if not all) of the matter in the disk during this stage
16 ultimately goes into the proto-Sun.

17 *2nd Stage: Disk dissipation.* The Sun forms during this stage, which lasts for
18 about 50,000 years (i.e., the Sun accretes at approximately 2×10^{-5} solar masses per
19 year). The disk mass is less than that of the proto-Sun. Most matter falling onto the
20 accretion disk is transported through the disk into the proto-Sun and angular
21 momentum is transported outward in the disk. The major dissipation (i.e.,
22 transport) mechanisms include spiral density waves, disk-driven bipolar outflows,
23 and the Balbus-Hawley magnetic instability. Cameron (1995) discusses why

1 turbulent viscosity driven by thermal convection is less important than these other
2 dissipative mechanisms, but some other modelers continue to rely on turbulent
3 viscosity as the main dissipative mechanism. The amount of outward mass
4 transport, that would tend to “contaminate” the outer nebula with products from
5 thermochemical processing in the innermost few AU of the nebula, is controversial
6 and uncertain. Near the end of this stage, some disk material survived and is
7 preserved in meteorites (e.g., ²⁶Al-bearing minerals).

8 3rd Stage: *Terminal accumulation of the Sun.* The final accumulation of the Sun
9 occurs during this stage, which lasts for about $(1-2) \times 10^6$ years. The Sun’s
10 accumulation rate decreases from about 10^{-7} to 10^{-8} solar masses per year. The
11 proto-Sun becomes a classical T Tauri star in this phase. Planetary accretion (almost
12 complete for Jupiter and Saturn, and less advanced for the other planets) occurs
13 during this stage.

14 4th Stage: *Loss of nebular gas.* The Sun becomes a weak line T Tauri star in
15 this stage, which lasts $(3-30) \times 10^6$ years, and is no longer accreting material from
16 the disk. The T Tauri wind removes gas in the inner nebula and photo-evaporation
17 due mainly to UV radiation from the T Tauri wind removes gas in the outer nebula.
18 Ultraviolet photochemistry may be important in the outer nebula, but its
19 importance depends on the poorly constrained and time dependent nebular column
20 density. Nebular gas – solid thermochemistry ceases sometime (although not
21 necessarily at the same time everywhere) during this stage.

22 In Cameron’s (1995) model of nebular evolution, accumulation of the Sun
23 consumed essentially all of the material accreted by the nebular disk during the

1 early stages of its history. Planets and all the other bodies in the solar system were
2 then assembled from material accreted after the Sun had formed (i.e., during the
3 time from the end of stage 2 into stage 4). Accretion of the terrestrial planets
4 proceeded via a multistage process of planetary embryo growth from nebular dust
5 grains (dust grains → chunks → boulders → km size bodies → asteroidal size bodies
6 → planetary embryos → planets). The number of objects decreased at each stage of
7 accretion until roughly a few hundred planetary embryos of lunar to Mars size are
8 produced. The four terrestrial planets formed by accretion of these planetary
9 embryos. For example, the last stage of Earth accretion apparently involved collision
10 of the $\sim 0.9 M_E$ proto-Earth with an $\sim 0.1 M_E$ Mars-size body.

11 The composition of the dust grains that were the starting point for
12 planetesimal growth and accretion was mainly determined by nebular
13 thermochemistry; thus we discuss constraints on chemistry of nebular solids from
14 chemical equilibrium calculations of gas – solid equilibria in solar composition gas.
15 Prinn & Fegley (1989) showed thermochemistry was the dominant chemical
16 process in the inner solar nebula where the terrestrial planets formed. At 1 AU they
17 found thermochemistry is 10 times more important than shock chemistry, 40,000
18 times more important than photochemistry, and over 13 million times as important
19 as radiochemistry. For example, absorption of UV radiation by water vapor (the
20 third most abundant gas in the solar nebula after H_2 and He) and scattering by dust
21 dramatically decreases the Ly- α photon flux from the proto-Sun at 1 AU. Hotter,
22 denser conditions inward of 1 AU in the solar nebula made thermochemistry even
23 more important closer to the proto-Sun. This is also due in part to increased

1 abundances at higher temperatures of CO and UV absorbing gases of rock-forming
2 elements (e.g., SiO, SiS, HS, H₂S, AlOH, Al₂O, AlS, AlH, AlO, PO, PN, PS, NaCl, HCl, KCl,
3 KOH, TiO, and TiO₂) that are thermodynamically stable in the inner region of the
4 solar nebula (e.g., see Table 2 and Figures 1-17 of Schaefer & Fegley 2010b). Some of
5 these gases absorb UV light at the same wavelengths as H₂O and others absorb at
6 shorter (e.g. CO, SiO) or longer wavelengths (e.g., H₂S). Methane, CO₂, and NH₃
7 become more abundant and contribute to UV opacity of the solar nebula at a few
8 hundred Kelvin where the CO – CH₄ (625 K at 10⁻⁴ bar total pressure) and N₂ – NH₃
9 equal abundance lines (345 K at 10⁻⁴ bar total pressure) are reached (e.g., see
10 Figures 14-15 in Schaefer & Fegley 2010b). With decreasing temperature below the
11 equal abundance lines, CH₄ and NH₃ become more important until they are the
12 major C- and N-bearing gases. The UV opacity due to all of the gases listed above
13 vanishes once the respective elements condense. For example at 10⁻⁴ bar total
14 pressure Si is 50% in the vapor as SiO and SiS and 50% condensed as forsterite plus
15 enstatite at 1310 K. The UV opacity due to H₂S persists to much lower temperatures
16 because sulfur is 50% condensed as FeS at 664 K. The UV opacity due to water
17 vapor persists until low temperatures of ~ 180 K (10⁻⁴ bar total pressure) where
18 50% of H₂O is in the vapor and 50% is condensed as water ice. At 10⁻⁴ bar total
19 pressure, ammonia condenses as NH₄OH (131 K) and CH₄ as CH₄ clathrate hydrate
20 at 78 K. Thus all of the gaseous UV opacity sources – except for CO – should be
21 absent from the outermost solar nebula.

22 In contrast, chemical modeling of protoplanetary disks by astronomers (e.g.,
23 Henning & Semenov 2013) uses chemical kinetic codes and focuses on lower

1 temperature, lower density disk regions that are “thin” to electromagnetic radiation
2 (e.g., $R \geq 10$ AU beyond the condensation fronts for molecules such as H_2O that
3 absorb UV radiation). Indeed, the calculations of Prinn & Fegley (1989) showed that
4 stellar UV photochemistry is important in these outer nebular regions (see pp. 85-
5 92 of their paper). For example, the CO photochemical models of Lyons and Young
6 (2005) for production of oxygen isotopic anomalies are done at 30 AU and require a
7 far UV flux about 10^3 times larger than the local interstellar medium. But as
8 mentioned earlier, we are interested in the higher temperature, higher density inner
9 disk regions that are opaque (hence convective), where chemical equilibrium is
10 reached within the disk lifetime.

11 In the next 10 – 20 years we can expect quantitative information about the
12 composition of protoplanetary disks from ALMA (Atacama Large Millimeter/
13 submillimeter Array), JWST (James Webb Space Telescope), and other telescopes.
14 Ultimately we may have good constraints on the composition of the dust and gas as
15 a function of radial distance in the solar nebula from astronomical observations of
16 solar metallicity protoplanetary disks, but at the present time we must rely on
17 chemical equilibrium models.

18 Until the discovery of planets and planetary systems around other stars
19 (exoplanets) it was generally believed that the Earth formed at about its present
20 location from the Sun. However, many of the exoplanets discovered to date are gas
21 giant planets very close to their parent stars (e.g., see the catalog at exoplanet.eu).
22 The accepted model for formation of these extrasolar gas giant planets involves
23 formation at much larger radial distances and radial migration inward to their

1 present positions (Perryman 2011). Thus it may be possible that the Earth also
2 formed much farther outward of its present position and migrated inward to one
3 astronomical unit (AU; 1 AU = Earth's average distance from the Sun), e.g., as in the
4 giant gaseous protoplanet models of Cameron and colleagues (DeCampli 1978;
5 DeCampli & Cameron 1979; Slattery 1978). We cannot rule out this model
6 definitively but we think it is extremely unlikely for two reasons. First, formation of
7 the Earth from a giant gaseous protoplanet that has migrated inward to 1 AU
8 involves the loss of large amounts of H₂, He, other noble gases, water, and C-bearing
9 compounds. For example, a solar composition giant gaseous protoplanetary Earth
10 (with 14.96% Mg in the "rocky + metallic" portion as in the bulk Earth) would have
11 to lose ~ 180 Earth masses (M_E) of H₂, ~ 60 M_E of He, and ~ 2.7 M_E of Ne, H₂O, N-,
12 and C-compounds (~ 243 M_E total) to get to its present composition. Second,
13 calculations by DeCampli & Cameron (1979) show that a giant gaseous protoplanet
14 rapidly collapses to a state where removal of light elements (H, He) is impossible
15 within the lifetime of the solar nebula. As a result the formation of the Earth by
16 sedimentation of condensed material within the giant gaseous protoplanet leads
17 instead to a Jovian planet rich in H and He (Slattery 1978; Slattery et al. 1980). It
18 may be interesting to explore the chemistry of giant gaseous protoplanets for
19 application to rocky exoplanets with H₂-bearing atmospheres in other planetary
20 systems. However these models seem irrelevant to formation of the Earth and thus
21 our discussion assumes the Earth formed at 1 AU and accreted material at about this
22 location.

1 Figures 1 and 2 show the chemical equilibrium calculations of Barshay
2 (1981) given as condensate abundances versus inverse radial distance ($1/R$) from
3 the proto-Sun in astronomical units. These calculations are done for a convective
4 solar nebula model with an adiabatic temperature – pressure profile with these
5 characteristics: $T_0 = 600$ K, $P_0 = 10^{-4}$ bar, $R_0 = 1$ AU. The variation of temperature
6 with radial distance and pressure with temperature in the midplane of the nebula
7 are given by (Lewis 1974)

$$\frac{T}{T_0} = \left(\frac{R}{R_0}\right)^{-1.1}$$
$$\frac{P}{P_0} = \left(\frac{T}{T_0}\right)^{C_P/R}$$

8 To first approximation the details of this model are irrelevant because (1) the
9 condensation sequence is relatively insensitive to total pressure (see Fig 1 in Lewis
10 1974; Fig 3.8 in Lodders & Fegley 2011) and (2) other models of the solar nebula
11 accretion disk give the same basic result – T and P decreasing with increasing radial
12 distance from the proto-Sun (e.g., Fig 3.5 in Lodders and Fegley 2011).

13 The major conclusion from Barshay’s chemical equilibrium calculations is
14 that the Earth-forming material at 1 AU should have chondritic relative abundances
15 of rock-forming “metals” (e.g., Mg, Si, Fe, S, Ni, Al, Ca, Na, K, Ti) because compounds
16 of these elements are fully condensed at higher temperatures (smaller radial
17 distances) from the proto-Sun (see the discussion of accretion functions below). His
18 calculations did not include other minor and trace elements (e.g., Cr, Mn, P, Co,
19 refractory lithophiles, refractory siderophiles) that are fully condensed at 600 K in
20 the solar nebula but based on other calculations (e.g., Larimer 1967; Grossman &

1 Larimer 1974; Lewis 1972; Lodders 2003) we know which elements are fully
2 condensed by 600 K, 10^{-4} bar, 1 AU. Barshay's main result thus agrees with
3 arguments of other geoscientists that Earth is chondritic to *first approximation* in
4 major element chemistry (e.g., Wänke 1981; Kargel & Lewis 1993; Palme & O'Neill
5 2014). His results predict a CI chondritic Mg/Si ratio of 0.90 for the Earth (vs. 0.92
6 in our model in Table 2), which is not the case unless significant amounts of Si are
7 dissolved in the core.

8 It is likely that the original composition of solids condensed in the solar
9 nebula was altered – to a greater or lesser extent - as accretion proceeded and
10 grains eventually grew into planetesimal-size meteorite parent bodies. Aqueous
11 alteration, dry thermal metamorphism, and shock metamorphism are evident in
12 various types of chondritic meteorites. For example, thermal metamorphism on
13 meteorite parent bodies altered the chondrites in our meteorite collections.
14 Originally, chondritic material was plausibly more volatile-rich than even the most
15 volatile-rich ordinary chondrite samples in meteorite collections today. The larger
16 volatile abundances in the unequilibrated ordinary chondrites (i.e., the H3, L3, LL3
17 chondrites), which are less metamorphically altered than the grade 4–6 ordinary
18 chondrites, support this argument (Schaefer & Fegley 2007). However, it is also
19 known that even the extensive aqueous alteration on the CI chondrite parent body
20 did not alter their elemental abundances even though their mineralogy was changed
21 (e.g., Anders & Grevesse 1989; Lodders 2003).

22 The question of how collisions may have altered planetesimal compositions
23 is important, but not yet answered. On the one hand collisional mixing is evident in

1 our meteorite collections through the presence of “meteorites in meteorites” –
2 xenoliths of one type of meteorite enclosed in another (Wilkening 1977). On the
3 other hand, the “meteorite in meteorite” samples are the exception rather than the
4 rule. Collisions between large bodies, such as the lunar to Mars size planetary
5 embryos that are believed to have formed the terrestrial planets are very energetic.
6 For example, extensive melting and partial vaporization may have occurred on the
7 post Giant Impact Earth (Lupu et al. 2014; Fegley & Schaefer 2014), but the amount
8 of “volatiles” lost from the post-impact Earth is poorly constrained, and may have
9 been small because of Earth’s large escape velocity (e.g., see Genda & Abe 2003a,
10 2005; Pahlevan 2010; Lupu et al. 2014). Even hydrodynamic escape of vapor from
11 the proto-lunar disk is problematic because of the strong gravity field (Genda & Abe
12 2003b).

13 Collisional erosion is another process suggested to alter composition of
14 planetary embryos by loss of the outer layers, perhaps early formed crust, on the
15 embryos (e.g., O’Neill and Palme 2008). These new models are motivated in part by
16 the ^{142}Nd excess in terrestrial samples (e.g., Boyet & Carlson 2005; Caro & Bourdon
17 2010) but as argued by Huang et al. (2013) the observed excesses are within the
18 range of observed ^{142}Nd variations in chondritic meteorites. Another motivation is
19 the high metal to silicate ratio of the planet Mercury. In this case the geochemical
20 analyses by the MESSENGER spacecraft support the idea that much of its silicate
21 portion was lost by collisional erosion (e.g., see Cameron et al. 1988 for a discussion
22 of alternative models for producing Mercury’s high metal to silicate ratio). Excluding

1 the planet Mercury, we conclude that at present we simply do not know how
2 collisions of planetary embryos altered their chemical compositions.

3 What is clear is that the terrestrial planets accreted material formed over a
4 range of radial distances in the solar nebula. Barshay (1981) modeled this process
5 by convolving his nebular chemistry calculations with simple accretion functions
6 (e.g., square wave, triangular, Gaussian) with variable widths defined by the full
7 width at half maximum ($\text{FWHM} = 0.06 - 0.60 \text{ AU}^{-1}$). This may have been the first
8 attempt to combine a model of solar nebula chemistry with a model of planetesimal
9 accretion. Barshay (1981) used accretion functions of different geometric shape and
10 size as a proxy for planetary accretion from smaller planetesimals over a range of
11 radial distances (Figure 3 - 5). For example, if Earth collected material within a
12 Gaussian accretion function centered at 1 AU^{-1} with FWHM of 0.60 AU^{-1} , its feeding
13 zone stretched from $0.625 - 2.50 \text{ AU}$ (i.e., inward of Venus at 0.723 AU to outward of
14 Mars at 1.52 AU). The smaller width accretion functions simulate smaller feeding
15 zones. The narrowest accretion functions studied correspond to a feeding zone of
16 $0.94 - 1.06 \text{ AU}$ for Earth. It is possible that Earth, Venus, and Mars had different size
17 feeding zones and that the size of the feeding zones of each planet varied with time.

18 Barshay compared the zero pressure density; mean atomic weight, and
19 volatile element mass fractions (for water, carbon, and sulfur) for the Earth and
20 other terrestrial planets for different accretion functions of variable width. The zero
21 pressure density is the uncompressed density of the mineralogy for each planet and
22 the mean atomic weight in atomic mass units (amu) is the atom fraction weighted
23 atomic weight of all metal - and rock - forming elements, e.g.,

$$\bar{\mu} = F_O\mu_O + F_{Si}\mu_{Si} + F_{Mg}\mu_{Mg} + F_{Fe}\mu_{Fe} + F_S\mu_S + F_{Al}\mu_{Al} + F_{Ca}\mu_{Ca} + \dots$$

1 The general equation for computing the mean atomic weight is thus

$$\bar{\mu} = \sum_i F_i\mu_i$$

2 The index “i” represents an element and the summation is carried out for all
 3 elements in the calculations. For example, the mean atomic weight of the bulk Earth
 4 models in Table 2 are 25.2 (MF14), 25.9 (Kargel & Lewis 1993), 26.2 (McDonough
 5 2003), and 26.3 (Morgan & Anders 1980). The BSE model of Palme & O’Neill (2014)
 6 has a mean atomic weight of 21.1 amu. Figure 5 shows calculated mean atomic
 7 weights of ~ 25.2 to ~ 25.7 for the widest to narrowest Gaussian accretion
 8 functions, respectively. These values fall within the range of mean atomic weights
 9 for our bulk Earth model (MF14) and Kargel & Lewis (1993). Higher mean atomic
 10 weights, like those from the McDonough (2003) and Morgan & Anders (1980) bulk
 11 Earth models, are produced in the square wave and triangular accretion function
 12 calculations in Figures 3 and 4.

13 For comparison the mean atomic weights (in amu) of some of the major
 14 chondrite groups are 15.0 (CI), 17.2 (CM), 22.4 (CV), 24.0 (CO), 24.7 (H), 23.3 (L),
 15 22.7 (LL), and 25.9 (EH). The values for the EH and H chondrites are closest to those
 16 for the bulk Earth models in Table 2 and in Figures 3-5. The variations in the mean
 17 atomic weight of the different chondrite groups are related to their volatile (water,
 18 C, N) content (e.g., compare CI vs. CM, CV, CO chondrites) and Fe content (e.g.,
 19 compare H, L, LL chondrites).

1 Another important conclusion from Barshay (1981) is that the chemical
2 compositions (i.e., mean atomic weight) of the terrestrial planets Venus, Earth, and
3 Mars are similar to one another because their accretion zones overlapped one
4 another in the solar nebula. These results are consistent with prior ideas that the
5 Earth formed from a mixture of nebular materials (e.g., the two component models
6 of Ringwood and Wänke). It would be interesting to update his work using more
7 sophisticated models of planetary accretion.

8 **B-2. BSE and Bulk Earth composition**

9 **Similarity to chondritic meteorites (chondrites)**

10 The overall composition of the BSE (in particular see Table 1 and Fig 2 in
11 Palme & O'Neill 2014) and bulk Earth (e.g., Larimer 1971; Kargel & Lewis 1993) is
12 close to chondritic, i.e., the relative proportions of the major rock-forming elements
13 (Mg, Si, Fe, S, Al, Ca) are close to those found in chondritic meteorites (chondrites).
14 Before discussing this point in more detail we present some background
15 information about chondritic meteorites.

16 Chondrites are the most abundant kind of meteorites. They are unmelted
17 stony meteorites that contain Fe-Ni metal alloy, silicate, sulfide, and oxide minerals
18 in variable proportions. The chondrites are the oldest objects in the solar system
19 with ages up to ~ 4.567 Ga (e.g. Amelin et al. 2002; Bouvier et al. 2007; Jacobsen et
20 al. 2008). The relative abundance of rock-forming elements in chondrites is close to
21 their relative abundances in the solar photosphere (e.g., Anders & Grevesse 1989;
22 Lodders 2003; Palme et al. 2014; Suess & Urey 1956). Atmophile elements such as
23 H, C, N, O, and noble gases are depleted relative to solar composition, and the light

1 elements Li and B are enriched relative to solar composition (because they are
2 destroyed by thermonuclear reactions in the Sun), but otherwise there is a close
3 match between the composition of chondrites and that of the Sun. The five CI
4 carbonaceous chondrites (Alais, Ivuna, Orgueil, Revelstoke, and Tonk), all of which
5 are observed falls, are the closest in composition to the solar photosphere (Anders &
6 Grevesse 1989; Lodders 2003; Palme et al. 2014).

7 The major different classes of chondrites, and the major groups within each
8 class, are (1) carbonaceous chondrites (CI, CM, CO, CV, CK, CH, CB), comprising 3.1%
9 by number of all chondrites, (2) ordinary chondrites (H, L, LL), which are 96.2% of
10 all known chondrites, (3) enstatite chondrites (EH, EL), making up 0.6% of all
11 chondrites, and (4) other chondritic classes (R, K) that are <0.1% of all chondrites
12 (Krot et al. 2014). The different classes of chondrites are distinguished by different
13 metal/silicate abundances, lithophile element ratios (e.g., Mg/Si, Al/Si, Na/Si), redox
14 state, and oxygen isotopic (16, 17, 18) composition. All chondrites have been heated
15 to varying extents and chondrite metamorphic grades are distinguished by various
16 chemical and petrographic criteria such as presence or absence of glass,
17 homogeneity of ferromagnesian silicates, abundance of volatile elements and
18 presolar grains (McSween et al. 1988; Huss et al 2006).

19 As mentioned above, the chondrites are the most abundant kind of
20 meteorites, and achondrites (melted stony meteorites), stony – iron meteorites, and
21 iron meteorites are less abundant. As of the time of writing (June 2014), there are
22 44,332 known chondritic meteorites out of 47,520 meteorites of all kinds. Strictly
23 speaking these statistics only give the abundance of meteoritic material in orbits

1 that intersect the Earth and not the abundance of meteoritic material formed in the
2 solar nebula and early solar system or existing in the asteroid belt today (e.g.,
3 Cloutis et al. 2014). We return to this question in the next section.

4 **Chondritic material.**

5 We emphasize that chondrites are not *pristine* samples of nebular material
6 because the compositions of chondrites have been more or less altered by dry
7 thermal metamorphism and/or aqueous alteration on their meteorite parent bodies
8 (McSween et al. 1988; Huss et al. 2006). As discussed in the rest of this chapter we
9 are interested in determining the type(s) of chondritic material that was (were) the
10 building block(s) of the Earth. Following Schaefer & Fegley (2007, 2010) and Fegley
11 & Schaefer (2014) we use the term “chondritic material” to refer to the pristine
12 nebular material that formed chondrites. Thus carbonaceous chondritic material
13 was the nebular precursor to carbonaceous chondrites, ordinary chondritic material
14 was the nebular precursor to ordinary chondrites, and enstatite chondritic material
15 was the nebular precursor to enstatite chondrites. Using this nomenclature, we do
16 not have samples of chondritic material in our meteorite collections. Interplanetary
17 dust particles (IDPs) are another analog to the chondritic material that existed in the
18 solar nebula, but their bulk chemical and isotopic compositions are not as well
19 known as that of meteorites. Perhaps in the future returned samples of relatively
20 unaltered interior regions of comets will provide a closer approach to the original
21 composition of some types of chondritic material. At the present time chondritic
22 meteorites are the best samples that we have available; hence we use them in our
23 discussion.

1 **Preferred bulk Earth model**

2 Table 2 gives our composition (MF14) for the bulk Earth based on BSE and
3 core compositions given in the literature (e.g., Badro et al. 2014; Lodders & Fegley
4 1998, 2011; McDonough 2003; Palme & O'Neill 2014) and from arguments in this
5 paper. It is calculated using equations analogous to the one for the bulk earth
6 concentration of Mg, i.e., a weighted average of BSE and core concentrations of each
7 element. Our bulk Earth composition uses the best-fit core composition of Badro et
8 al. (2014), and solar Fe/Ni and Fe/Co ratios in the core. The bulk Earth oxygen
9 abundance is identical to the arithmetic mean value for H-chondrites (within 1σ
10 uncertainty), but the Mg/Si ratio is much higher than that for H-chondrites (0.82)
11 and is identical to that for the more oxidized CO chondrites.

12 This may not be unexpected because Hart & Zindler (1986) emphasized that
13 “the Earth is not like any chondrite (in major elements) but is composed of its own
14 blend of accretion products, with a bias toward a higher proportion of the high
15 temperature refractory components (or equivalently, a lower proportion of the
16 volatiles and partially refractory components).”

17 Also, if Earth sampled material from a range of radial distances in the solar
18 nebula, as physical accretion models predict (e.g., see the review by Chambers
19 2014), it will contain material of variable elemental composition. For example, the
20 amount of oxidized Fe (FeSiO_3 in pyroxene, Fe_2SiO_4 in olivine, and magnetite)
21 increases with decreasing temperature in the solar nebula (see Figures 1 and 2).

22 Badro et al. (2014) also found a core model containing 5.4% O, remainder Fe-
23 Ni alloy also fit the seismic velocity and density data. In this case we compute a bulk

1 Earth model with ~ 35.3% O, 14.3% Si, 29.8% Fe, 1.68% Ni, and otherwise identical
2 to that shown in Table 2. The oxygen abundance for this model is intermediate
3 between the average values for H (33.86%) and L chondrites (36.93%), but the
4 Mg/Si ratio of 1.05 is significantly higher than that of H (0.82) and L (0.80)
5 chondrites or any of the major chondrite groups.

6 **Chondritic vs. Achondritic Earth**

7 Larimer (1971) considered whether the Earth is chondritic or achondritic
8 (like eucrites) and concluded it is chondritic to first order. His arguments are worth
9 revisiting because dating by three relative chronometers (^{182}Hf – ^{182}W , ^{26}Al – ^{26}Mg ,
10 and ^{53}Mn – ^{53}Cr) indicates that the EHD (eucrite – howardite – diogenite, presumably
11 from the asteroid 4-Vesta) meteorite parent body differentiated during the first 1–
12 10 Ma of solar system history (e.g., Jacobsen et al., 2008; Schiller et al., 2011;
13 Trinquier et al., 2008). The EHD meteorites are the major kind of achondrites (51%
14 of all achondrites by number). Lead–lead (^{207}Pb – ^{206}Pb), ^{26}Al – ^{26}Mg , and ^{53}Mn – ^{53}Cr
15 dating also indicate that the parent body of the Asuka 881394 basaltic meteorite
16 formed and differentiated within 3 Ma of solar system formation (Wadhwa et al.,
17 2009). Consequently, Earth may have accreted a mixture of chondritic and
18 achondritic material during its formation.

19 Table B-3 compares abundances of volatile lithophile elements in the bulk
20 silicate Earth, average ordinary chondrites, and in the silicate portion of the eucrite
21 parent body – here called bulk silicate Vesta BSV. (The bulk silicate Vesta models are
22 described in the references cited.) Table B-3 shows that the bulk silicate Earth is
23 depleted in volatile lithophiles relative to ordinary chondrites by factors of 0.04 (for

1 C and N) to 0.66 for F. Zinc, which behaves both as a lithophile and chalcophile, is
2 not depleted relative to ordinary chondrites in the BSE. The large depletions for C
3 and N in the BSE may also reflect their partial sequestration in the Earth's core as
4 both elements occur in meteoritic metal and behave as siderophiles under some
5 conditions. We do not give H contents for BSV because no reliable data are available.
6 Sarafian et al. (2013, 2014) report analyses of OH-bearing apatite in eucrites but the
7 H₂O content of the parental melts cannot be determined uniquely from apatite
8 analyses (Boyce et al. 2014). The depletions for the alkalis (Na 0.37, K 0.30, Rb 0.29,
9 Cs 0.30) are well known (e.g., Gast 1960; Hurley 1968; Larimer 1971) although the
10 BSE data of Palme & O'Neill (2014) correspond to larger alkali abundances (i.e.,
11 smaller depletions) than estimated earlier. The explanations proposed for the
12 observed alkali depletions in the BSE include (1) nebular fractionation of proto-
13 Earth material, (2) evaporative loss during accretion, or (3) sequestration into
14 Earth's core (e.g., see Palme & O'Neill 2014; Kargel & Lewis 1993; Lodders 2000).
15 The first model implies that all elements with similar volatility will be equally
16 fractionated. This is not the case because Zn is much less depleted in the BSE than
17 Rb or Cs, which have similar 50% condensation temperatures (Lodders 2003). The
18 second model requires loss of vapor from Earth's gravity field either by thermal
19 escape or physical blow-off. The third model requires partitioning into Earth's core
20 during its formation, and there is little experimental evidence for this (e.g., Corgne et
21 al. 2007). Whatever the cause(s) for alkali depletion in the BSE may be, Table B-3
22 shows that volatile lithophile element depletions in bulk silicate Vesta are
23 significantly larger than in the BSE. The volatile lithophile depletions on Vesta are

1 presumably either inherited from the material accreted by Vesta or due to heating of
2 Vesta. In any case, achondritic material like the EHD meteorites cannot supply the
3 terrestrial abundances of carbon, nitrogen, halogens (Cl, Br), Zn, or alkalis (Na, K,
4 Rb, Cs). Other types of achondrites are also depleted in volatile lithophiles relative
5 to the BSE, e.g., angrites, mesosiderites, pallasites, and ureilites. The enstatite
6 achondrites (aubrites) contain more volatile lithophiles than other achondrites and
7 are an exception.

8 It is unlikely for at least two reasons that the Earth accreted *only* achondritic
9 material during its formation. First, if the Earth did so, then its oxygen isotopic
10 composition would be identical to that of achondritic material, e.g, the eucrites. This
11 is not the case (e.g., see Figure 1 of Lodders & Fegley 1997). Second, chondritic
12 material is significantly more abundant in our meteorite collections and in the
13 asteroid belt than achondritic material (e.g., Cloutis et al. 2014). It would be difficult
14 to believe that the Earth accreted *no* chondritic material. Instead it is more plausible
15 that Earth accreted a mixture of achondritic and chondritic material. Third, the
16 Earth has so many isotopic similarities to enstatite chondritic material that it seems
17 likely that enstatite chondrites and the Earth are somehow related to one another.
18 This could not happen if the Earth formed solely from achondritic material. For
19 example, oxygen isotope mixing models (Lodders 1991, 2000; Lodders & Fegley
20 1997) predict that E-chondritic material is an important building block of the Earth,
21 Mars, and 4-Vesta.

22 It is possible that accretion of volatile – poor achondritic material could be
23 balanced by accretion of more volatile – rich chondritic material. In principle the

1 relative mass fractions of achondritic and chondritic components can be constrained
2 by an oxygen isotopic mixing model (e.g., Lodders 1991, 2000; Lodders & Fegley
3 1997), but this is beyond the scope of this review chapter because the abundances
4 of all natural elements – not only volatile lithophiles – need to be considered
5 simultaneously in the modeling.

6 **Isotopic arguments:**

7 Until the early 1970s, it was assumed that the hot solar nebula was chemically
8 and isotopically homogeneous; however, the discoveries of isotopic anomalies in
9 refractory inclusions of meteorites, which cannot be explained by radioactive decay,
10 cosmogenic effects or mass fractionations, have led to revisions of this concept
11 (Clayton et al. 1973). Planetary processing such as core formation or magmatic
12 differentiation can only produce mass-dependent isotopic fractionations and
13 therefore do not modify isotopic anomalies, so terrestrial surface samples can be
14 considered isotopically representative of the bulk Earth for comparison with
15 meteoritic materials.

16 Following the discovery of oxygen isotopic variations among meteorites and
17 planetary materials, isotopic variability has been found for other elements, and
18 combining these different isotopic systems is one of the best tracers to determine
19 the Earth's building blocks.

20 Isotopic variability between solar system materials can be accounted for by
21 few mechanisms:

22 -Stable isotope fractionations, which originate from vibrational energy partitioning
23 between coexisting phases at equilibrium or under kinetic conditions (e.g.

1 Bigeleisen & Mayer 1947). At first order, this process is proportional to the mass-
2 difference between the isotopes; however, non-mass dependent effects have been
3 observed in some systems (e.g. Thiemens 1999; Moynier et al. 2013).
4 -Nuclear reactions such as the decay of long-lived (e.g. ^{87}Rb - ^{87}Rb) or short-lived (e.g.
5 ^{26}Al - ^{26}Mg) radioactive isotopes or spallation by cosmic rays or solar wind.
6 -Inheritance of isotopic heterogeneities, which originated from an incomplete
7 mixing of nucleosynthetic products. These effects are observed after correction of
8 isotopic ratios for stable isotope fractionation, radioactive decay, and spallation
9 effects.

10 To identify which group(s) of meteorites (if any) represents the composition
11 of the Earth, nucleosynthetic anomalies, radiogenic isotopes produced by short-
12 lived radioactivity (e.g. ^{142}Nd) and stable isotope fractionations (e.g. Si isotopes) can
13 be used. In the following section we will present these different arguments.

14

15 **Applications of isotopic anomalies**

16

17 Since isotopic anomalies cannot be modified by planetary differentiation they
18 are usually considered to be very robust tracers of the Earth's building blocks.

19 Among the different meteorite groups, the Enstatite (E) chondrites are the closest to
20 the terrestrial mantle in term of isotopic composition (See Figure 6). Isotopic
21 anomalies are either reported as the deviation from the mass-fractionation line in a
22 three-isotope diagram (the so-called Δ notation (e.g. $\Delta^{17}\text{O}$)) or using the ϵ -notation
23 which represents the per ten thousand deviation of an isotopic ratio normalized to

1 another isotopic ratio of the same element. Therefore, isotopic anomalies can only
2 be investigated for elements with at least three isotopes.

3 Elements for which isotopic anomalies have been found in one or more
4 groups of meteorites are: oxygen (e.g. Clayton 1993), titanium (Trinquier et al.
5 2009; Zhang et al. 2012), calcium (Simon et al. 2009; Moynier et al. 2010),
6 chromium (e.g. Trinquier et al. 2007; Qin et al. 2010), nickel (e.g. Regelous et al.
7 2008; Steele et al. 2012), strontium (Moynier et al. 2012), zirconium (Akram et al.
8 2013), molybdenum (e.g. Dauphas et al. 2002; Yin et al. 2002; Burkhardt et al.
9 2011), ruthenium (Chen et al. 2010), barium (Carlson et al. 2007, Andreasen and
10 Sharma 2007, Ranen et al. 2007), neodymium (Carlson et al. 2007) and samarium
11 (Andreasen and Sharma 2007). The elements for which all solar system materials
12 have similar isotopic composition within error are: zinc (Moynier et al. 2009), iron
13 (Wang et al. 2011; Tang and Dauphas 2012), tellurium (Fehr et al. GCA 2006),
14 osmium (Yokoyama et al. 2007), silicon (Pringle et al. 2013), and hafnium (Sprung
15 et al. 2010). The absence of isotopic anomalies for some elements but presence of
16 anomalies for others is not completely understood; to date the best explanation
17 suggests a decoupling between the phases carrying the elements with anomalies
18 and those without, which are homogenized to different degrees.

19 Most elements show a similar isotopic composition between the Earth
20 (estimated by measurements of mantle rocks) and enstatite chondrites (EH and EL)
21 (see figure 6). This isotopic coincidence has been used to propose a strong genetic
22 link between the Earth and enstatite chondrites, and in some cases to use enstatite
23 chondrites as the main building blocks for the Earth (Javoy et al. 1995; Javoy et al.

1 2010; Jacobsen et al. 2012). The main problem with making the Earth from enstatite
2 chondrites comes when considering the chemical composition (see above); among
3 other dissimilarities, they have insufficient FeO, low Mg/Si ratio, and overabundant
4 volatile elements. In order to reconcile the chemistry of enstatite chondrites with
5 what we know of the terrestrial mantle, Javoy et al. (2010) proposed that enstatite
6 chondrites were devolatilized prior to accreting to form the Earth (to account for
7 the depletion of the Earth in volatile elements) and that the Earth is chemically
8 heterogeneous and the remainder of the chemical differences are stored in the
9 lower mantle. Alternatively, Jacobsen et al. (2012) proposed that the material that
10 formed the Earth and the E-chondrites had a common nebular precursor, but a
11 secondary event modified the chemical composition of the enstatite chondrites
12 without altering the isotopic composition.

13 It must be noted that three recent studies have shown that the terrestrial
14 isotopic composition of Mo (Burkhardt et al. 2011), Ti (Zhang et al. 2012) and O
15 (Herwartz et al. 2014) do not exactly match E-chondrites and the Earth. While
16 Zhang et al. (2012) do not discuss this possible difference in Ti isotopes between E-
17 chondrites and the Earth, Burkhardt et al. (2011) propose that no known type of
18 chondrites are representative of the bulk Earth for Mo isotopes. However, when the
19 analytical errors are taken into account (see Figure 6) EH are similar to Earth for
20 both Ti and Mo isotopes, while EL are slightly different. In addition, only one EH and
21 one EL have been analyzed for Mo isotopic composition, and more data are needed
22 to resolve this issue.

1 On the other hand, the recent high precision oxygen isotopes of Herwartz et
2 al. 2014 show a clear $\Delta^{17}\text{O}$ difference between the Earth, the Moon (12ppm heavier
3 than Earth) and the E-chondrites (60 ppm heavier than Earth). This represent a
4 major observation which suggests that the Earth cannot be formed from E-
5 chondrites alone as developed above based on major element composition and as
6 we will developed below based on isotope ratio.

7 Another line of interpretation of the isotopic anomalies is that the Earth
8 represents a mixing between different types of chondrites (Lodders 2000, Warren et
9 al. 2011). Lodders (2000) used O isotopic compositions to calculate the best mixing
10 model in order to account for the composition of the Earth and obtained 70% EH,
11 21% H, 5% CV, and 4% CI. Following the same logic, Fitoussi and Bourdon (2012)
12 expanded this work by combining multiple isotopic systems (O, Cr, and Ni isotopes).
13 They found that a good mixing relation would involve 63% LL, 16% CI and 23% CO.

14 Mixing different types of chondrites can clearly reproduce the isotopic
15 composition of the Earth, the very close proximity between E-chondrites and the
16 Earth suggest that these meteorites may have close connection to the Earth in terms
17 of their isotopic composition but does not simply prove that the Earth has been
18 made of E-chondrite materials.

19

20 **Radiogenic isotopes**

21 The discovery of a 20ppm excess of the $^{142}\text{Nd}/^{144}\text{Nd}$ in terrestrial rocks
22 compared to any chondrite group had fundamental consequences on our
23 understanding of the Earth's mantle (Boyet and Carlson 2005). ^{142}Nd is produced by

1 the radioactive decay of ^{146}Sm (half life of 103 Ma). This is a short-lived radioactive
2 system that can only record Sm/Nd fractionation that occurred during the first
3 500Ma of Earth's history. This terrestrial excess in ^{142}Nd has been interpreted as the
4 result of the decay of ^{146}Sm in a suprachondritic Sm/Nd reservoir, which formed by
5 partial melting of the Earth's primitive mantle and is referred to as the early-
6 depleted reservoir (see Carlson et al. this volume). Its counterpart, the early
7 enriched reservoir, with a low Sm/Nd ratio and a depletion in ^{142}Nd (compared to
8 chondrites), would have been either incorporated within the Earth's mantle and not
9 recorded in geological samples (a hidden reservoir, Boyet and Carlson 2005) or lost
10 to space following an asteroid impact (impact erosion, e.g. O'Neill and Palme 2008;
11 Caro and Bourdon 2010). A hidden reservoir would mean that the Earth's mantle
12 has a chondritic composition for the refractory lithophile elements, whereas an
13 impact erosion loss of an early-enriched reservoir would imply that the bulk silicate
14 Earth does not have a chondritic abundance of lithophile elements.

15

16 **Stable isotope fractionation**

17 Stable mass-dependent isotopic variations between meteorites and planetary
18 bodies are attributable to processes that fractionated isotopes during nebular
19 events (e.g. Luck et al. 2003) or during planetary events such as core formation (e.g.
20 Georg et al., 2007; Moynier et al., 2011). Among the major elements, only O, Si, and
21 Ca show mass-dependent isotopic fractionation between different chondrite groups
22 and can potentially be used as tracers of the Earth's building blocks (e.g. Clayton et
23 al. 1993; Fitoussi et al. 2011; Valdes et al. 2014). Other multi-isotopic major

1 elements such as Mg (e.g. Teng et al. 2007) and Fe (e.g. Poitrasson et al. 2004) do not
2 show any mass-dependent isotopic variations between chondrite groups and
3 therefore are not useful to investigate the Earth's building blocks and will not be
4 discussed here.

5 A small heavy Si isotopic enrichment in Bulk Silicate Earth (BSE) compared
6 to chondrites has been interpreted as evidence for the incorporation of ~4-7 wt.%
7 silicon as a light element into the Earth's core (Georg et al., 2007; Fitoussi et al.,
8 2009; Savage and Moynier 2013; Armytage et al., 2011). Fitoussi and Bourdon
9 (2012) used the observation that enstatite chondrites are significantly lighter than
10 Earth in Si isotope compositions to argue that the BSE cannot consist of more than
11 15% of enstatite chondrite precursor material. Their logic was that since the BSE
12 has a $^{30}\text{Si}/^{28}\text{Si}$ ratio ~0.30 permil heavier than the E-chondrites, unrealistically large
13 amounts of Si (>20 wt.%) would need to have entered the Earth's core if the bulk
14 Earth had E-chondritic Si isotope compositions; therefore, the density constraints
15 placed on the amount of light elements in the Earth's core coupled with the fact that
16 E-chondrites are Si-rich significantly limits the amount of E-chondritic material as
17 building blocks of Earth. On the other hand, Savage and Moynier (2013) have shown
18 that the light Si isotopic composition of the E-chondrites is carried by the metal
19 phases, and enstatite minerals have a similar Si isotopic composition to the
20 carbonaceous chondrites. They argued that E-chondrites could not be the building
21 blocks of the Earth, but materials enriched in refractory siderophile elements that
22 condensed in the same region as the E-chondrites could be a major component of
23 the Earth.

1 Calcium isotopes are potentially very useful tracers of the Earth's building
2 blocks, but until recently there were no high precision Ca isotope data available
3 (Simon and DePaolo 2011, showed that different chondrite groups have unique
4 stable Ca isotopic compositions (see Figure 7): the carbonaceous chondrites are
5 isotopically lighter and the E-chondrites are heavier than BSE. On the other hand,
6 the ordinary chondrites were isotopically similar to BSE. This led Simon and
7 Depaolo to exclude E-chondrites and C-chondrites as representative building blocks
8 for the Earth. However, a more recent study has shown that although most C-
9 chondrite groups are isotopically lighter than the Earth, the CO chondrites are
10 similar to Earth in Ca isotopes (Valdes et al. 2014, see figure 7). In addition, this new
11 study has shown that the E-chondrites are similar to the Earth, and therefore it is
12 not possible to exclude the E- chondrites as building blocks of Earth based on Ca
13 isotopes (Valdes et al. 20014; Huang et al. 2012).

14 In conclusion, stable isotopes are not as powerful tracers for the Earth's building
15 block as nucleosynthetic anomalies since their abundances can be modified by
16 planetary processes. However, it seems clear that based on Si isotopes, it is
17 improbable to form the Earth from pure E-chondrites since this would require
18 amounts of Si in the core in excess of 20 wt.%. It should be noted that a recent
19 theoretical study (Huang et al. 2014), has shown that Si isotopes might be
20 fractionated within the mantle. Due to the large difference in pressure within the
21 Earth's mantle, high-pressure minerals containing Si (e.g. perovskite-structured
22 silicate) have a different structure than those at lower pressure (e.g. olivine or
23 ringwoodite). This phenomenon is known as a phase transition and results in a

1 change in atomic bonding, or coordination; the calculations of Huang et al. (2014)
2 indicate that Si isotopes may be fractionated between silicate minerals with
3 different coordinations of Si. If these results are correct, they could have important
4 implications for the composition of the core and the conditions of formation of the
5 Earth. Specifically, even a small fractionation of Si isotopes in the mantle could
6 drastically decrease the need for large quantities of Si in the Earth's core to account
7 for the difference between the measurable upper mantle and chondrites in Si
8 isotope composition. This would change the conclusions regarding the building
9 blocks of the Earth based on the Si isotopes. Since these isotopic fractionation
10 results are only theoretical, this effect must be tested experimentally before strong
11 conclusions can be made. In addition, Pringle et al. (2014) have found that angrite
12 meteorites, which are highly oxidized achondrites, have the same Si isotopic
13 composition as the Earth and therefore different from chondrites. Since these
14 meteorites are oxidized it is very unlikely that the core of the angrite parent body is
15 very rich in Si. These results suggest that other mechanisms of isotopic fractionation
16 (e.g. volatilization) may fractionate Si isotopes in the early solar system, and that Si
17 isotopes might not be such a strong argument to exclude enstatite chondrites from
18 the Earth's building blocks.

19

20 **Conclusions**

21 In this review paper we propose a new estimate for the bulk chemical composition
22 of the Earth by combining seismological observations, chemical analyses of the
23 atmosphere, biosphere, hydrosphere, crust, and mantle, experimental results of

1 elemental partitioning, ratios of elements with very similar geochemical behavior
2 and recent theoretical estimates of the core composition by molecular dynamics
3 simulations of density and sound speed (Table 2). High-precision isotopic studies
4 are fundamental in establishing compositional relationships between meteorites
5 and the Earth. We show that non-mass-dependent isotopic variations, which are not
6 modified by planetary processes, are the best tracers to search for the genetic origin
7 of the Earth since crustal rocks can be directly compared to meteorites. Enstatite
8 chondrites are the meteorites isotopically closest to Earth. However, they are
9 chemically very different from the estimate of the bulk Earth composition (See Table
10 2), which suggests that either (1) the Earth is not made of any known meteorites or
11 from the mixing of different groups of meteorites in proportions that would fit the
12 isotopic composition of the Earth or (2) the Earth and enstatite chondrites share a
13 common ancestor but their chemical evolution diverged early in the Solar System
14 history.

19 **Figure captions**

20 Figure 1. Chemical equilibrium abundances of stable condensates in the solar nebula
21 as a function of inverse radial distance (AU^{-1}) along an adiabatic P – T profile. The
22 condensate abundances are the logarithm of each condensate partial pressure (in
23 bar) if the condensate were vaporized to a molecular gas of the same composition
24 (see the mineral/formula key). The average orbital distances of the terrestrial

1 planets Mercury, Venus, Earth, and Mars are indicated by their astrological symbols
2 along the bottom of the figure. This figure shows the higher temperature region and
3 Figure 2 shows the lower temperature region of the inner solar nebula. Reproduced
4 from Barshay (1981) with the permission of Dr. Barshay.

5

6 Figure 2. Chemical equilibrium abundances of stable condensates in the solar nebula
7 as a function of inverse radial distance (AU^{-1}) along an adiabatic P – T profile. The
8 abbreviation F/N is used where the abundances of feldspar and nepheline are
9 subequal. The total pressure curve gives 10^{-4} times the total pressure at any
10 temperature, e.g., 10^{-4} bar at 600 K. Reproduced from Barshay (1981) with the
11 permission of Dr. Barshay.

12

13 Figure 3. The computed mean atomic mass (amu) as a function of inverse radial
14 distance (AU^{-1}) for square wave accretion functions of variable width (see text). The
15 shape of the square wave accretion function used to generate each curve is drawn to
16 scale and its width is given. The present orbits of the terrestrial planets Mercury,
17 Venus, Earth, and Mars are marked with their astrological symbols along the
18 horizontal scale. Reproduced from Barshay (1981) with Dr. Barshay's permission.

19

20 Figure 4. The computed mean atomic mass (amu) as a function of inverse radial
21 distance (AU^{-1}) for triangular accretion functions of variable width (see text). The
22 shape of the triangular accretion function used to generate each curve is drawn to
23 scale and its full width at half maximum (FWHM) is given. The present orbits of the

1 terrestrial planets Mercury, Venus, Earth, and Mars are marked with their
2 astrological symbols along the horizontal scale. Reproduced from Barshay (1981)
3 with Dr. Barshay's permission.

4

5 Figure 5. The computed mean atomic mass (amu) as a function of inverse radial
6 distance (AU^{-1}) for Gaussian accretion functions of variable width (see text). The
7 shape of the triangular accretion function used to generate each curve is drawn to
8 scale and its full width at half maximum (FWHM) is given. The wings of the Gaussian
9 accretion functions are drawn out as far as the distance at which $\sim 0.1\%$ of the
10 available mass is accreted into the planet. The present orbits of the terrestrial
11 planets Mercury, Venus, Earth, and Mars are marked with their astrological symbols
12 along the horizontal scale. Reproduced from Barshay (1981) with Dr. Barshay's
13 permission.

14

15

16

17

18 Figure 6. Isotopic anomalies for elements which show difference between different
19 meteorite groups. $\Delta^{17}\text{O} = \delta^{17}\text{O} - 0.52\delta^{18}\text{O}$. The $\epsilon^a\text{X}_{b/c}$ corresponds to the per ten
20 thousand deviation of the ratio $^a\text{X}/^c\text{X}$ internally normalized to the $^c\text{X}/^c\text{X}$ ratio (see
21 main text for details). Data are from Clayton and Mayeda (1996, 1999), Clayton and
22 Mayeda (1991), Burkhardt et al. (2011), Chen et al. (2010), Zhang et al. (2012),
23 Trinquier et al. (2009), Moynier et al. (2012), Steele et al. (2012).

Figure 7. Ca isotope composition of various group of meteorites measured by different groups. The data are reported as the permil deviation of the $^{44}\text{Ca}/^{40}\text{Ca}$ ratio compared to the SRM914a standard. Contrary to previously proposed, E chondrites have very similar Ca isotope composition with terrestrial rocks (such are ordinary chondrites, and CO chondrites). Data are from Valdes et al. (2014), Simon and DePaolo (2010), Schiller et al. (2012) and Huang and Jacobsen (2011, 2012).

Table 1 Earth's geochemical reservoirs^a

Reservoir	Mass (kg)	Mass Fractions	
		of Bulk Silicate Earth ^b	of Total Earth
Total Atmosphere	5.137×10¹⁸	1.27×10⁻⁶	8.60×10⁻⁷
Troposphere	4.22×10 ¹⁸	1.05×10 ⁻⁶	7.06×10 ⁻⁷
Stratosphere	0.906×10 ¹⁸	2.25×10 ⁻⁷	1.52×10 ⁻⁷
Upper Atmosphere	4×10 ¹⁵	9.9×10 ⁻¹⁰	6.7×10 ⁻¹⁰
Biosphere	1.148×10¹⁶	2.85×10⁻⁹	1.92×10⁻⁹
Hydrosphere	1.664×10²¹	4.13×10⁻⁴	2.79×10⁻⁴
Total petrosphere^c	4.031×10²⁴	0.9995	0.6748
Continental Crust	1.522×10 ²²	3.77×10 ⁻³	2.55×10 ⁻³
Oceanic Crust	0.845×10 ²²	2.10×10 ⁻³	1.41×10 ⁻³
Total Crust	2.367×10 ²²	5.87×10 ⁻³	3.96×10 ⁻³
Upper Mantle	1.068×10 ²⁴	0.2648	0.1788
Lower Mantle	2.939×10 ²⁴	0.7287	0.4920
Total Mantle	4.007×10 ²⁴	0.9936	0.6708
Total Core	1.941×10²⁴	—	0.3249
Outer Core	1.839×10 ²⁴	—	0.3078
Inner Core	0.102×10 ²⁴	—	0.0171
Entire Earth	5.9736×10²⁴		1.0000

^aModified from K. Lodders and B. Fegley "The Planetary Scientist's Companion," Oxford, New York, NY, 1998.

^bTotal mass of the bulk silicate Earth (BSE) is 4.033×10²⁴ kg.

^cWe define lithosphere as the silicate portion of the BSE, i.e., crust + entire mantle.

	mean μ (amu)	26	25.87	26.21	26.26	15.01	24.68	25.91

^aValues in ppm by mass ($\mu\text{g/g}$) unless otherwise noted for selected elements.

^bThis work using Palme & O'Neill (2014) BSE abundances, that are recomputed as 0.675(BSE value), the best fit core model of Badro et al. 2014 (3.7% O, 1.9% Si, remainder $\text{Fe}_{94}\text{Ni}_6$ by mass), and solar Co/Fe in the core (0.0029 by weight).

Table 3 Volatile elements in bulk silicate Earth, bulk silicate Vesta, and ordinary chondrites

Element	BSV (ppm) ^a	BSE (ppm) ^b	BSV/BSE	Chondrites ^d	BSE/chondrites
H	?	120	?	470	0.26
C ^c	10 – 30	100	0.1 – 0.3	2570	0.04
N ^c	0.05 – 1.3	2	0.025 – 0.65	54	0.04
Zn	0.36	53.5	0.0067	53.2	1.0
Na	757	2590	0.29	6950	0.37
K	66	260	0.25	860	0.30
Rb	0.06	0.605	0.10	2.1	0.29
Cs	0.002	0.018	0.11	0.06	0.30
F	4.8	25	0.19	38	0.66
Cl	4.6	30	0.15	93	0.32
Br	0.03	0.075	0.40	0.5	0.15

^aBSV values are mainly from Dreibus & Wanke (1980) and Dreibus et al. (1997)

^bBSE values are from Palme & O'Neill (2014)

^cCarbon and nitrogen values for BSV are eucrite data from Grady & Wright (2003)

^dAverage ordinary chondrite data are from Schaefer & Fegley (2007, 2010)
