Keywords: Ti-Al ohmic-contacts, Ti_3SiC_2 , p-type 4H-SiC, TFE

Abstract. In this study, the electrical properties of Ti_3SiC_2 based ohmic contacts formed on p-type 4H-SiC(0001) 4°-off substrates were studied. The Ti_3SiC_2 thin films were grown by thermal annealing (from 900°C to 1200°C) of $\text{Ti}_{50}\text{Al}_{50}$ layer deposited by magnetron sputtering. XRD analyzes were performed on the samples to further investigate the compounds formed after annealing. Using TLM structures, the Specific Contact Resistance (SCR) at room temperature of all contacts was measured. The temperature dependence (up to 600°C) of the SCR was studied to understand the current mechanisms at the interface and to determine the barrier height value by fitting the experimental results using the thermionic field emission theory. Aging tests showed that Ti_3SiC_2 based contacts were stable up to 200h at 600°C under Ar.

Introduction

The high-temperature functionality of SiC devices is useless without ohmic contacts that are also capable of operation under the same conditions. However, during long-term operation at high temperatures, reactions between metal and SiC can continue to evolve, thus leading to an alteration of the interface properties. The aim of this work is to realize an ohmic contact on p-type SiC that is as stable as possible after high temperature ageing.

P-Type 4H-SiC has a high work function (around 6-7 eV) and it does not exist any conventional metal that leads to low Schottky barrier height when deposited on P-Type 4H-SiC [1]. Such contacts are generally employed containing aluminium [2], and a great deal of attention has been focused on Al-Ti [3]. Toward this aim, Titanium Silicon Carbide (Ti_3SiC_2) is one of the best candidate materials, because this carbide has a very interesting combination of metallic and ceramic properties, together with an excellent chemical stability with SiC. Ti_3SiC_2 can be obtained by annealing of Ti/SiC [4] or Ti-Al/SiC [3].

This paper reports on the electrical characterization of Ti_3SiC_2 ohmic contact to p-type 4H-SiC. We study the effect of Ti-Al annealing temperature for the formation of ohmic contact. Finally, the behaviours of the ohmic contact at very high temperature (up to 600°C) and after 200 h of aging are discussed.

Experimental section

P-type epilayers (~1.3 μm thick) doped with Al in the $[1 - 4] \times 10^{19} \text{ cm}^{-3}$ range on 4H-SiC (0001) 4°off substrates were used. The samples were chemically cleaned to remove any surface pollution. This implied acetone and ethanol ultrasonic degreasing for 5 min each, followed by two times H_2SO_4 : H_2O_2 (2 : 1) for 10 minutes and finally HF acid diluted at 5% for 4 min, before rinsing with deionized water. Then, mesa structures were formed by reactive ion etching (RIE) for isolating the p-layer. After RIE, the samples underwent a second chemical cleaning as mentioned above, which was followed by the deposition of 200 nm $\text{Ti}_{50}\text{Al}_{50}$ stacking by magnetron sputtering from $\text{Ti}_{50}\text{Al}_{50}$ target in a high vacuum system. The deposition was carried out at room temperature with RF plasma formed at an Ar constant pressure of 5×10^{-3} mbar.

After metal deposition, Transfer Length Method (TLM) structures were fabricated on the mesa in order to characterize electrically the metal/SiC p-type contact. The geometric patterns for the TLM measurements were obtained through a photolithographic procedure. The unwanted metal was removed by wet etching using commercial Al-etch solution at 60°C. The TLM contact consists of seven rectangular electrodes (500 $\mu\text{m} \times 100 \mu\text{m}$) with increasing spacing of 3, 6, 10, 20, 40, 80 and 120 μm . For ohmic contact formation, high temperature annealing was performed in a Rapid Thermal Annealing (RTA) furnace under argon at atmospheric pressure with advanced backing steps (3 times pumping followed by argon filling) before the annealing in order to decrease the residual oxygen concentration in the RTA chamber [5]. After a heating rate of 20°C/s the annealing temperature of the 10 min plateau was varied from 900 to 1200°C.

Samples characterizations

Fig. 1-a shows X-ray diffraction (XRD) θ -2 θ scan of typical samples annealed at 900, 1000, 1100 and 1200°C. As seen, the diffraction peaks unambiguously reveal the formation of the hexagonal Ti_3SiC_2 structure which is in epitaxial relation with the substrate. Transmission Electron Microscopy characterization (not shown here) shows that the 4H-SiC substrate is entirely covered by a Ti_3SiC_2 layer, which is itself covered by an Al-riche layer (mixture of pure Al and Al_3Ti) [5]. The current-voltage (I-V) characteristics measured between two adjacent TLM pads (Fig. 1-b) shows a non-ohmic behavior on as-prepared samples and on samples annealed at 900°C. But for the samples annealed at 1000°C or above, I-V behaviors are linear and prove that the contact is ohmic. Fig. 1-c shows the Specific Contact Resistance (SCR) ρ_c extracted from TLM measurements from those contacts that displayed ohmic characteristics. As seen, the SCR increases with annealing temperature. The $\text{Ti}_{50}\text{Al}_{50}$ annealed at 1000°C yielded the lowest SCR of $1.1 \times 10^{-4} \Omega \cdot \text{cm}^2$, and hence this sample was selected for further electrical measurements at high temperature, between 300 K and 875 K.

Fig. 1: (a) XRD patterns of the $\text{Ti}_{50}\text{Al}_{50}$ contacts onto 4H-SiC (0001), after annealing at different temperatures, (b) I-V characteristics measured between 2 adjacent pads as-deposited and after annealing at different temperatures, (c) Evolution of the SCR with the annealing temperature.

From the temperature dependence of the TLM measurements performed on 1000°C annealed sample, the evolution of the sheet resistance (R_{sh}) of the p-layer (Fig. 2) and of the SCR (Fig. 3) were extracted as a function of the measurement temperature. Both R_{sh} and SCR were found to decrease with increasing measurement temperature, respectively from ~ 2 k Ω /sq to 0.2 k Ω /sq and from 1.1×10^{-4} to $9.8 \times 10^{-6} \Omega \cdot \text{cm}^2$.

Fig. 2: Temperature dependence of the R_{sh} of the p-layer for the sample annealed at 1000°C.

Fig. 3: Temperature dependence of the SCR for the sample annealed at 1000°C.

To determine exactly the doping concentration N_A of the p-layer, the R_{sh} experimental data, reported in Fig. 2, were fitted using the expression of the sheet resistance defined by:

$$R_{sh}(T) = \frac{1}{q\mu_p(T)p(T)e} \quad (1)$$

where “ q ” is the elementary charge; “ $\mu_p(T)$ ” is the holes mobility, “ $p(T)$ ” is the free hole concentration and “ e ” is the thickness of the p-layer (in our case $e \sim 1.3 \mu\text{m}$).

The temperature dependence of the holes mobility $\mu_p(T)$ and the free hole concentration $p(T)$ is given by the following relations :

$$\mu_p(T) = \mu_p(300) \left(\frac{T}{300} \right)^{-\beta} \quad (2)$$

$$\frac{p(T) \times (p(T) + N_D) - n_i^2}{N_A - N_D - p(T) + n_i^2 / p} = \frac{N_V}{g} \exp\left(-\frac{E_A}{kT}\right) \quad (3)$$

where “ β ” is an empirical parameter depending on the doping concentration N_A , “ $\mu_p(300)$ ” the hole mobility at 300 K, “ k ” the Boltzmann constant, “ N_D ” the concentration of compensating donors, “ n_i ” the intrinsic carrier density, “ N_V ” the effective density of states in the valence band, “ g ” the degeneracy factor for acceptors and “ E_A ” the ionization energy of acceptors referred to the top of the valence band. This ionization energy is given by [6]:

$$E_A(eV) = 0.265 - 3.6 \times 10^{-8} \left(1 - \frac{N_D}{N_A} \right)^{1/3} N_A^{1/3} \quad (4)$$

Where (N_D/N_A) is the compensation ratio.

In these calculations, the doping concentration N_A and the compensation ratio (N_D/N_A) were considered as fitting parameters. From the best fit in Fig. 2, we found $N_A = 3 \times 10^{19} \text{cm}^{-3}$ (with 3% compensation). This value of N_A was used to determine the Schottky barrier height (ϕ_B) of the contact from the fitting of the SCR experimental data (Fig. 3) using the TFE model. In this model, the SCR can be expressed as [7]:

$$\rho_c = \frac{1}{qA^*} \times \frac{k^2}{\sqrt{\pi(\phi_B + V_p)E_{00}}} \times \cosh\left(\frac{E_{00}}{kT}\right) \times \left[\sqrt{\coth\left(\frac{E_{00}}{kT}\right)} \right] \times \exp\left(\frac{\phi_B + V_p}{E_0} - \frac{V_p}{kT}\right) \quad (5)$$

where:

$$E_{00} = \frac{qh}{4\pi} \left(\frac{N_A}{m^* \epsilon} \right)^{1/2} \quad (6)$$

$$E_0 = E_{00} \coth\left(\frac{E_{00}}{kT}\right) \quad (7)$$

and where “ h ” is Planck’s constant, “ m^* ” the effective mass of the tunneling hole, “ ϵ ” the dielectric permittivity (in the case of SiC, $\epsilon = 9.7\epsilon_0$, ϵ_0 being the vacuum permittivity), A^* the Richardson constant (in the case of SiC, $A^* = 146 \text{ Acm}^{-2}\text{K}^{-1}$) and V_p is the energy difference between the valence-band and the Fermi level.

In these calculations, ϕ_B was considered as fitting parameter. The extracted value of ϕ_B from curve in Fig. 3 is found to be 0.85 eV.

Aging tests on this sample were performed at a constant temperature of 600°C in an Ar atmosphere. The contact resistivity was monitored before and after the tests. In fixed time intervals (24, 48, 100 and 200 hours), the contacts were cooled down to room temperature, and the contact resistivity was measured. After 100 h of ageing, the SCR was found to evolve in a positive way by a decrease below $1 \times 10^{-4} \Omega.\text{cm}^2$ and the value kept rather constant up to 200h, which is the maximum ageing time of this study. This evolution suggests that there may be a slight modification (if any) of the $\text{Ti}_3\text{SiC}_2/\text{SiC}$ interface but this modification is not detrimental to the contact. As a consequence, we believe that Ti_3SiC_2 can be considered as a reliable high temperature ohmic contact on SiC.

Fig. 4: SCR after aging test of the sample annealed at 1000°C.

Summary

We formed epitaxial Ti_3SiC_2 onto 4H-SiC (0001) 4°-off from 200 nm of $\text{Ti}_{50}\text{Al}_{50}$ alloy, deposited by sputtering and annealed in a rapid thermal annealing. According to the TLM measurements, the sample annealed at 1000°C resulted in the lowest SCR ($1.1 \times 10^{-4} \Omega.\text{cm}^2$) and hence was selected for the high temperature characterizations. The temperature dependence of the SCR indicated that thermionic field emission is the dominant transport mechanism and the extracted values of ϕ_B from TFE model is 0.85 eV. Finally, to investigate the thermal stability of Ti_3SiC_2 contact, aging tests done at 600°C up to 200h led to SCR decrease which is very promising for high temperature use of bipolar SiC with ohmic contacts on p-type epilayers.
