10 **Abstract:**

11 Some portions of the porous rock matrix in the karst unsaturated zone (UZ) can contain large
12 volumes of water and play a major role in water flow regulation. The essential results are presented
13 of a local-scale study conducted in 2011 and 2012 above the Low Noise Underground Laboratory
14 (LSBB – Laboratoire Souterrain à Bas Bruit) at Rustrel, southeastern France. Previous research
15 revealed the geological structure and water-related features of the study site and illustrated the
16 feasibility of specific hydrogeophysical measurements. In this study, the focus is on hydrodynamics at
17 the seasonal and event time scales. Magnetic resonance sounding (MRS) measured a high water
18 content (more than 10 %) in a large volume of rock. This large volume of water cannot be stored in
19 fractures and conduits within the UZ. MRS was also used to measure the seasonal variation of water
20 stored in the karst UZ. A process-based model was developed to simulate the effect of vegetation on
21 groundwater recharge dynamics. In addition, electrical resistivity tomography (ERT) monitoring was
22 used to assess preferential water pathways during a rain event. This study demonstrates the major
23 influence of water flow within the porous rock matrix on the UZ hydrogeological functioning at both
24 the local (LSBB) and regional (Fontaine de Vaucluse) scales. By taking into account the role of the
25 porous matrix in water flow regulation, these findings may significantly improve karst groundwater
26 hydrodynamic modelling, exploitation, and sustainable management.

27 **Keywords:** Karst, France, Hydrogeophysics, Carbonate rocks, Matrix porosity

28 **1. Introduction**

29 Karstified rocks cover a large portion of the world's surface (Gunn 2004), particularly around the
30 Mediterranean Sea (Bakalowicz and Dörfli 2005). Unfortunately the complexity of karst
31 hydrosystems continues to impede sustainable water exploitation and management (e.g. Mangin
32 1975; Bakalowicz 1995; Ford and Williams 2007; Goldscheider and Drew 2007; White 2007). In the
33 context of climate change, additional stress on water resources may require more intense
34 exploitation of karst hydrosystem water resources. These factors and sustainable management
35 require improved knowledge about how karst hydrosystems function.

36

37 **Fig. 1:** Karst system model showing the Fontaine de Vaucluse hydrosystem and the Low Noise
38 Underground Laboratory of Rustrel (LSBB).
39

40 Karst is a complex medium with multi-scale heterogeneity. Water flow pathways are present
41 throughout the entire medium, from rock matrix to fractures and karst features (Fig. 1). The
42 hydrodynamic role of these water pathways is still poorly understood (e.g. Bailly-Comte et al. 2010)
43 and water flow regulation within karst hydrosystems remains an important issue. On one hand, karst

44 hydrosystems have high permeability because a large amount of water moves quickly through karst
45 conduits and rapid pressure transfer occurs. On the other hand, karst hydrosystems provide an
46 important buffer effect because spring discharge remains high even during long dry periods, as at the
47 Fontaine de Vaucluse spring in France. Several hypotheses have been advanced to explain the
48 important water flow regulation capacity of karst hydrosystems: (i) significant water storage within
49 the saturated zone in karst conduits (e.g. Mangin 1975; Marsaud 1996); (ii) water storage in the
50 epikarst, (fractured and weathered near-surface karst) (e.g. Aquilina et al. 2006; Ford and Williams
51 2007); and (iii) delayed infiltration or travel time within the entire unsaturated zone (UZ) (e.g. Celle-
52 Jeanton et al. 2003; Emblanch et al. 2003; Mudarra and Andreo 2010; Mudarra et al. 2012). However,
53 this regulation capacity within the UZ is not related to identified geological features (e.g. fractures,
54 matrix). Finally, few researchers consider water storage in the UZ zone to be significant enough to
55 play a role in water flow regulation and the capacitive function of karst.

56 Due to these complexities, distributed hydrogeological modeling of karst systems remains difficult to
57 implement and is not often done (e.g. Kiraly 1998; Larocque et al. 1999; Scanlon et al. 2003;
58 Worthington 2009; Worthington and Ford 2009). The usual approach to karst hydrosystems is the so-
59 called “black box” model (e.g. Mangin 1975; Marsaud 1996; Labat et al. 2000a; Labat et al. 2000b;
60 Rimmer and Salinger 2006; Fleury et al. 2007; Moussu et al. 2011; Hartmann et al. 2012). However,
61 “black box” models are site-specific. The lack of physics and geology in such models makes difficult their
62 transfer from one karst system to another. Moreover, “black-box” modeling (e.g. Fleury et al. 2007) and
63 hydrochemical estimates (e.g. Batiot et al. 2003) have indicated large residence time differences
64 within a single karst hydrosystem.

65 Most techniques traditionally used in hydrogeology are of limited success in a complex and
66 heterogeneous media such as karst (Bakalowicz 2005). Hydrogeologists often apply techniques
67 commonly used in surface hydrology, such as natural and artificial tracers or rainfall/runoff models.
68 In recent years, surface based geophysics was added to the methodological suite to improve the
69 analysis of spatial and temporal variability of underground properties (Berkowitz 2002). Numerous

70 techniques are available, each with its strengths and weaknesses. Chalikakis et al. (2011) proposed a
71 general overview of geophysical methods for karst media and more recently Kaufmann and
72 Deceuster (2014) published an overview on the use of geophysical surveys to detect ghost rock. In
73 recent years, an increasing number of hydrogeophysical projects aimed at studies of karst
74 hydrogeological functioning have appeared (e.g. Jacob et al. 2008; 2009; 2010; Gondwe et al. 2010;
75 Zhu et al. 2011; Deville 2013; Mazzilli et al. 2013).

76 This paper presents an integrated hydrogeophysical approach based on several ground-based
77 geophysical methods combined with geological and hydrogeological techniques. This integrated
78 approach provides additional insight into karst UZ structure and functioning. It also proposes a
79 conceptual hydrogeological model to explain the multi-annual dynamics of the studied karst
80 hydrosystem. This conceptual model will likely promote additional and more accurate hydrodynamic
81 modeling. The methodological approach was developed and tested in a typical Mediterranean karst
82 hydrosystem observatory: The Fontaine de Vaucluse – Low Noise Underground Laboratory (LSBB)
83 karst watershed.

84

85 ***2. Experimental site***

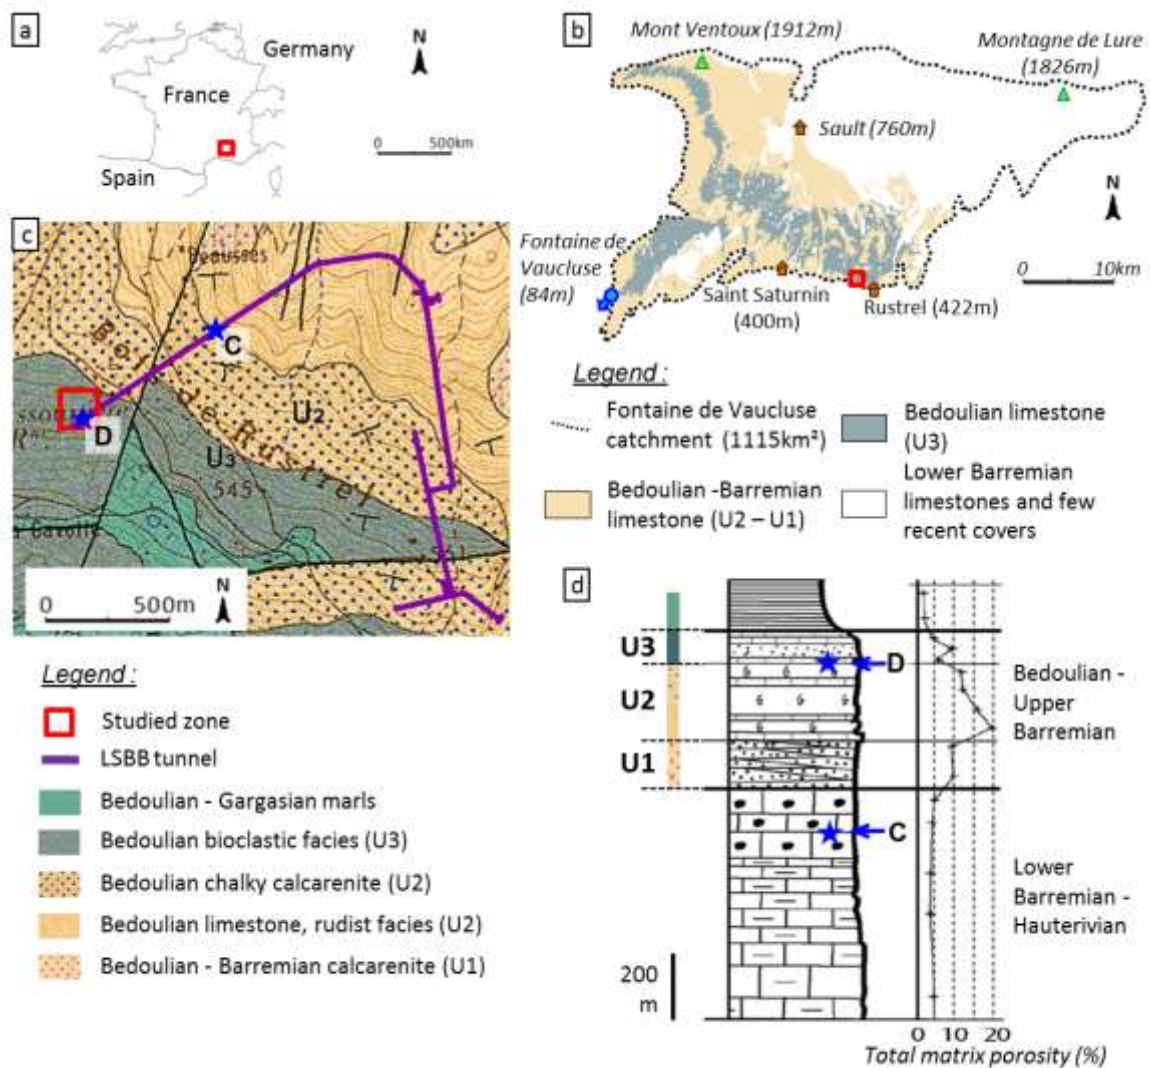

86 ***2.1. General geological and hydrogeological context***

87 The LSBB, a nearly horizontal underground passageway originally dug for military purposes, was
88 converted to a research laboratory in 1997 (Fig. 1 and 2c). It is situated in the Fontaine de Vaucluse
89 hydrosystem karst UZ, in the village of Rustrel. The rock cover over the passageway ranges in
90 thickness from 0 to 519 m depending on the topography. The general saturated zone of the karst
91 system is approximately 400 m beneath the LSBB. The 3.8 km long passageway traverses the karst
92 medium and arbitrarily intersects faults and karst networks. As a result, the passageway also
93 intersects some flow paths in the UZ. Since 2003 more than 61 flow points have been identified and
94 studied within the laboratory. Three of the flow points are permanent and 58 are temporary; they

95 are located between approximate depths of 33 m and 440 m (Garry 2007; Blondel 2008; Barbel-
96 Perineau 2013).

97 One permanent flow point is located 33 m below the surface at the western extremity of the LSBB
98 passageway (Fig. 2c). This point, called “point D,” has an average discharge of approximately
99 130 mL/min (Perineau et al. 2011). The flow at point D is of great hydrogeological interest because it
100 occurs in a featureless zone in a karst environment: no major fault, no apparent karstification (in
101 both surface - exokarst - and at depth); furthermore, it is located several tens of meters below the
102 so-called “epikarst” zone (according to Mangin's schema (Mangin 1975)). However, it presents
103 surprisingly smooth water dynamics compared to other flow points in the LSBB. The flow at D has
104 sometimes increased after a rain event; however at other times flow has remained unchanged after
105 a similar amount of rain (Barbel-Perineau 2013). The geological context associated with this puzzling
106 hydrogeological behavior led to a research focus on the area located above point D.

107 The study site is located within the Fontaine de Vaucluse karst hydrosystem in southeastern France.
108 The Fontaine de Vaucluse is the largest karst spring in Europe; between 1877 and 2004 it produced
109 an average daily outlet discharge of 19 m³/s (Cognard-Plancq et al. 2006). The catchment area is
110 approximately 1115 km² (Fig. 2b) and the karst UZ is particularly thick; its average thickness is
111 approximately 800 m (Puig 1987). The large size is due to the presence of a nearly 1500 m thick
112 massive and continuous limestone (Masse 1969; 1976) comprising Nocomanian marls to upper
113 Aptian marls. A part of this carbonate platform is composed of reef limestone, which may reach a
114 thickness of approximately 450 m in the region (Fig. 2d). This reef limestone contains Urganian facies
115 that are traditionally divided into three sub-divisions: U1, U2, and U3 (Leenhardt 1883). A part of this
116 Urganian limestone has exceptionally high total matrix porosity for a limestone and it covers at least
117 half of the Fontaine de Vaucluse catchment (e.g. Masse 1969; Léonide et al. 2014). However, the role
118 of this porosity in water dynamics is still unknown.

119

120 **Fig. 2:** (a) The Fontaine de Vaucluse basin located in France; (b) The Rustrel experimental site located in the Fontaine de Vaucluse basin; (c) Excerpt of local geological map, n°942 (after Blanc et al. 1973); (d) Total porosity of limestone outcropping on Fontaine de Vaucluse hydrosystem measured in a small sample (after Guglielmi 2010).

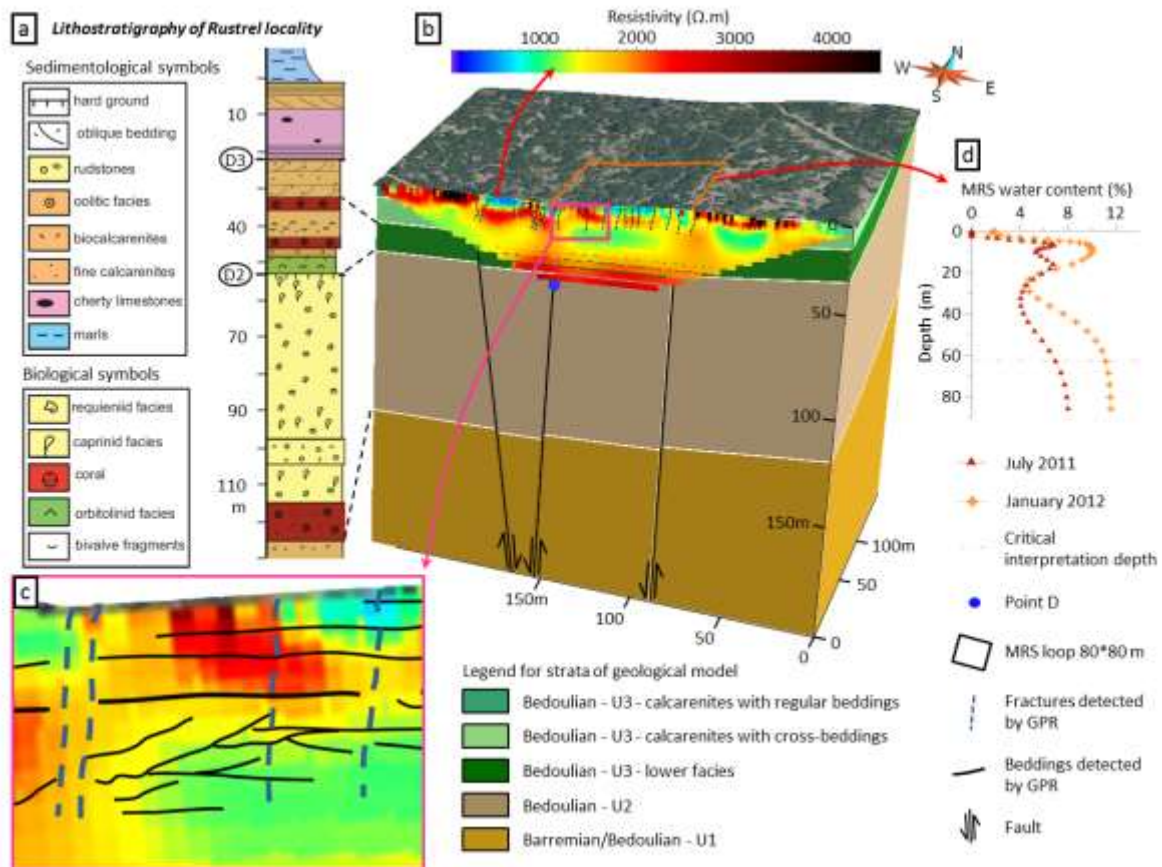

122

125 2.2. Local geological structure investigated in previous studies

126 The geological structure of the study site was investigated using geophysical and geological surveys (Carrière et al. 2013) and geological modeling (Ollivier et al. 2013). To detect geological structure, a combination of ground penetrating radar (GPR) and electrical resistivity tomography (ERT) were used to identify geological features that may impact groundwater dynamics. The GPR results provide near surface high-resolution imaging and thus can provide relevant geological information such as stratification and fractures (Fig. 3b and c). Despite the exceptional quality of the results, GPR's

132 investigational depth remains limited to around 12 m. ERT is able to investigate down to 40 m, but it
133 is an integrative technique that has lower resolution than GPR. In the study area, the investigated
134 limestone is commonly an electrically resistive formation (more than 2000 Ω .m). However, below a
135 depth of 5-7 m, the ERT profiles reveal several zones of moderate resistivity (around 900 Ω .m). In
136 these zones, cross-stratifications were clearly identified by GPR. The combination of both GPR and
137 ERT results, in addition to field geological studies and geotechnical observations (recorded during
138 underground passageway construction), lead to a well-founded geological interpretation (Fig. 3).
139 Cross-stratifications formed under certain sedimentation conditions (high energy, for example) may
140 have produced a more porous limestone. However, during the first phase of the study, it was
141 impossible to determine the exact role of the identified geological features. What are the respective
142 roles of the detected faults, fractures, or crushed zones? Is it possible to monitor water recharge
143 dynamics in the moderate resistivity zone? These questions were answered during the second phase
144 of the study presented in this paper.

145 Ollivier et al. (2013) performed geological modeling (Fig. 3b) using GOCAD software to combine all
146 available geophysical, geological, and geotechnical information. This geological modeling made it
147 possible to propose a well-founded interpretation for geological structures and to extend the analysis
148 of the site below the depth investigated by geophysics.

149

150 **Fig. 3:** Comparison between different types of geological and geophysical information: (a) Regional
 151 lithostratigraphic log (Masse and Fenerci-Masse 2011 (modified)); (b) 3D geological model (Ollivier et
 152 al. 2013) with 252 m long electrical resistivity tomography (ERT) section LSBB03, inverted in three
 153 iterations; (c) Zoom on ERT section LSBB03 with bedding and fractures detected by ground
 154 penetrating radar (GPR); (d) Magnetic resonance soundings (MRS) of July 2011 and January 2012
 155 (Carrière, 2014).

156

157 **3. An integrated hydrogeophysical approach: methods and tools**

158 The approach used in this study combines several tools (surface based geophysics, geology and
 159 tectonics, geotechnical information, hydrodynamics, and infiltration modeling) to explain the
 160 functioning of the local hydrosystem.

161

162 **3.1. Effective infiltration assessment**

163 To assess as accurately as possible the effective infiltration entering locally into the karst
 164 hydrosystem, exchanges between soil/plant/atmosphere were modeled using CASTANEA (Davi et al.

165 2005; Dufrêne et al. 2005). This model calculates the effective infiltration by taking into account the
166 following processes: canopy water interception, tree transpiration, soil and litter evaporation,
167 dynamics of soil water content and drainage. This model is based on the Penmann-Monteith
168 equation for calculating evapo-transpiration. The model includes the downregulation of soil drought
169 on transpiration via stomata closure. CASTANEA is a species-specific model that considers features of
170 the forest environment in the study area. CASTANEA was validated in a similar environment
171 (Mediterranean shrubby forest with holm oak) at the Puéchabon site (southern France) using eddy-
172 covariance measurements (Davi et al. 2006; Martin 2012). A requisite inventory of forest species was
173 conducted for a representative zone measuring 120 m by 20 m to define stand-specific input
174 parameters; it included a tree inventory to assess the standing biomass, hemispherical photographs
175 to assess the canopy Leaf Area Index (Davi et al. 2008), and soil pits to estimate soil water content.
176 Meteorological data were recorded at the Centre d'Information Régional Agro-Météorologique et
177 Economique (CIRAME) station at Saint Saturnin-les-Apt (Fig. 2). Between 2004 and 2012, average
178 daily temperatures ranged between -7.2 and 28.7°C. The average annual temperature was 13.5°C
179 and the average annual rainfall was 660 mm.

180

181 **3.2. Flow measurement**

182 The discharge rate at point D has been monitored since 2003 to study the response of the UZ to
183 natural rainfall events (Garry 2007; Blondel 2008; Barbel-Perineau 2013). Flow point D shows smooth
184 hydrodynamic behavior even though it is located at a depth of 33 m (Fig. 4 and 5).

185 Within the LSBB passageway, 42 other flow points have also been monitored since 2003. In this
186 paper, we compare point D to point C; these two points show the maximum difference in terms of
187 hydrodynamics. The measurement frequency was almost weekly (349 measurement campaigns at
188 the end of 2012). Discharges are measured by collecting water in a graduated cylinder over a period
189 of time.

190 **3.3. Geophysics implementation, acquisition strategy, and field constraints**

191 After extensive testing with a large array of geophysical methods (electromagnetic, electric,
192 gravimetric, and nuclear magnetic resonance), (Carrière, 2014), two efficient and accurate
193 techniques were selected to study hydrodynamics at the local scale (few hundred meter squares):
194 ERT and magnetic resonance sounding (MRS). These geophysical techniques make it possible to
195 image temporal variation in complementary physical properties of the subsurface (until 90 m). This
196 variation may be related to variation in water content and thus may shed light on hydrodynamic
197 behavior.

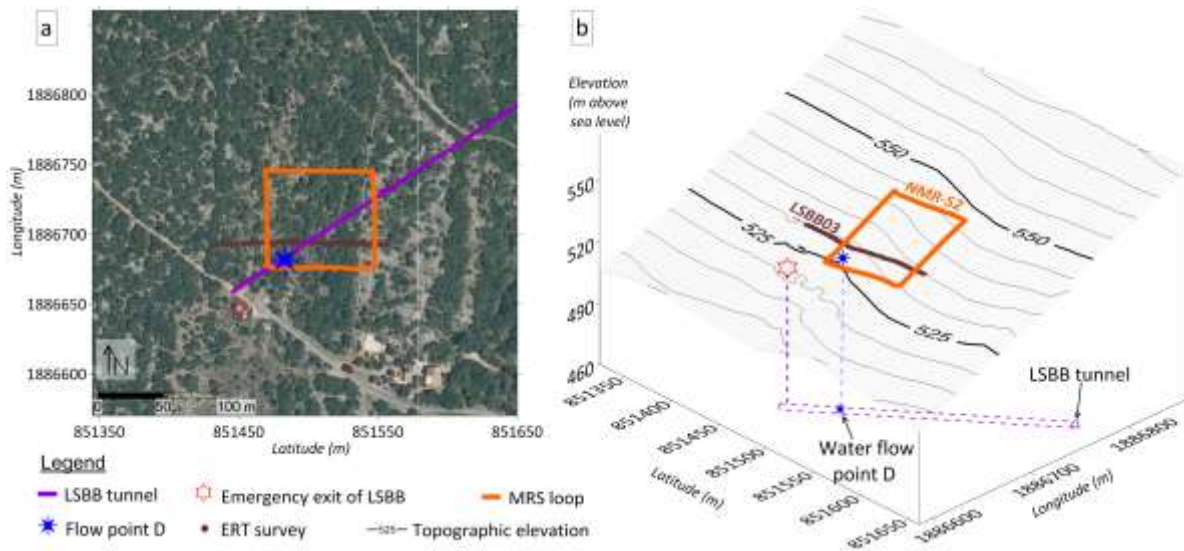

198 Measurements at the study site were conducted at two time scales: (i) with a seasonal time step to
199 detect rough variations, and (ii) with a short time step during a large rain event to detect fast water
200 flows.

201 At the experimental site (Fig. 4), the slope, the vegetation, and the gravel cover required extensive
202 preparation prior to measurements. The exact position of all geophysical measurements was
203 measured with the real time kinematic (RTK) acquisition method every 2 m using the differential
204 global positioning system (GPS) TRIMBLE 5800.

205

206 3.3.1 MRS

207 MRS is the only ground-based geophysical method that can obtain a signal directly related to the
208 presence of water to a depth of several meters. MRS, which is designed for a quantitative description
209 of aquifer formations, is based on the phenomenon of hydrogen proton magnetic resonance. The
210 MRS array generates a signal with a specific frequency to excite the hydrogen protons in water
211 molecules, and the MRS signal received is specifically related to groundwater (e.g. Legchenko et al.
212 2002; Vouillamoz et al. 2003).

213

214 **Fig. 4:** Experimental site of the Low Noise Underground Laboratory (LSBB): (a) location of geophysical
 215 measurements on aerial photo; (b) pseudo 3D location of geophysical measurements discussed in
 216 this paper.
 217

218 The minimal amount of time necessary to conduct an MRS survey (approximately one day per
 219 sounding) and the high cost of the equipment led to the use of this geophysical technique at the
 220 seasonal time step for imaging seasonal variations in water content. Only two MRS surveys were
 221 repeated at the seasonal time step and the results of both show the same dynamics. In this paper,
 222 the temporal variability of only one MRS sounding, MRS S2, is presented and discussed. This
 223 sounding was chosen because it is located above the moderate resistivity zone detected with ERT.
 224 The acquisition system used is a Numis Plus by IRIS instruments. The measurements were collected in
 225 summer (July 2011) and in winter (January 2012). To integrate a large area above water point D, a
 226 wide MRS array (80x80 m) was chosen for these surveys. It is important to mention that for both
 227 MRS surveys, electromagnetic noise was low compared to signal amplitude (ratio signal to noise >1.5)
 228 which ensure interpretability and comparability between measurements (e.g. Legchenko et al., 2002).
 229 The details of MRS results from this site were discussed and presented by Mazzilli et al. (2012) and
 230 Chalikakis et al. (2014). These results indicated the presence of a significant amount of water in the
 231 UZ karst to a depth of 90 m (MRS sometimes indicated a water content greater than 10 %). Eight
 232 MRS were conducted at the experimental site to study the spatial variability of MRS signals. All

233 soundings exhibit similar forms. However, significant lateral variation in water content was observed
234 between soundings (Mazzilli et al. 2012), revealing that the karst UZ is also a heterogeneous
235 environment in terms of water content.

236

237 3.3.2 ERT

238 The ERT technique has been widely used in karst areas because it is robust and reliable (e.g.
239 Cardarelli et al. 2006; Robert et al. 2012). The sensitivity of electrical resistivity to moisture variations
240 and the rapidity of ERT measurements (approximately one hour per section) led to the selection of
241 this geophysical technique to image rapid resistivity variation during heavy rainfall. During the 30 day
242 campaign, ERT time-lapse acquisition ranged from every three hours during the rain event (17 days)
243 to one section a day after the rain event.

244 The acquisition system used is an ABEM Terrameter SAS 4000 (Dahlin 2001) with four channels and
245 64 electrodes. Implantation of the ERT electrodes, mainly at limestone outcrops, required holes that
246 were mechanically dug into the rock; saltwater and mud were added to ensure a good quality ground
247 contact. The ERT section LSBB03 acquired with Gradient array is presented in this paper (Fig. 4). The
248 section is oriented east-west. This direction is perpendicular to the general slope, is sub-
249 perpendicular to one of the main fault and lineament directions, and is the most heterogeneous
250 direction in terms of apparent resistivity spatial distribution (Carrière et al. 2013). The Gradient array
251 was chosen for this survey because of its robustness and its rapidity (Dahlin and Zhou 2004).

252 A portion of the first ERT results were presented by Carrière et al. (2015) to evaluate the
253 effectiveness and technical limits of ERT to monitor water infiltration via previously recognized karst
254 features under natural conditions.

255 Apparent (directly measured) resistivity (ρ_a) analysis is not usually considered in ERT surveys.
256 However, Carrière et al. (2015) demonstrate that with the current technology, in this kind of
257 complicated media, existing inversion schemes are not adequate. It was hoped that raw results with
258 no artifacts related to inversion schemes could provide relevant information. If one analyzes

259 variation in resistivity of inverted sections, it is only possible to observe general evolution of the near
260 surface. Due to its integrative character, the inversion process smooths any fine variation even if one
261 tries to observe only inverted resistivity variation between two consecutive time steps. In this
262 context, apparent resistivity variations ($\Delta\rho_\alpha$) between two consecutive time steps were analyzed.
263 These variations were normalized by the delay (Δ_T) between consecutive measurements (ρ_n and ρ_{n-1})
264 using the following equation (Eq.1).

$$265 \quad \Delta\rho_\alpha = \left(\frac{\rho_{n-1}}{\rho_n} - 1 \right) \frac{100}{\Delta_T} \quad (1)$$

266

267 **4. Results and interpretation**

268 The hydrodynamics of flow points C and D as a function of recharge (rain and effective infiltration) is
269 presented first, followed by the results of geophysical monitoring at both seasonal and event time
270 scales.

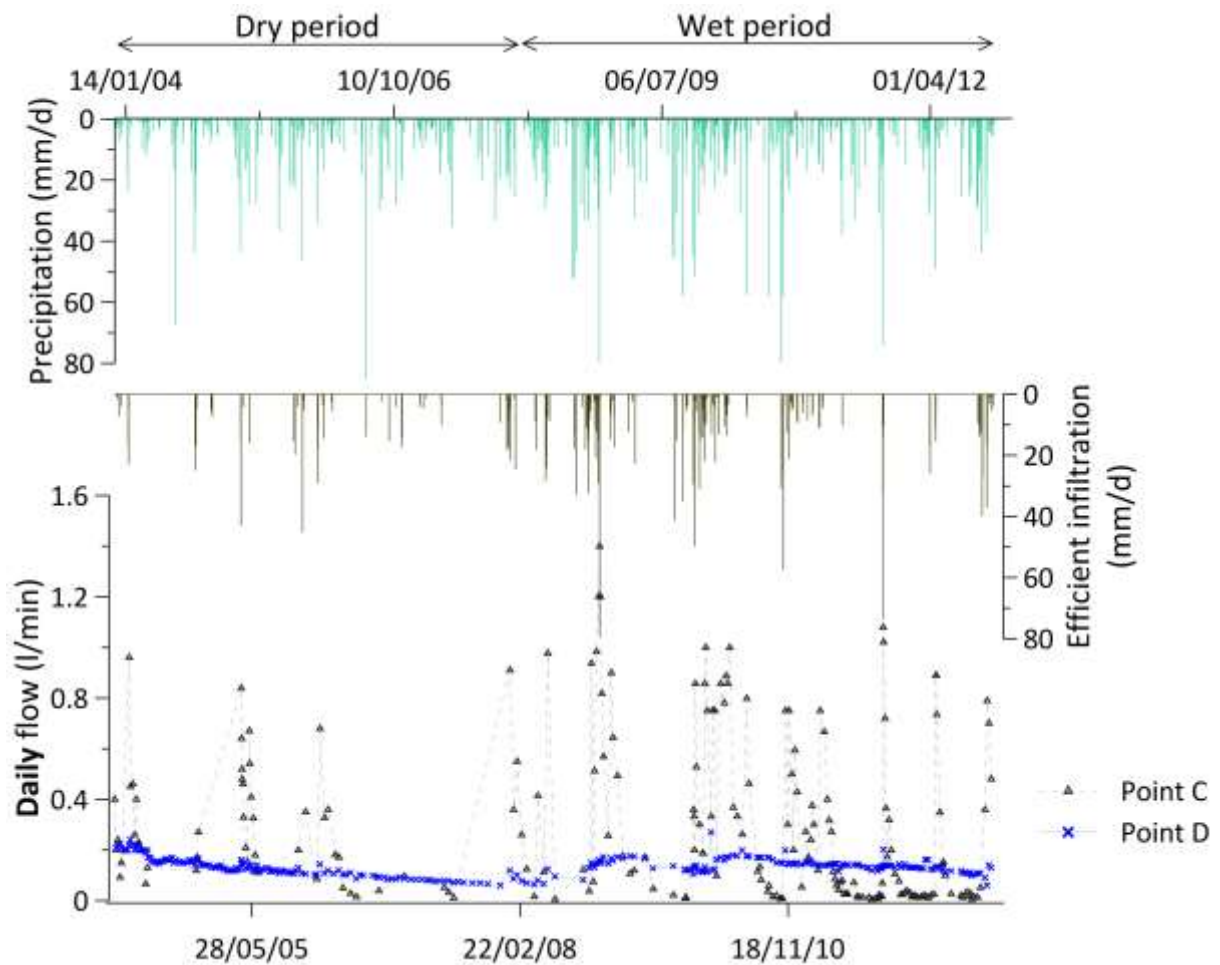

271 **4.1. Flow dynamics versus rain and effective infiltration**

272 Two hydrological periods can be observed: a dry period from 2004 to 2007 and a rainy period from
273 2008 to 2013 (Fig. 5) (Barbel-Perineau et al. 2013). Effective infiltration modeling using CASTANEA
274 (Fig. 5) confirms this alternation of wet and dry periods. One notes that effective infiltration is quite
275 limited between 2004 and 2007. Rigorous modeling of effective infiltration is essential in supporting
276 subsequent interpretations because the difference between rain and effective infiltration can be
277 quite large and can lead to misinterpretation.

278 During the first dry period, the water discharge at point D generally decreases and there is no clear
279 reaction during rain events. On the contrary, during the second rainy period, this water discharge
280 increases and responses to rain events are more apparent. The regularity of point D is obvious when
281 comparing variation ranges between points D and C.

282 Point C discharge is highly reactive to rainfall; it shows typical karstic dynamics even though it is
283 located at a depth of 256 m (Fig. 5). Note that the reactivity of flow point D to a rain event differs

284 from dry period (no variation) to wet period (rapid discharge increases for strong rainy events).
 285 However, the flow rate at point C increases proportionally with effective infiltration in both dry and
 286 wet periods. Without more arguments, it is difficult to explain the difference between D and C. One
 287 can only point out that point D is located within porous Urgonian limestone and C is located within
 288 lower Barremian limestone (Fig. 2d).

289
 290 **Fig. 5:** Precipitation and effective infiltration calculated using CASTANEA compared with flow
 291 dynamics at points C and D between 2004 and 2012.

292
 293 **4.2. Hydrogeophysical monitoring**

294 4.2.1 Seasonal dynamics

295 MRS was used to detect the seasonal variation in storage in the karst UZ between summer 2011 and
 296 winter 2012. In processed MRS results (Fig. 3d), two layers reveal unusual water contents for karst
 297 UZ. The first interval with high water content (10 % water content according to MRS) is at a depth of

298 approximately 15 m (above low point D); the other high water content interval (12 % water content
299 according to MRS) is deeper than 40 m.

300 Although these elevated water contents are surprising for a karst hydrosystem UZ, these values
301 agree with the high porosity estimated by other geophysical methods used at the LSBB (Maufroy
302 2010; Bereš 2013) and total matrix porosity measured in plugs in the region (e.g. Masse 1969;
303 Léonide et al. 2014) (Fig. 2d).

304 Significant temporal variations in MRS water content are observed at several depth levels (Fig. 3d).
305 The measured variations are as high as 3 % water content. This result indicates that these storage
306 variations could participate in seasonal water flow regulation in the karst UZ.

307 It is difficult to conceive that such a large volume of water could be stored in fracture and conduits
308 porosity of karst UZ. For this reason, in this geological context where limestone can be very porous,
309 the majority of this water content can be attributed to the porous matrix.

310 The high water content level detected by MRS near the depth of 15 m corresponds to location of the
311 cross-stratifications and a moderate resistivity zone detected by GPR and ERT (Fig. 3b and c). This
312 feature probably contains a stock of water located above point D, and supplies this water to point D.
313 Its hydrogeological role will be discussed in the next section.

314

315 4.2.2 Event dynamics

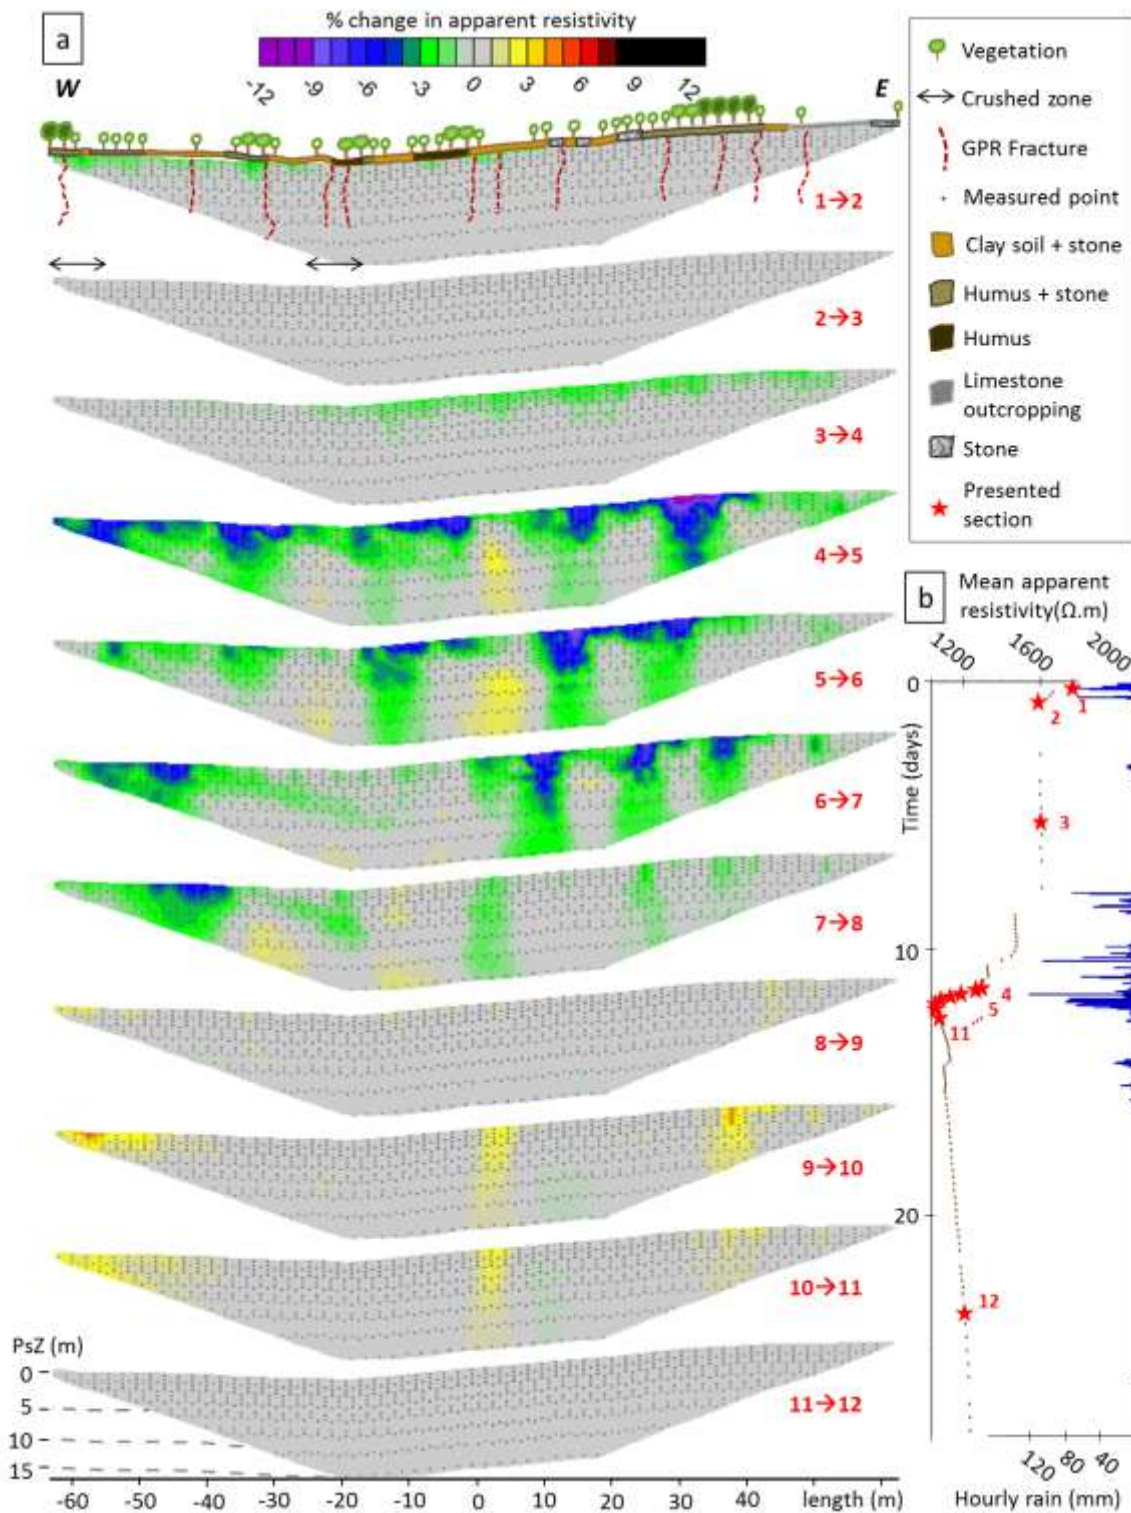

316 This unique large-scale ERT surface based experiment was conducted during a typical Mediterranean
317 autumn rain event (17 days). A total of 230 mm of rain were recorded and 120 ERT time-lapse
318 sections were measured over the same profile (LSBB03) during and after the rain event (a total of 30
319 days).

320 Apparent resistivity values have been arithmetically averaged for each section. Apparent resistivity
321 decreased sharply during the rain event, from 1750 to 1050 Ω .m (Fig. 6b). These variations do not
322 seem to be related to temperature variations because air temperature and water temperature (at

323 point D) remained stable during the experiment (Carrière 2014). Thus, these electrical resistivity
324 variations can be reasonably related to variation in water content in the subsurface. Analysis of this
325 mean apparent resistivity indicator made it possible to select the twelve critical time steps presented
326 in Fig. 6a: before, during, and after the rain event. These results are presented (Fig. 6a) as hourly
327 percentage changes in ρ_{α} with a basic representation of vegetation and soil cover around the profile.
328 Previously recognized karst features (Carrière et al. 2013) are also represented.

329 At the beginning of the rain event (Fig. 6a, section 1→2), ρ_{α} decreased moderately and
330 homogeneously along the section. This resistivity decrease could be related to moistening of near
331 surface horizons. After the first rain event (Fig. 6a, section 2→3), ρ_{α} stabilized quickly. During the
332 following heavy rain episode (Fig. 6a, sections 4→5 to 7→8), the moistening process appeared to be
333 quite heterogeneous and some zones resembled water pathways or preferential infiltration zones.
334 However, it would be unwise to link observed ρ_{α} variations at depth with deep moistening processes.
335 The observed variations can also be directly influenced by near surface variations. Immediately after
336 the rain (Fig. 6a, sections 9→10 and 10→11), ρ_{α} increased in some zones. This result may be related
337 to drainage processes. These zones correlate well with zones previously identified as preferential
338 pathways. This second observation reinforced the hypothesis of preferential pathways playing a
339 hydraulic role that can be traced with ERT monitoring. However, it is still not possible to specify
340 properties such as the geometry of these pathways. Other zones where such drainage processes are
341 not identifiable may be related to zones where soil is thicker and remains moist after rainfall.

342 The assumed water pathways identified on the basis of apparent resistivity do not seem to be related
343 to vegetation density or soil cover variations (Fig. 6). However, these zones appear related to
344 fractures or fault zones previously detected by GPR (Carrière et al. 2013). Note also that resistivity
345 variations in fractures are different from those measured in the crushed zone located in the western
346 part of the profile. A crushed zone may provide a larger water pathway than a fracture. It is
347 important to emphasize that the methods used in this study do not image the pathways with
348 certainty.

349

350 **Fig. 6:** (a) Hourly change in apparent resistivity between two consecutive time steps. Positions of
 351 fractures previously detected by ground penetrating radar (GPR) and basic representation of
 352 vegetation and soil cover; (b) Evolution of mean apparent resistivity during monitoring versus rain.
 353 Each brown point represents one electrical resistivity tomography section (Carrière et al. 2015). PsZ is
 354 pseudo depth.
 355

356 **5. Discussion**

357 5.1 Local scale: study area

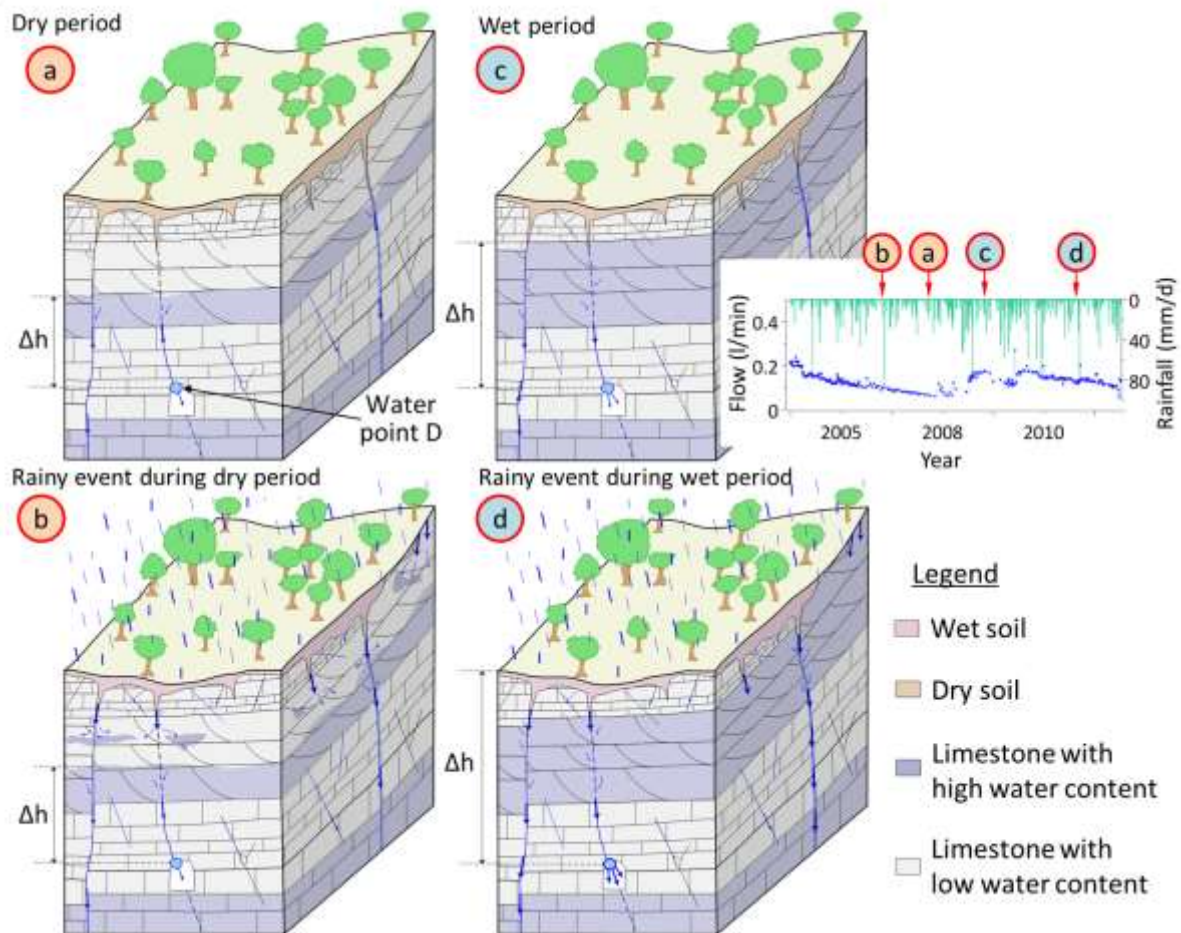

358 This integrated hydrogeophysical approach at two different time scales has improved the current
359 understanding knowledge of the hydrogeological functioning of study site. At the seasonal time step,
360 MRS made it possible to identify water storage variation above and below flow point D. These
361 variations are related to slow water dynamics within matrix porosity. This hypothesis is consistent
362 with the regular flow dynamics at point D, which were observed during both dry and recharge
363 periods (Fig. 5). Moreover, it is consistent with the large total matrix porosity within Urgonian
364 limestone, which may reach 20 % (Fig. 2d).

365 At the rain event time scale, ERT monitoring revealed heterogeneity in infiltration (Fig. 6). Some
366 fractures or faulted zones previously detected by GPR (Fig. 3) were identified as probable
367 preferential water pathways (Fig. 7b and d).

368 During wet periods, when water fills these vertical structures, hydraulic head (Δh) increases above
369 flow point D, which induces a prompt increase in flow at D as in October 2011 (Fig. 7d) during ERT
370 monitoring (Fig. 6). During this type of rain event, this increased flow may push forward older, less
371 mobile water according to the water schema proposed by Barbel-Perineau (2013) who studied
372 hydrochemistry within the LSBB.

373 During long dry periods, as for example, between 2004 and 2007 (Fig. 7a), flow point D did not
374 respond to rain pulses even during extreme events (Fig. 7b). Thus, there is probably no significant
375 hydraulic continuity between near-surface water-filled fractures and the deeper porous matrix
376 reservoir. Thus, there is no transmission of a pressure pulse to cause increased flow at point D. This
377 absence of connection is probably due to partial drying of the porous matrix reservoir above point D.
378 The evolution of the dry porous matrix to water-filled matrix may take several years. This timeframe
379 can explain the multi-annual inertia to recharge the stock that supplies point D, as was observed
380 between 2007 and 2010 (Fig. 5).

381 To confirm this interpretation, three 50 m boreholes were dug around flow point D at the end of
 382 2014, at a distance of approximately twenty meters. In each borehole the water level was measured
 383 at a depth of approximately 40 m. Another hydrogeological study is currently in progress to examine
 384 borehole dynamics and water circulation.

385 **Fig. 7a-d:** Synthetic functioning model of the local hydrosystem that supplies flow point D. D flow
 386 variation depends on rain conditions.
 387
 388

389 5.2 Regional scale: Fontaine de Vaucluse hydrosystem

390 How can this knowledge about the local hydrosystem at point D help explain karst hydrodynamics at
 391 a larger scale, such as the entire Fontaine de Vaucluse hydrosystem?

392 It is particularly relevant to study the relationship between rainfall and water discharge during the
 393 period from 2004 to 2012 because recharge was highly variable during this period. A long dry period
 394 between 2004 and 2007 was followed by a more rainy period between 2008 and 2012. The annual

395 dynamics of rainfall, effective infiltration, and water discharge presented in Fig. 8 illustrate these dry
396 and wet periods.

397 Although these results are applicable to a discussion of the relationship between rainfall and output
398 flow at LSBB flow points, the relationship with spring discharge at the Fontaine de Vaucluse should
399 be approached with caution. However, the total annual rainfall in Saint Saturnin-les-Apt (Fig. 2b) is
400 representative enough of inter-annual rainfall variation in the region to allow the following
401 discussion.

402 These inter-annual recharge variations cause changes in discharge rates at the outlet of the karst
403 system as a whole (Fontaine de Vaucluse spring) and at local outlets of karst sub-systems such as
404 water points C and D in the LSBB. However, these variations are highly variable between the Fontaine
405 de Vaucluse and water points C and D, and are summarized as follows:

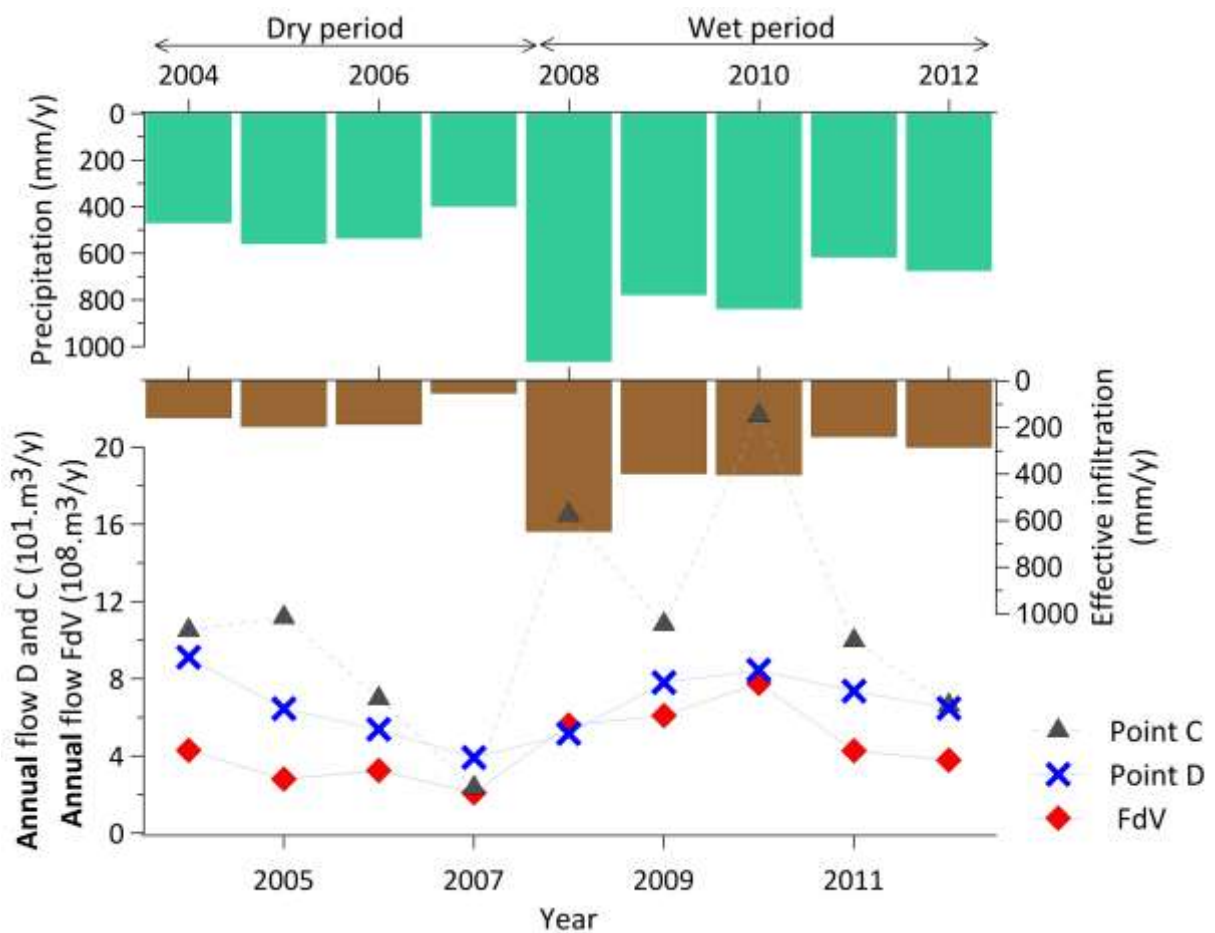

406 - Water point C exhibits typical karst dynamics with large flow range (a factor of 10)
407 depending on the quantity of annual effective infiltration. This relationship was clearly demonstrated
408 in 2007 when effective infiltration was at a minimum and water flow at C was very low.

409 - The water point D has different dynamics because its water discharge is quite regular; the
410 range of its annual discharge variation is only a factor of 2. The flow rate at point D decreased
411 continuously between 2004 and 2007, after which its flow increased regularly until 2010. However,
412 effective infiltration decreased significantly between 2008 and 2010. Thus, there is a kind of delayed
413 dynamic. The results highlight the importance of porous matrix on water flow, even in a karst
414 limestone aquifer system.

415 - The annual water discharge of the Fontaine de Vaucluse exhibits dynamics similar to those
416 at point D (Fig. 8) although its flow variation range is slightly larger than point D, a factor of 3.5.
417 Similar to point D, the flow rate at the Fontaine de Vaucluse also increased between 2007 and 2010;
418 however effective infiltration decreased significantly from 2008 to 2010. This observation suggests
419 that water flow regulation mechanisms observed at point D are site-specific. Similar mechanisms of
420 water flow regulation through the porous matrix may play an important role in the entire Fontaine

421 de Vaucluse hydrosystem (Fig. 8). Considering the large volume of Urgonian porous formations in the
 422 hydrosystem (Fig. 2b), this assumption is a plausible explanation of part of the multi-annual dynamics
 423 of the Fontaine de Vaucluse spring.

424 Even so, at a daily time step, the Fontaine de Vaucluse spring can be highly reactive, similar to flow
 425 point C. However, even if floods at the Fontaine de Vaucluse can be impressive, they represent only a
 426 limited part of the annual water discharge. The annual flow dynamics of the Fontaine de Vaucluse
 427 seem to be predominantly influenced by slow water flow within a porous matrix, as is the case at
 428 point D.

429
 430 **Fig. 8:** Comparison of annual water discharge for Fontaine de Vaucluse (FdV) and flow points D and C
 431 with annual precipitation and effective infiltration modeled for the period of 2004 to 2012 by
 432 CASTANEA.
 433

434
 435 **6. Conclusions**

436 This study was conducted at a local scale around the LSBB underground laboratory to improve the
437 current understanding of the local karst hydrosystem. The results presented in this paper
438 demonstrate that a considerable volume of water can be stored within matrix rock in the karst UZ.
439 Masse (1969) measured exceptional matrix porosity for limestone (up to 20 %) on the Urgonian
440 platform around Fontaine de Vaucluse catchment area. However, the hydrodynamic role of this
441 matrix porosity was not yet known.

442 MRS surveys confirmed high free water content (5 to 10 %) within the karst UZ. This high water
443 content indicates a large volume of water that cannot be stored within fractures or karst conduits in
444 the UZ. This water is stored within limestone layers that were also identified by previous ERT and
445 GPR surveys. Moreover, MRS surveys identified seasonal variations in stored water (around 3 %),
446 which indicates that this water reserve is active. The ERT monitoring at the event scale made it
447 possible to demonstrate that despite the presence of porous limestone, the study site has
448 characteristics of a fractured/karstified area in which recharge processes are highly heterogeneous.
449 Rapid water circulation can occur through preferential water pathways and cause flow peaks at point
450 D.

451 Without additional measurements, the geophysical survey cannot be used to extend the
452 hydrodynamic properties observed at the LSBB site to the Fontaine de Vaucluse hydrosystem, either
453 wholly or in part. That is why it is not reasonable to try to quantify the consequences of the presence
454 of porous limestone on the Fontaine de Vaucluse spring flows. However, considering that Urgonian
455 limestone covers more than half the surface area of the Fontaine de Vaucluse basin (Fig. 2b) and that
456 Masse (1969) measured high matrix porosity on the entire Urgonian platform, there are necessarily
457 repercussions in Fontaine de Vaucluse outlet flow that may explain the multi-annual dynamics of
458 water flow (Fig. 8).

459 If Urgonian limestones play an important role in Fontaine de Vaucluse hydrodynamics, similar
460 geological formations can similarly impact the hydrodynamics of other karst hydrosystems, including
461 areas far from the Mediterranean Sea where the sedimentary conditions are similar. For example,

462 Cenozoic carbonate rocks in the Gulf of Mexico and the Caribbean are highly porous (Halley and
463 Schmoker, 1983). Therefore, on the basis of these results presented, it is essential to consider the
464 role of the porous matrix in water flow regulation within a karst UZ. Hydrodynamic modelling should
465 be adjusted accordingly to assess properly the groundwater resource potential and improve
466 sustainable management and exploitation of karst hydrosystems.

467 **Acknowledgments**

468 The authors would like to express their gratitude to CIRAME, to ORE H+ and to all the LSBB team for
469 their technical and logistic help. This study was funded by a French ministry of education and
470 research PhD grant. This work was performed within the framework of the FDV/LSBB observation
471 site, part of the KARST observatory network (www.sokarst.org) initiative of INSU/CNRS, which seeks
472 to support knowledge sharing and promote cross-disciplinary research on karst systems. We also
473 thank the editorial board of Hydrogeology Journal, S. White, M. Saribudak and an anonymous
474 reviewer for helping us improve this paper.
