**Abstract.** Titanium dioxide,  $\text{TiO}_2$ , is a refractory species that could play a crucial role in the dust-condensation sequence around oxygen-rich evolved stars. We present and discuss the detections of 15 emission lines of  $\text{TiO}_2$  with ALMA in the complex environment of the red supergiant VY CMa. The observations reveal a highly clumpy, anisotropic outflow in which the  $\text{TiO}_2$  emission likely traces gas exposed to the stellar radiation field. We find evidence for a roughly east-west oriented, accelerating bipolar-like structure, of which the blue component runs into and breaks up around a solid continuum component. We see a distinct tail to the south-west for some transitions, consistent with features seen in the optical and near-infrared. We find that a significant fraction of  $\text{TiO}_2$  remains in the gas phase outside the dust-formation zone and suggest that this species might play only a minor role in the dust-condensation process around extreme oxygen-rich evolved stars like VY CMa.

## 1. Introduction

The driving mechanism of the winds of oxygen-rich evolved stars is not well understood. Radiation pressure on dust through absorption and scattering of stellar light is thought to play a crucial role. The size and chemical composition of dust grains are critical to the efficiency of these processes. It is hence essential to address which gas-phase species provide the primary seeds for the dust-formation sequence in oxygen-rich outflows.  $\text{TiO}_2$  is considered an important seed refractory species with possibly higher nucleation rates than SiO [1, 2]. Detections of presolar  $\text{TiO}_2$  grains [3] support the importance of this species in the dust-condensation sequence.

Emission from gas phase  $\text{TiO}_2$  has to date only been detected towards VY CMa [4, 5, 6], an extreme red supergiant at 1.2 kpc distance [7]. VY CMa’s circumstellar environment exhibits a high degree of morphological complexity, from optical to radio wavelengths and on spatial scales from a few to several thousands of AU [6, 8, 9, 10, 11, 12, 13]. ALMA observations spatially resolved the  $\text{H}_2\text{O}$  maser emission and the submillimeter continuum emission, leading to a most

accurate determination of the stellar position [14] and the discovery of a bright continuum component south-east of the star [15].

## 2. Observations

We retrieved ALMA science verification data on VY CMa from the ALMA archives. The observations, data calibration and reduction are described by [14]. An overview of the spectral coverage and representative rms noise values for the six spectral windows in ALMA's band 7 ( $\sim 0.9$  mm;  $\sim 320$  GHz) and one in band 9 ( $\sim 0.45$  mm;  $\sim 660$  GHz) is given by [4]. With projected baselines of 14 m up to 2.7 km, the spatial resolution at  $\sim 320$  GHz and 658 GHz is  $\sim 0.2''$  and  $\sim 0.1''$ , respectively, and the maximum recoverable scales are  $8.3''$  and  $4.0''$ .

## 3. Results

We analysed spectra extracted for a  $1''$  diameter region around the stellar position, since no  $\text{TiO}_2$  emission is detected beyond this aperture. We detect 15 lines with upper-level energies  $E_{\text{up}}/k$  in the range  $48 - 676$  K and signal-to-noise ratios  $S/N \approx 5 - 17$  at velocity resolutions  $0.9 - 7.6 \text{ km s}^{-1}$  (table 1, figure 1). Of the 15 lines of  $\text{TiO}_2$  detected with ALMA, only 2 were detected with SMA, owing to a  $\sim 10$  times lower noise level in the ALMA data.

The  $\text{TiO}_2$  emission is for the first time spatially resolved in the ALMA observations and shows a high level of morphological complexity, described in detail by [4]. The  $\text{TiO}_2$  emission traces multiple wind components, as seen in figure 2. We find a red-shifted outflow to the west and a blue-shifted outflow to the east. At increasingly blue-shifted velocities the emission moves towards the bright clump C south-east of the star and then appears to curve and break up around it with the northern peak brighter than the southern one. With the clear exception of this interaction of the  $\text{TiO}_2$  gas with C, the west and east outflows seem roughly symmetric around the star and aligned with the axis connecting the star and C. We rule out an equatorially enhanced environment such as a disk or ring, based on the spatial distribution of the  $\text{TiO}_2$  emission at different velocities. We rather suggest an accelerating bipolar-like outflow at lower densities. We also find a predominantly blue-shifted south-west outflow, approximately perpendicular to the axis connecting the star and C, connecting the star and the south-west clump, a feature detected in the mid-infrared [11].

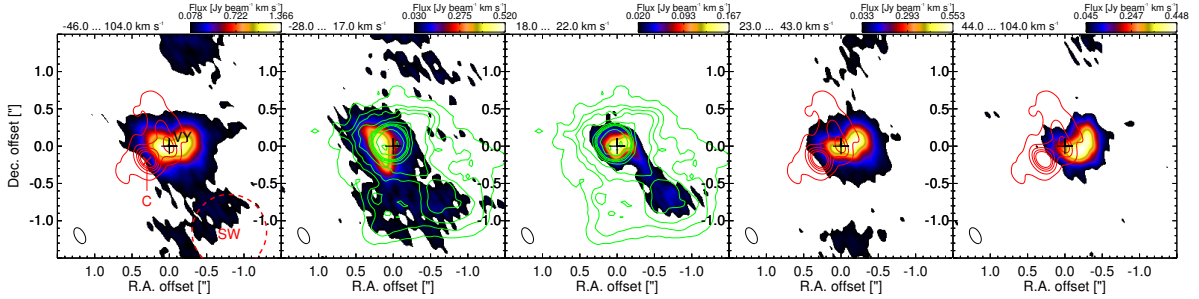

Whereas the  $\text{H}_2\text{O}$  maser emission in the “valley” between the star and C implies that C is

**Figure 1.**  $\text{TiO}_2$  spectra extracted for a  $1''$  diameter aperture around the stellar position. The vertical dashed lines indicate the stellar  $v_{\text{LSR}}$  of  $22 \text{ km s}^{-1}$ , the shaded areas the  $v_{\text{LSR}}$ -ranges from table 1. We indicated (tentative) identifications of species other than  $\text{TiO}_2$  in the panels.

**Table 1.** Overview of detected TiO<sub>2</sub> lines as detected in the spectrum extracted in a 1'' diameter aperture centred on the star. Columns list transition, rest frequency, upper-level energy, minimum and maximum  $v_{\text{LSR}}$  reached, velocity resolution and rms noise at which the identification was made, and peak and integrated flux.

**Figure 2.** TiO<sub>2</sub> morphology. Colour maps of emission at 310.78 GHz integrated over the  $v_{\text{LSR}}$ -ranges indicated at the top left of each panel, cut off at  $3\sigma$ . Red contours (1st, 4th, and 5th panel) show the 321 GHz continuum at  $[3, 20, 40, 60, 80]\sigma$ ; green contours (2nd and 3rd panel) show HST emission at  $[3, 5, 7, 10, 20, 30, 40, 50, 100, 200]\sigma$  [12]. In the 1st panel we marked the position of the star (+, VY; black) and of the continuum component (x, C; red) to the south-east [14, 15], and the position and approximate extent of the south-west clump (SW, dashed 1'' diameter circle; red) [11]. The apparent north-south emission is thought to arise from dynamic-range limitations in the peak channels.

close to or in the plane of the sky [14], the observations suggest that the TiO<sub>2</sub> gas breaks up around C while moving towards the observer, placing C “at least partially” in front of the plane of the sky. It is therefore likely that the H<sub>2</sub>O masers and the TiO<sub>2</sub> emission probe parts of the outflow east of the star with different physical properties. Whereas the masers are probably excited through shocks at high densities [14], TiO<sub>2</sub> is more likely excited through radiation, at lower outflow densities (see below). In the denser regions, TiO<sub>2</sub> might not be excited and/or it might be efficiently depleted from the gas phase. The latter is, however, less likely (see below). We therefore suggest that TiO<sub>2</sub> traces the blue-shifted wind to the east with lower densities

which runs into and curves around C.

From a rotational-diagram analysis we derive a column density  $N_{\text{col}} = 5.65 \pm 1.33 \times 10^{15} \text{ cm}^{-2}$  and a rotational temperature  $T_{\text{rot}} = 198.0 \pm 28.5 \text{ K}$ , in agreement with [5], although the kinetic temperature in the excitation region of  $\text{TiO}_2$  varies from more than 1000 K down to  $\sim 100 \text{ K}$  [16]. Assuming an average mass-loss rate of  $2 \times 10^{-4} M_{\odot} \text{ yr}^{-1}$ , an average velocity of  $20 \text{ km s}^{-1}$ , and an  $0.9''$  diametric extent, at 1.2 kpc, we find an abundance  $\text{TiO}_2/\text{H}_2 \approx 3.8 \pm 0.9 \times 10^{-8}$ . We however urge careful interpretation of these numbers, since the high dipole moment of  $\text{TiO}_2$  supports efficient radiative excitation and possibly electron- $\text{TiO}_2$  collision rates large enough to exceed  $\text{H}_2$ - $\text{TiO}_2$  collision rates in case of a sufficient ionisation degree close to the star [4]. These effects could invalidate the LTE approach used in this simple analysis.

Taking into consideration the high dipole moment of  $\text{TiO}_2$ , the ratio between the collisional and radiative transition rates of  $\text{TiO}_2$ , and the strong resemblance between the  $\text{TiO}_2$  emission measured with ALMA and the earlier scattered-light observations at  $1 \mu\text{m}$  we put forth that the  $\text{TiO}_2$  gas is radiatively excited. As such, the measured emission traces parts of the outflow where the stellar radiation field is least attenuated. From the comparison to the continuum at  $\sim 321 \text{ GHz}$ , we derive that  $\text{TiO}_2$  is excited in the directions with lower dust densities. The absence of detected  $\text{TiO}_2$  emission north of the star could then point at efficient obscuration of this part of the outflow, in line with the observations of e.g. [12]. Attenuation of the stellar radiation field to the east and west of the star is limited. From this, we do not expect an equatorial enhancement of the mass-loss rate, since this would likely have induced more efficient dust formation, which is not seen in the continuum.

Since the  $\text{TiO}_2$  emission is seen at radial distances from the star far beyond the dust-condensation region, and along directions where dust continuum is observed, we claim that  $\text{TiO}_2$  is not a tracer for overall low grain-formation efficiency, but that much of it remains in the gas phase. The strong correspondence between the  $\text{TiO}_2$  emission and the south-west tail of dust-scattered stellar light supports this. We also consider the high derived column density and suggest that  $\text{TiO}_2$  might play only a minor role as a primary dust seed around VY CMa.
