(Dated: March 2, 2017)

We propose a concept of chiral photonic limiters utilizing topologically protected localized midgap defect states in a photonic waveguide. The chiral symmetry alleviates the effects of structural imperfections and guarantees a high level of resonant transmission for low intensity radiation. At high intensity, the light-induced absorption can suppress the localized modes, along with the resonant transmission. In this case the entire photonic structure becomes highly reflective within a broad frequency range, thus increasing dramatically the damage threshold of the limiter. Here we demonstrate experimentally the loss-induced reflection principle of operation which is at the heart of reflective photonic limiters using a waveguide consisting of coupled dielectric microwave resonators.

The emerging field of topological photonics aims to realize photonic structures which are resilient to fabrication imperfections by utilizing ideas developed in topology [1–10]. In photonics, the topological phases are defined on the reciprocal space and usually are associated with the formation of topologically protected (TP) defect states within photonic band-gaps. In this endeavor the manipulation of various symmetries has been proven extremely useful. An example case are resonator arrays with chiral symmetry [11] where a topological defect state appears to be insensitive to positional imperfections of the resonators [11, 12]. In this paper we connected the chiral symmetric array to leads, thus turning the TP defect mode to a *quasi-localized resonant mode*. We investigated its transport properties and established conditions for its robustness in the presence of losses and imperfections. Finally we utilized the TP resonant mode for the proposal of a new class of waveguide photonic limiters.

Limiters are protecting filters transmitting low power (or energy) input signals while blocking the signals of excessively high power (or energy) [13–18]. Usually, a passive limiter absorbs the high-level radiation, which can cause its overheating. The input level above which the transmitted signal intensity doesn't grow with the input is the limiting threshold (LT). Another critically important characteristic is the limiter damage threshold (LDT), above which the limiter sustains irreversible damage. The domain between LT and LDT is the dynamic range (DR) of the limiter - the larger it is, the better. Unfortunately, material limitations impose severe restrictions on both thresholds. It is, therefore, imperative to utilize appropriate photonic platforms which are both flexible enough to provide simultaneously tunable and low LT and high enough LDT. Importantly, these structures should be tolerant to deviation of the material and geometrical parameters from their ideal values.

Along these lines, the defect modes hosted by photonic band-gap [19–21] (or other resonant [22]) structures have been exploited as an alternative to achieve flexible,

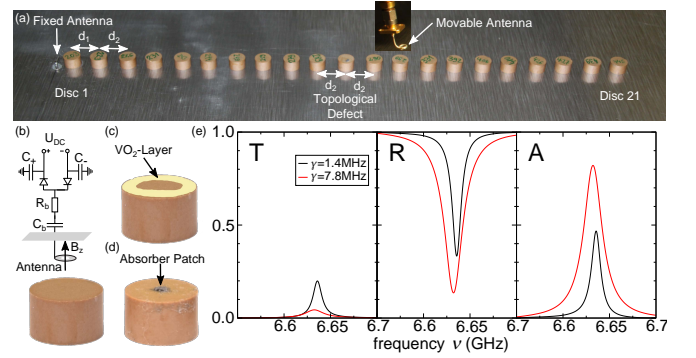

FIG. 1. (a) The experimental set-up: The resonators are separated by distances d_1 or d_2 with $d_1 < d_2$. A central defect is introduced by repeating the spacing d_2 ; Various proposals for the implementation of non-linear losses in the defect resonator: (b) A circuit with various module (sensing antenna, diode, threshold DC voltage); (c) An epitaxial growth of a material that experiences a thermally induced insulator-to-metal phase transition; (d) Our measurements involve a defect resonator, which includes a manually modulated absorbing patch; (e) Measured transmittance T , reflectance R and absorption A for two different patches. The linewidth γ (1.4 and 7.8 MHz) of the reflected signal mainly characterizes the losses due to the absorbing patches.

high efficiency photonic limiters. In most occasions, however, limiting action is achieved by a non-linear frequency shift of the transparency window of the photonic structure. Such a shift is inherently small and, therefore, cannot provide broadband protection from high-power input. Other schemes, specifically in the microwave domain, exploit PIN diodes (having spike leakage problems) [23], TR tubes or self-attenuating superconducting transmission lines that require high power consumption [24]. To address these issues we have recently proposed the concept of *reflective photonic limiters* [25, 26]. Such limiters reflect the high radiation, thereby, protecting themselves - not just the receiving device - while they provide a strong resonant transmission for low incident radiation.

Here we propose the use of chiral coupled resonator waveguides (C-CROW) with alternating short and long distances from one another (see Fig. 1), as a fertile platform to implement structurally robust reflective waveguide limiters with a wide DR. In the presence of a phase slip defect [27, 28], chiral symmetry provides topological protection to a midgap defect localized mode [11, 12]. For low incident power (or energy) it can provide high transmittance shielded from (positional) fabrication imperfections. When (non-linear) losses at the defect resonator (triggered from high power - or energy- incident radiation) exceed a critical value, the resonant defect mode and the associated resonant transmission are dramatically suppressed turning the C-CROW highly reflective (not absorptive!) for a *broad frequency range*. As a result, the LDT increases with a consequent increase of the DR of the limiter. Using a microwave C-CROW arrangement we have tested experimentally the operational principle of this new class of TP reflective photonic limiter by investigating the sensitivity and transport characteristics of the TP *resonant* defect mode in the presence of losses.

The set-up (see Fig. 1a) consists of $N = 21$ high index cylindrical resonators (radius $r = 4\text{mm}$, height $h = 5\text{mm}$, made of ceramics with refraction index $n \approx 6$) with eigenfrequency around $\nu_0 = 6.655\text{GHz}$ and linewidth $\gamma = 1.4\text{MHz}$ [29]. The resonators are placed at alternating distances $d_1 = 12\text{mm}$ and $d_2 = 14\text{mm}$ corresponding to strong ($t_1 = 38\text{MHz}$) and weak ($t_2 = 21\text{MHz}$) evanescent couplings, respectively. A topological defect at the 11th resonator is introduced by repeating the spacing d_2 [11, 12]. On the left hand side of the array, close to the first resonator, we have placed a kink antenna that emits a signal exciting the first TE_1 resonant mode of the resonators. The structure is shielded from above with a metallic plate (not shown) where a movable loop antenna (receiving antenna) is mounted and is coupled to the 13th resonator. The kink antenna couples to the electric field that is in the xy -plane, whereas the loop antenna couples to the magnetic field, which is in the z -direction.

We assume that the defect resonator incorporates a nonlinear absorption mechanism, i.e. we assume that its losses are self-regulated depending on the strength of the incident radiation. One option to incorporate nonlinear losses is via an external element (fast diodes), see Fig. 1(b). This option provides on-the-fly reconfigurability of the LT via an externally tuned DC voltage U_{DC} . An alternative mechanism is associated with temperature driven insulator-to-metal phase transition materials, like VO_2 [30–33], which can be deposited on top of the defect resonator (see Fig. 1c).

In our experiment we are not concerned with the physical origin of the nonlinear losses at the defect resonator. Rather we focus on demonstrating their effects on the transport properties of the photonic structure and thus establishing the operational principle of (structurally) robust reflective photonic limiters with wide dynamical

range. Therefore, we have included losses γ_D by placing an absorbing patch on top of the resonator [see Fig. 1(d)]. This process results in a slight shift of the real part of the permittivity of the defect resonator, which we corrected by using resonators with slightly higher eigenfrequency. The linewidth γ has been used in order to quantify the losses of the resonators.

In Fig. 1(e) we show the transmittance T , reflectance R , and absorption $A = 1 - T - R$ for two resonators with different losses. The transmittance is measured from the kink antenna to the loop antenna, which was positioned above the resonator. The reflectance is measured from the kink antenna. We observe that the transmittance of the stand-alone lossy resonator reduces as the losses increase, thus acting as a limiter. However this reduction comes to the expense of increasing absorption, i.e. *the stand-alone lossy resonator acts as a sacrificial limiter*.

The photonic structure is described by a one-dimensional (1D) tight-binding Hamiltonian

$$H_P = \sum_n \nu_n |n\rangle\langle n| + \sum_n t_n (|n\rangle\langle n+1| + |n+1\rangle\langle n|), \quad (1)$$

where $n = 1, 2, \dots, 21$ enumerates the resonators, $\nu_n = \nu = \nu_0 - i\gamma$ is the resonance frequency of the n th individual resonator and $t_n (= t_1 \text{ or } t_2)$ is the coupling between nearest resonators. The band-structure consists of two mini-bands $\nu_0 - t_1 - t_2 < \nu < \nu_0 - |t_1 - t_2|$ and $\nu_0 + |t_1 - t_2| < \nu < \nu_0 + t_1 + t_2$ separated by a finite gap of width $2|t_1 - t_2|$. In the presence of the defect resonator at $n_0 = 11$ a TP defect mode at $\nu_D = \nu_0$ [11],[12] is created. This mode is exponentially localized around the defect resonator. Its shape, in the limit of infinite many resonators, is [11]

$$\psi_n^D \sim \begin{cases} \frac{1}{\sqrt{\xi}} e^{-|n-n_0|/\xi}; & n \text{ odd} \\ 0; & n \text{ even} \end{cases} \quad (2)$$

where ψ_n^D is the amplitude of the defect mode at the n th resonator and $\xi = 1/\ln(t_1/t_2)$ is the so-called localization length of the mode [11]. Hamiltonian Eq. (1) is invariant under a chiral symmetry i.e. $\{H_P, C\} = 0$ where $\{\dots\}$ indicates an anti-commutation and $C = P_{\text{even}} - P_{\text{odd}}$ satisfies the relations $C^2 = 1$ ($P_{\text{even/odd}}$ is the projection operator in the even/odd sites). The staggering form of ψ^D is a consequence of the chiral symmetry which also provides topological protection to ψ^D and ν_D against reasonable variations of t_1 and t_2 [11, 12].

We are modeling the transmitted (reflected) antenna, coupled to $n_T = 1$ ($n_R = 13$) resonator, by a 1D semi-infinite tight-binding lattice with coupling constant $t_L = (t_1 + t_2)/2$ and on-site energies $\nu_L = \nu_0$. The associated scattering matrix takes the form [35]

$$\hat{S} = -\hat{1} + \frac{2i \sin k}{t_L} W^T \frac{1}{H_{\text{eff}} - \nu} W; \quad H_{\text{eff}} = H_P + \frac{e^{ik}}{t_L} W W^T, \quad (3)$$

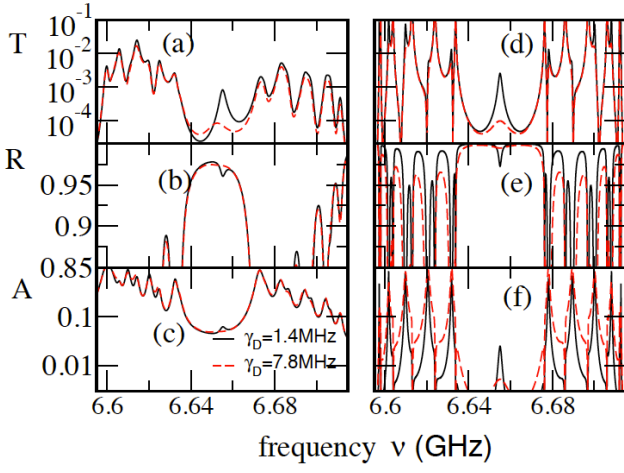

FIG. 2. Measurements of the (a) transmittance T ; (b) reflectance R ; and (c) absorption A for the C-CROW of Fig. 1. We considered two different values of $\gamma_D = 1.4$ MHz and $\gamma_D = 7.8$ MHz. All other resonators have $\gamma = 1.4$ MHz. Numerical calculations for the (d) transmittance T ; (e) reflectance R and (f) absorption A where we assumed that all resonators are lossless, i.e. $\gamma = 0$, apart from the defect resonator which has $\gamma_D = 1.4$ MHz (solid lines) and $\gamma_D = 7.8$ MHz (dashed lines).

where $\hat{1}$ is the 2×2 identity matrix, $W_{nm} = w_T \delta_{n,n_T} \delta_{m,1} + w_R \delta_{n,n_R} \delta_{m,2}$ is a $N \times 2$ matrix that describes the coupling between the array and the antennas, $\nu = \nu_L + 2t_L \cos k$ is the frequency of propagating waves at the antennas and k is their associated wavevector.

When the system is coupled to the antennas, ψ^D becomes a quasi-localized resonant mode at frequency $\nu_D \approx \nu_0$, with a large but finite lifetime τ :

$$\tau^{-1} \sim \left\langle \psi^D \left| \frac{e^{ik}}{t_L} W W^T \right| \psi^D \right\rangle = |w_T|^2 |\psi_1^D|^2 + |w_R|^2 |\psi_{13}^D|^2, \quad (4)$$

where $|\psi_1^D|^2, |\psi_{13}^D|^2$ are given by Eq. (2).

The measured transmittance $T = |S_{12}|^2$, reflectance $R = |S_{11}|^2$ and absorption $A = 1 - T - R$ versus frequencies ν of the C-CROW (with global $\gamma = 1.4$ MHz $= \gamma_D$) are shown in Figs. 2(a,b,c) (solid lines). Measurements of the widths of the mini-bands and of the gap allow us to extract the couplings $t_1 = 38$ MHz, $t_2 = 21$ MHz. We find that the presence of the defect resonator results in a transmission peak at $\nu = \nu_D$ inside the band gap. A fitting of the height of this peak, for various γ_D values, gives $w_T = 10.915$ MHz, $w_R = 3.6875$ MHz (see Fig. 3). The small peak in the absorption (solid line in Fig. 2(c)) is associated with the fact that all our resonators have a small ohmic component. In Fig. 2(a) we also report (dashed lines) the measured transmittance for a defect with additional losses, i.e. $\gamma_D = 7.8$ MHz. We find that even a small increase in γ_D strongly suppresses the resonant transmission, see Fig. 2(a).

In Fig. 2(b) we show $R(\nu)$ of the C-CROW for $\gamma_D =$

FIG. 3. The transmittance T (up) and absorption A (down) versus γ_D : (Left) for the C-CROW with resonator losses $\gamma = 1.4$ MHz (black lines-numerics/circles-experiment) and for the stand-alone resonator (blue dashed-dotted lines-numerics/diamonds-experiment). (Right) Numerics for the ideal C-CROW (red dashed lines) with $\gamma = 0$ at all other resonators. Symbols (blue dashed-dotted lines) correspond to measurements (numerics) of T and A for the stand-alone resonator. Shaded areas indicate deviations in T, A due to randomness in the couplings.

1.4 MHz and $\gamma_D = 7.8$ MHz (solid and dashed lines, respectively). We find that the suppression in $T(\nu_D)$ is accompanied by an increase in $R(\nu_D)$. Moreover $A(\nu_D)$ is decreasing as γ_D increases, see Fig. 2(c). In other words, our photonic structure becomes *reflective* (not absorptive) as the losses of the defect resonator increase. This behavior is in distinct contrast to the case of a single (sacrificial) lossy resonator [see Fig. 1(e)] where the drop in transmittance is associated with an increase of absorption. These features are also observed in the simulations of an ideal C-CROW where all resonators have zero intrinsic losses $\gamma = 0$, see Figs. 2(d,e,f).

An overview of the measured (black circles) $T(\nu_D)$, $A(\nu_D)$ and the corresponding numerical results (black solid lines) for the C-CROW of Fig. 1 versus γ_D are reported at the left column of Fig. 3. We find that an increase of γ_D leads to a decrease of $T(\nu_D)$ and $A(\nu_D)$ of the photonic structure. This behavior is contrasted with the measurements (diamonds) and numerical calculations (dashed-dotted lines) of a stand-alone lossy resonator. In the latter case we observe relatively large T values $T \sim 10^{-1}$ as opposed to $T \sim 10^{-4}$ for the photonic structure, i.e. ultralow LT. For moderate γ_D -values the absorption of the stand-alone resonator reaches large values $A(\gamma_D = 0.004 \text{ GHz}) \approx 0.8$ corresponding to low LDT. In contrast, the C-CROW takes absorption values, which are at least one order of magnitude smaller (high LDT). At the right column of Fig. 3, we report the simulations

FIG. 4. (a) Simulations for an ideal C-CROW consisting of lossless resonators with $\gamma = 0$. Filled black circles correspond to Eq. 2 for the defect mode profile. Solid lines correspond to the simulations of the resonant defect mode profile for various γ_D . For symmetry reasons we assumed that the antennas are coupled to the first and last resonator. (b) Experimental resonant mode profiles for various γ_D -values. The measured losses at all resonators are $\gamma = 1.4$ MHz.

for $T(\nu_D)$, $A(\nu_D)$ for an ideal ($\gamma = 0$) C-CROW (dashed lines) versus the losses γ_D of the defect resonator. Again, we compare these results to the theoretical/experimental (dash-dotted lines/diamonds) results for the stand-alone lossy resonator. Both cases show the same qualitative behavior. However, the C-CROW shows a two-order lower LT (i.e. smaller γ_D -value for which the decay of transmittance occurs) as compared to a stand-alone resonator. At the same time the LDT of the photonic structure is at least two orders of magnitude higher than the one associated with the stand-alone resonator. The latter acquires a maximum value of absorption $A \approx 0.8$ at $\gamma_D \approx 0.01$ as opposed to $A \approx 0.01$ acquired by the C-CROW. The maximum absorption for the photonic structure occurs at much lower values of $\gamma_D \sim 10^{-4}$ which in the case of a non-linear lossy mechanism correspond to rather small, and therefore harmless, incident radiation.

The transport features of the TP resonant mode have been further investigated in case of positional randomness corresponding to a box distribution for the coupling constants $t_{1,2} \in [t_{1,2} - 2\text{MHz}, t_{1,2} + 2\text{MHz}]$. The shaded area in Fig. 3 indicates the variations in T, A . For $\gamma_D \approx 0$ (not shown) the resonant frequency $\nu_0 \approx 6.655$ GHz remains protected and the resonant transmission is unaffected for both a perfect C-CROW $\gamma = 0$ and for resonator with losses $\gamma = 1.4$ MHz. Moreover the experimental data in Fig. 3 incorporate an intrinsic disorder associated with the variation of the bare resonance frequencies, within a range of 1 MHz, and the precision of the resonator positioning, of the order of 0.2 mm (coupling uncertainty ≈ 500 kHz). Nevertheless, the transport features remain largely unaffected, see Fig. 3.

The fragility of the resonant localised mode at moderate γ_D -values is further analysed in Fig. 4. In Fig. 4(a) we report the simulated resonant defect fields for an ideal C-CROW (i.e. $\gamma = 0$) and for various γ_D -values. For $\gamma_D = 0$, a nice agreement between the numerics

and Eq. (2) is observed, indicating that the coupling to the antennas does not affect the resonant mode profile. As γ_D increases, a gradual deviation from the profile of Eq. (2) occurs and eventually a suppression of the defect mode is observed. At $\gamma_D = 20$ MHz the resonant localized mode is suppressed enough so that the field intensity in the vicinity of the defect lossy resonator is two orders smaller than the corresponding one for $\gamma_D = 0$. Thus the lossy defect resonator is protected from damages induced by heat or electrical breakdown. For the C-CROW of Fig. 1a it implies a huge increase in its DR. The comparison with the experimental data [see Fig. 4(b)], where $\gamma = 1.4$ MHz, indicates that the underlying mechanism which is responsible for the destruction of the resonant defect mode remains unaffected.

The destruction of the resonant defect mode can be understood intuitively as a result of a competition between two mechanisms that control the dwell time of photons in the resonant state. The first one is associated with the boundary losses due to the coupling of the photonic structure to the antennas. It results to a resonant linewidth $\Gamma_{\text{edge}} \sim \tau^{-1}$, see Eq. 4. The other mechanism is associated with bulk losses and it leads to an additional broadening of the resonance linewidth. From first order perturbation theory $\Gamma_{\text{bulk}} \approx \gamma_D |\psi_{11}|^2 + \gamma \sum_{n \neq 11} |\psi_n|^2 = (\gamma_D - \gamma)/\xi + \gamma$. For small values of γ_D such that $\Gamma_{\text{bulk}} < \Gamma_{\text{edge}}$, the dwell time is determined by Γ_{edge} and it is essentially constant. Thus the absorption of the photons that populate the resonant state increases, as they are trapped for relatively long time in the lossy C-CROW [see the peak of the black line in Fig. 2(c)]. When $\Gamma_{\text{bulk}} \approx \Gamma_{\text{edge}}$, the dwell time itself begins to diminish, and the resonant mode is spoiled. For even larger values of γ_D the photons do not dwell at all in the resonant state and reflection from the whole structure becomes the dominant mechanism. As a result, the absorption decreases to zero. The above argumentation applies equally well for the stand-alone defect and for the photonic structure. However, in the latter case the condition for the destruction of the resonant mode $\Gamma_{\text{bulk}} \approx \Gamma_{\text{edge}}$ is achieved for exponentially smaller values of γ_D . It is exactly this effect that our proposal is harvesting in order to increase the damaging threshold (and the DR) of the photonic waveguide limiter.
