Abstract—One approach to verify the correctness of a system is to prove that it implements an executable (specification) model whose correctness is more obvious. Here we define a kind of automata whose state is the product of values of multiple variables that we name State Transition Systems (STS for short). We define the semantics of TLA+ constructs using STSs, in particular the notions of TLA+ models, data hiding, and implication between models. We implement these concepts and prove their usefulness by applying them to the verification of C programs against abstract (TLA+ or STS) models and properties.

Keywords—Anything; Something; Everything else.

I. INTRODUCTION
As software systems become large and error-prone, formal verification methods become an essential key concept to ensure their correctness. Model Checking [1] provides an automated technique to check and detect errors in computer programs. But despite its promise, the verification process may be complex due to the size of these systems. One useful technique to reduce the complexity of verification process is abstraction. Generally, an abstract model specify “what” the system do while the concrete model describes “how”. The idea is to map the concrete set of states to a smaller set of states resulting in an approximation of the system with respect to the property of interest. We say that the concrete model implements the abstract one. Verifying the abstract model is generally more efficient than verifying properties of the original.

a) Contributions: We define an operational semantics of a TLA+ specification in terms of automata, that we called “state transition system” (STS). We remind the concepts of implementation relation and refinement mapping in TLA+ that we formalize in terms of relations between STSs. The refinement between specifications can be checked with the TLC model checker. Verified properties on the abstract specification can thus be deduced in the concrete specification. A way to abstract details of the concrete specification is to hide its irrelevant variables. TLA+ can express data hiding, but TLC can’t support this type of construct. So, we have implemented the notion of data hiding by constructing a STS that we call “quotient STS”, which is constructed by extending the TLC model checker. In order to let the quotient STS be analyzed by existing tools, we extend the TLC model checker to produce an LTS that can be checked by the CADP toolkit. We apply the mentioned concepts on C programs using our tool C2TLA+. Preliminary results shows the importance of using an abstract model to reduce the complexity of verification.

b) Outline: The remainder of the paper is structured as follows. We give an overview of TLA+ and its operational semantics in Section 2. Section 3 reminds the concepts of refinement mapping and the implementation relation between specifications and describe a way to construct the quotient STS. In Section 4, we apply these concepts to verify the correctness of the C implementation with respect to their specification and we report some preliminary experimental results obtained. We discuss related work in Section 5. Section 6 concludes and presents future research directions.

II. AN OPERATIONAL SEMANTICS FOR TLA SPECIFICATION
In this section, we explain some basics concerning the syntax and the semantics of TLA [2]. Then, we describe the operational semantics of TLA using a State Transition System.

A. Overview of TLA+
TLA+ is a formal specification language based on the Temporal Logic of Actions (TLA) [3] for the description of reactive and distributed systems. TLA itself is a variant of linear-time temporal logic. The semantics of TLA is defined in terms of states. A state is a mapping from variables to values. A state function is a nonboolean expression built from constants, variables and constant operators, that maps each state to a value. For example, \( y + 3 \) is a state function from a state \( s \) to three plus the value that \( s \) assigns to the variable \( y \). An action is a boolean expression containing constants, variables and primed variables (adorned with “\(^\prime\)" operator). Unprimed variables refer to variable values in the actual state and primed variables refer to their values in the next-state. Thus, an action represents a relation between old states and new states. For example, \( x = y + 2 \) is an action asserting that the value of \( x \) in the old state is two greater that the value of \( y \) in the new state. A state predicate (or predicate for short) is an action with no primed variables.

Syntactically, TLA formulas are built up from actions and predicates using boolean operators (\( \neg \) and \( \land \) and others that can be derived from these two), quantification over logical variables (\( \forall, \exists \)), the operators \( \land \) and the unary temporal operator \( \square \) (always) of linear temporal logic [4].

The expression \( [A]_{vars} \) where \( A \) is an action and \( vars \) the tuple of all system variables, is defined as \( A \land (vars' = vars) \). It states that either \( A \) holds between the current and the next state or the values of \( vars \) remain unchanged when
passing to the next state. For any action \( A \), the state predicate \( \text{Enabled}(A) \) describes whether the action \( A \) can be executed in the current state \( s \), i.e., there exists some state \( t \) such that \( s \rightarrow t \) is an \( A \) step.

To specify a system in TLA, one describes its allowed behaviors. A behavior is an infinite sequence of states that represents a conceivable execution of the system. The system specification can be given by the temporal formula \( \Phi \) defined as a conjunction of the form:

\[
\Phi \triangleq \text{Init} \land \Box [\text{Next}]_{\text{vars}} \land F
\]

where, \( \text{Init} \) is the predicate describing all legal initial states, \( \text{Next} \) is the next-state action defining all possible transitions between states and \( F \) is a conjunction of fairness assumptions about the execution of actions. However, other forms of specification are possible and can occasionally be useful.

A TLA formula is true or false on a behavior, which is a sequence of states. Let \( \sigma = (s_0, s_1, \ldots) \) be a behavior. \( \sigma \) satisfies \( \Phi \) iff \( \text{Init} \) is true of the first state \( s_0 \) and every state that satisfies \( \text{Next} \) or a “stuttering step” that leaves all variables unchanged.

\[ \text{Init} \rightarrow \sigma \]

\[ \text{Next} \rightarrow \sigma \]

A State Transition System

In TLA, the behavior of a system is modeled as an infinite sequence of states. The operational semantics of a TLA specification can be given in terms of a State Transition System (STS), which is easier to work with than sets of sequences.

\[
\Phi \triangleq (x = 0 \land y = 0) \land \Box[ (x' = (x + 1) \% 4 \land y' = x \div 2 )]_{(x,y)}
\]

(a) TLA specification

\[ \text{Init} \rightarrow x = 0 \]

\[ y = 0 \]

\[ x = 1 \]

\[ y = 0 \]

\[ x = 2 \]

\[ y = 1 \]

\[ x = 3 \]

\[ y = 1 \]

(b) The STS of \( \Phi \)

**Figure 1. The operational semantics of a TLA specification**

**Definition 1:** A State Transition System is a 3-tuple \( \mathcal{T} = (\mathcal{Q}, \mathcal{I}, \delta) \) given by

- a finite set of states \( \mathcal{Q} \),
- a set \( \mathcal{I} \subseteq \mathcal{Q} \) of initial states,
- a transition relation \( \delta \subseteq \mathcal{Q} \times \mathcal{Q} \).

Figure 1 shows a TLA specification and its corresponding STS \( \mathcal{T}_\Phi = (\mathcal{Q}_\Phi, \mathcal{I}_\Phi, \delta_\Phi) \) which encodes all its possible behaviors (\( \div \) symbol denotes integer division). The specification \( \Phi \) is translated into \( \mathcal{T}_\Phi \) as follows:

- \( \mathcal{T}_\Phi \) has initial state(s) \( \mathcal{I}_\Phi \) specified by the predicate \( x = 0 \land y = 0 \),
- every state \( s \in \mathcal{Q}_\Phi \) corresponds to a valuation of the state function \( (x, y) \),
- each transition \( t \in \delta_\Phi \) corresponds to satisfying the predicate \( [x' = (x + 1) \% 4 \land y' = x \div 2]_{(x,y)} \).

**III. Refinement and Abstraction of TLA Specifications**

A way to reduce the verification task is to define an abstract model as a specification, and then relate behaviors of the abstract model to those of the implementation. Properties checked on the abstract model can be deduced on the concrete one. We use concrete model to refer to high-level specification and abstract model to refer to low-level specification. This section describes the semantics of refinement between a high-level and a low-level TLA+ specifications. Then, we present a way to automatically construct a reduced model, which abstracts the detailed behavior of the concrete TLA+ specification.

**A. Refinement Mapping**

Abadi and Lamport [5] described that a high-level specification \( \Psi \) implements a low-level specification \( \Phi \) iff for each behavior of \( \Psi \), there is a behavior of \( \Phi \) with the same sequence of externally visible states, allowing stuttering, e.g., if the state \( \Phi \) does not change during a finite number of steps. This implementation relation is proved by defining a refinement mapping between specifications.

Let \( \Psi \) and \( \Phi \) be two TLA specifications, \( x_1, \ldots, x_n \) and \( y_1, \ldots, y_n \) the variables occurring in the specifications \( \Psi \) and \( \Phi \) respectively. A (concrete) specification \( \Phi \) implements an abstract specification \( \Phi \) if \( \Psi \Rightarrow \Phi \). The proof of this implication consists in defining state functions \( \bar{y}_1, \ldots, \bar{y}_n \) in terms of the variables \( y_1, \ldots, y_n \) and prove that \( \Psi \Rightarrow \Phi \), where \( \Phi \) denote the formula \( \Phi \) obtained by substituting \( \bar{y}_i \) for the free occurrences of \( y_i \), for all \( i \).

The set of state functions \( \bar{y}_1, \ldots, \bar{y}_n \) is called a refinement mapping. The “barred variable” \( \bar{y}_i \) is the state function with which \( \Psi \) implements the variable \( y_i \) of \( \Phi \). So, if \( \sigma \) is the behavior \( s_1 \rightarrow s_2 \rightarrow s_3 \ldots \) of \( \Psi \), we define the behavior \( \sigma \) to be \( \bar{s}_1 \rightarrow \bar{s}_2 \rightarrow \bar{s}_3 \ldots \) We say that \( \Phi \) implements \( \Psi \) under this refinement mapping iff, for each behavior \( \sigma \) satisfying \( \Psi \), the behavior \( \sigma \) is a behavior of \( \Phi \).

**B. Implementation Relation and Property Preservation**

The proof \( \Psi \Rightarrow \Phi \) under a refinement mapping is sufficient to verify that \( \Psi \) implements \( \Phi \) [5]. The key to the implication relation is that TLA allows to write only formula that are insensitive to stuttering, i.e., given a TLA formula \( \Phi \) and two stuttering equivalent runs \( \sigma \) and \( \sigma' \), \( \Phi \) holds along \( \sigma \) if and only if it holds along \( \sigma' \) [3]. This implementation relation between TLA specifications can be viewed as a weak simulation relation between its corresponding STSs.

**Definition 2:** Let \( \mathcal{T}_\Psi = (\mathcal{Q}_\Psi, \mathcal{I}_\Psi, \delta_\Psi) \) and \( \mathcal{T}_\Phi = (\mathcal{Q}_\Phi, \mathcal{I}_\Phi, \delta_\Phi) \) denote two STSs. A simulation \( \mathcal{R} \) relation from \( \mathcal{Q}_\Psi \) to \( \mathcal{Q}_\Phi \) is a function that satisfies the following conditions:

- \( \forall s \in \mathcal{I}_\Psi, \mathcal{R}(s) \subseteq \mathcal{I}_\Phi \) (initial states are mapped to initial states).
- For each state pairs \( (s_1, s_2) \in \delta_\Psi \), \( (\mathcal{R}(s_1), \mathcal{R}(s_2)) \in \delta_\Phi \) (state transitions are mapped into state transitions or stuttering steps).
If a lower-level specification, expressed by a TLA formula \( \Psi \), implements an abstract specification \( \Phi \), \( \Psi \) preserves all TLA properties of \( \Phi \) if and only if for every formula \( \phi \), if \( \Phi \models \phi \) is valid, then so is \( \Psi \models \phi \). This is true if \( \Psi \models \Phi \).

C. Data Hiding in TLA

A very useful form of data abstraction is variable hiding, which refers to providing only essential information to the outside world and hiding not needed information. In TLA, it is possible to hide some variables using the existential quantifier \( \exists \) (which differs from the quantifier of predicate logic). The formula \( \exists x : \Phi \) asserts that it doesn’t matter what the actual values of \( x \) are, but that there are some values \( x \) can assume for which \( \Phi \) holds. The meaning of \( \exists \) is defined by formula 2.

The formula \( \sigma \sim \tau \) is defined to be true iff \( \sigma \) can be obtained from \( \tau \) (or vice-versa) by adding and/or removing stuttering steps and changing the values of \( x \). Thus, the formula 2 is true for a behavior \( \sigma \) iff \( \Phi \) is true for some behavior \( \tau \) such that \( \sigma \sim \tau \) is true.

\[
\sigma \models \exists x : \Phi \iff \exists \text{behavior}(\sigma \sim \tau) \land (\tau \models \Phi)
\]

The existential operator is a very simple and useful way to abstract away details of the concrete specification \( \Phi \) (which differs from the quantifier of predicate logic). The formula \( \exists x : \Phi \) asserts that it doesn’t matter what the actual values of \( x \) are, but that there are some values \( x \) can assume for which \( \Phi \) holds. The meaning of \( \exists \) is defined by formula 2.

D. Computing a Quotient STS

Given a concrete STS \( T = (Q, \mathcal{I}, \delta) \) describing a TLA specification, one can obtain an abstraction of \( T \), a small STS that we call quotient STS and which is obtained by quotienting the states \( Q \) under a refinement mapping \( \gamma \).

Figure 2 shows a STS resulting from adding a refinement mapping \( \gamma \) in all states of the concrete STS. The quotient STS (at the right side of the figure) is constructed by collapsing all states related under the relation \( \gamma \) into the same state. Let \( T/\gamma = (Q/\gamma, \mathcal{I}/\gamma, \delta/\gamma) \) be the quotient state transition system of \( T = (Q, \mathcal{I}, \delta) \) under the refinement mapping \( \gamma \). The algorithm of constructing \( T/\gamma \) is given by the algorithm 1.

We extend the implementation of TLC to produce the quotient STS “on-the fly” when the TLC model checker computes the state space of a specification. In fact, TLC makes efficient use of disk. It doesn’t keep all states in memory which is the limiting factor of the explicit other model checkers. Instead, it stores just fingerprints of states, which is a 64-bit number generated by a “hashing” function. So, the probability that two states have the same fingerprint is \( 2^{-64} \) which is a very small number. So, the quotient STS is generated with the same fingerprint collision probability and without exploding the memory.

Algorithm 1 Construction of the quotient STS

1: procedure QUOTIENTSTS
2: \[ Q_\gamma \leftarrow \gamma(T) \]
3: NotSeen \( \leftarrow \{s' \in Q \mid s \in Q \text{ and } (s, s') \in \delta\} \)
4: while NotSeen \( \neq \{\} \) do
5: \[ \text{for } q \in \text{NotSeen do} \]
6: \[ \text{if } \gamma(q) \notin Q_\gamma \text{ then} \]
7: \[ Q_\gamma \leftarrow Q_\gamma \cup \{\gamma(q)\} \]
8: \[ \delta/\gamma = \delta/q \cup \{\{\gamma(q), \gamma(q')\} | (q, q') \in \delta\} \]
9: \[ \text{NotSeen} = \text{NotSeen} \setminus \{q\} \]
10: \[ \text{end if} \]
11: \[ \text{end for} \]
12: \[ \text{end while} \]
13: \[ \text{end procedure} \]

E. Translating a STS into a Labelled Transition System

In order to use existing tools to check properties on a STS, we transform the quotient STS into a Labelled Transition System (LTS), that we call quotient LTS.

Definition 3: A Labelled Transition System is 4-tuple \( T = (Q, \mathcal{L}, \delta, s_0) \), where:

- \( Q \) is the set of states,
- \( \mathcal{L} \) is the set of action labels,
- \( \delta \) is the transition relation (a subset of \( Q \times \mathcal{L} \times Q \)),
- \( s_0 \) is the initial state.

A transition \( (s_1, l, s_2) \) of \( \delta \), indicates that the system can move from state \( s_1 \) to state \( s_2 \) by performing action labelled by \( l \).

- Property preservation: The equivalence between checking a property given in \( \text{LTL}\_\gamma \) formula on the quotient LTS and checking it on the original LTS is ensured by the preservation.

Proposition 1: Let \( \varphi \) be an \( \text{LTL}\_\gamma \) formula, let \( T_\varphi \) and \( T_\Psi \) be two STSs such that \( T_\varphi \Rightarrow T_\Psi \). If \( T_\Psi \models \varphi \) then \( T_\Psi \models \varphi \).

F. Usefulness of the Quotient LTS

The quotient LTS abstracts away the details of the concrete specification, its main advantage is its small size. As properties are preserved between the concrete specification and its quotient, model checking properties can be done on the quotient LTS directly, which is a simple task. The quotient LTS is generated once and can be used to verify different properties (modulo the refinement mapping).

To express and check properties on the quotient STS, we use the CADP [6] toolkit. For this, we first adapt the label names such that LTS can be parsed by the CADP tools. Then, we express properties in the MCL (Model Checking Language) [7] language, the property specification language of CADP that can be verified by its associated model checker.
IV. APPLICATION OF C PROGRAMS

In this section, we implement the concept of refinement between TLA+ specifications and the quotient LTS on C programs. Figure 3 illustrates the verification flow of C programs. We use our tool C2TLA+ [8] to translate C programs into a (concrete) TLA+ specification. This latter can be checked directly against a set of properties, or against an abstract specification by defining the refinement mapping and the implementation relation between the concrete and the abstract specifications. Properties can be expressed in TLA to be verified using the TLC model checker. The quotient LTS is generated, and MCL properties can be verified by the CADP model checker.

In what follows, we briefly present how we specify the semantics of C in TLA+. We apply the described notions by considering the example of the dining philosophers. Finally, we assess the usefulness of using abstraction by giving results of properties verification using TLC and the CADP model checker.

A. TLA specification of a C program

C2TLA+ [8] generates a TLA specification that describes the behavior of the C program as a closed system according to a set of translation rules. A concurrent program consists in a set of C functions. In C2TLA+, concurrency is modeled by considering all possible interleaving of sequences of operations called processes (corresponding to threads in C). Each step of the complete specification is attributed to exactly one process. The C program is defined by a TLA formula in the form of

```c
#define N 4
#define LEFT(i) (i+N-1)%N
#define RIGHT(i) ((i+1)%N)
#define THINKING 0
#define HUNGRY 1
#define EATING 2
typedef int semaphore;
typedef int state[N];
typedef semaphore mutex;
typedef semaphore sem[N];

void take_forks(int i)
{
    P(&mutex);
    state[i] = HUNGRY;
    test(i);
    V(&mutex);
    P(&sem[i]);
}

void put_forks(i)
{
    P(&mutex);
    state[i] = THINKING;
    test(LEFT(i));
    test(RIGHT(i));
    V(&mutex);
}

void philosopher(int i)
{
    while (1)
    {
        think();
        take_forks(i);
        eat();
        put_forks(i);
    }
}
```

B. Illustrating Example

As an example, we consider the classic dining philosophers problem. One possible solution to this problem is the one that appears in Tanenbaum’s popular operating systems textbook [9], given in Figure 4.

In the implementation of this solution, the global semaphore `mutex` provides mutual exclusion for execution of critical sections and the semaphore `sem[i]` ensures synchronization. The latters perform `P()` to acquire a lock and `V()` to release it, using CAS (“Compare-and-swap”) primitive.

C. Refinement of Specifications

d) Abstract specification of the dining philosophers.: We define a coarsest-grained representation of the dining philosopher, illustrated by Figure 5 that captures the aspects of the system that interest us without giving all the details of its internal structure.

In order to check liveness properties we consider that the philosopher cannot starve waiting for a fork i.e., no philosophers is eating forever. This assumption is stated by the formula Fairness, where \(WF_{vars}(A)\) denotes weak fairness on action \(A\).

```
Fairness \(\triangleq\)
\[\forall i \in (0 \ldots N-1) : WF_{vars}(hungry(i)) \land WF_{vars}(eat(i))\]
\[\land \forall i \in (0 \ldots N-1) : \Box\Box(\text{ENABLED}(think(i))_{vars})\]
\[\implies (\Box\Box(eat(i))_{vars})\]
```

e) Specifying the refinement relation.: To check that the concrete specification, generated by C2TLA+, implements the abstract version of the dining philosophers, we define the
refinement relation as shown in Figure 6. In this section, we don’t illustrate the translation of the C code, as the translation rules are described in our previous work [8].

The implementation relation is an implication formula $Spec \Rightarrow Abstract\_instance!Spec$.

D. Expressing properties

An interesting property that the implementation should hold is that the critical sections are protected with the primitives $\mathcal{P}()$ and $\mathcal{V}(\cdot)$. This property can be simply expressed in TLA+ (on the abstract specification) as follows:

$$ mutual\_exclusion \triangleq \forall i \in (0 \ldots (N - 1)) : (\text{phil\_state}[i] = \text{"eat"}) \implies (\text{phil\_state}[\text{LEFT}(i)] \neq \text{"eat"} \land \text{phil\_state}[\text{RIGHT}(i)] \neq \text{"eat"}) $$

The dining philosophers problem captures many aspects of liveness. Among liveness properties of the dining philosophers is starvation-freedom and deadlock freedom that we expressed in TLA+ as follows:

$$ 
\begin{align*}
\text{DeadlockFree} & \triangleq & \forall \ i \in (0 \ldots (N - 1)) : (\text{phil\_state}[i] = \text{"hungry"}) \implies (\text{phil\_state}[i] = \text{"eat"}) \\
\text{NoStarvation} & \triangleq & \forall \ i \in (0 \ldots (N - 1)) : (\text{phil\_state}[i] = \text{"hungry"}) \implies (\text{phil\_state}[i] = \text{"think"})
\end{align*}
$$

E. Verification results and comparison

We check that the concrete TLA+ specification (generated by C2TLA+) implements the abstract TLA+ specification (given in Figure 6). We also check the set of properties on these two specifications. We extract the quotient LTS from the concrete specification that we checked against the set of properties that we express in MCL. Table I shows the number of states and the verification time of the concrete and the abstract specifications using TLC, and the numbers of states, transitions and the time verification of the quotient LTS using CADP model checker. For 5 philosophers, the state space of the concrete TLA specification exceeds 113 millions states and its verification takes more than 10 hours to check the properties.

<table>
<thead>
<tr>
<th>Philos</th>
<th>Concrete Spec. Time(s) States</th>
<th>Abstract Spec. Time(s) States</th>
<th>Verification using TLC Transitions</th>
<th>Verification using CADP Quotient LTS Time(s) Transitions</th>

</tr>
</tbody>
</table>

For the same number of philosophers, the abstract TLA specification generates 82 states and properties were checked in only 1 minute using TLC. On the other hand, the quotient LTS generated 47 states and its verification time is 42s. Due to the preservation properties, we can deduce that all the verified properties on the abstract TLA specification or on the quotient LTS are verified on the concrete specification. The use of

---

1Experiments were carried on an Intel Core Pentium i7-2760QM with 8 cores (2.40GHz each) machine, with 8Gb of RAM memory.
abstraction reduces considerably the complexity of verification of C implementations.

When TLC reports that a transition violates the implementation formula $Spec \Rightarrow Abstract\_instance!Spec$, there is an error either in the concrete specification, the abstract specification, or the refinement mapping function. The trace given by TLC can help to determine which one of those is the case. We use our tool to translate this trace in C and get the C execution sequence that leads to the error.

V. RELATED WORK

Predicate abstraction [10] is a technique to abstract a program so that only the information about the given predicates are preserved. This technique is being used in SLAM [11], BLAST [12] and MAGIC [13]. Their approach has been shown to be very effective on specific application domains such as device drivers programming. SLAM uses symbolic algorithms, while BLAST is an on the fly reachability analysis tool. The MAGIC tool uses LTS models, and weak simulation as a notion of conformance of a system and its abstract specification.

These tools are applied to C programs and use automated theorem prover to construct the abstraction of the C program. The difficulty of these refinement based approach is that performing a refinement proofs between an abstract and a refined model require non trivial human effort and expertise in theorem proving to get the prover to discharge the proof obligations. SLAM cannot deal with concurrency, BLAST cannot handle recursion.

Besides predicate abstraction, several verification techniques for C programs have been proposed. CBMC [14] is a bounded model checker for ANSI C programs which translates a program into a propositional formula (in Static Single Assignment form) which is then fed to a SAT solvers to check its satisfiability. CBMC explores program behavior exhaustively but only up to a given depth.

Compared to previous related works that use an over-approximation of the code implementation which is sound, our approach is based on constructing an executable abstract model, that can be expressed using TLA+ or by constructing the quotient LTS. Moreover, TLA+ is a logic that can express safety and liveness properties unlike SLAM, BLAST and CBMC which have limited support for concurrent properties as they only check safety properties.

VI. CONCLUSION AND FUTURE WORK

We have defined an operational semantics of a TLA+ specification in terms of State Transition Systems. We redefined the semantics of refinement between a high-level (concrete) and a low-level (abstract) TLA+ specifications using STSs and we illustrated a way to automatically construct a quotient STS from the concrete specification by extending the TLC model checker. We applied all these notions for verifying C programs. Experimental results show that verifying properties on the abstract model reduces considerably the complexity of the verification process.

As future work, we plan to extend this work on several interesting directions. We would like to generate TLA+ and MCL properties from the ACSL [15] specification language used in Frama-C. We envisage to benefit from Frama-C analysis of shared variables by several processes to generate TLA+ code with less interleaving between the processes, to reduce the state space. Finally, we aim to use the TLA+ proof system [16] to prove refinement between a concrete and abstract specifications.
