ABSTRACT

Some dairy farmers opt to omit one milking, either incidentally or weekly, without changing other milking times. This practice entails an extended milking interval of 24 h (24h-MI), which is associated with a decrease in milk yield. This decrease varies among cows and could be partly due to factors such as stage of lactation and milk yield level. The aim of this study was to describe the average and individual responses in terms of loss and carryover effects of a 24h-MI on milk yield. The influence of factors such as parity, stage of lactation, and milk yield potential were investigated, together with response repeatability. Our trial used 292 Holstein-Friesian cows, and consisted of 3 successive periods: 1 wk of twice-daily milking (TDM) as a control, one 24h-MI, and then 13 d of TDM. The number of observations per cow ranged from 1 to 9, with no more than three 24h-MI per lactation. The 24h-MI reduced milk yield by 23% (7.8 kg on average) and milk lactose content by 2.6 g/kg on the 24h-MI day. Milk fat and protein content, and somatic cell score increased by 3.0 g/kg, 0.5 g/kg, and 0.4 units, respectively. No significant carryover effect was found of a 24h-MI on milk yield or milk composition 2 wk after resumption of TDM. Milk yield loss and recovery varied widely (coefficient of variation 62%), and the relationship between milk loss and milk recovery showed substantial variation (residual standard deviation 2.1 kg/d). Cows with

a greater milk potential level lost more milk yield but recovered more milk, with no influence on recovery:loss ratio. Cows in early lactation recovered the lost milk yield faster. Repeatability of the responses to a 24h-MI was 44% for milk yield loss (kg/d), 57% for relative milk yield loss (%), 33% for milk yield recovery (kg/d), and 0% for milk recovery:loss ratio (%), suggesting a genetically determined ability to limit loss when one milking is omitted. To conclude, a 24h-MI caused higher milk yield losses than reported in previous studies. Stage of lactation, estimated potential milk yield level, and parity explained the cows' response to the 24h-MI, but did not account for all the individual variability.

Key words: dairy cow, 24-hour milking interval, milk loss and recovery, repeatability

INTRODUCTION

In most dairy systems, cows are milked twice daily to maximize milk collected per day with an acceptable labor cost. However, some farmers omit one milking weekly to reduce labor input, allow more flexibility in labor management (Pomiès and Rémond, 2008), or adapt to unforeseen circumstances (milking machine failure, milker's unavailability, and so on). In such cases, farmers either omit one milking without changing other milking times to keep their work pattern (milking and feeding routine), or adjust the length of milking intervals by postponing the previous milking (Ayadi et al., 2003; Meffe et al., 2003).

The omission of one milking without changing milking times entails an extended milking interval of 24 h (24-h milking interval, **24h-MI**) and is associated with an immediate decrease in milk yield observed on the day of milking omission, and carryover effects on

milk yield, with a gradual return to initial state in the next 2 d (Labussière and Coindet, 1968; Radcliffe et al., 1973). In dairy cows the rate of milk secretion is known to decrease curvilinearly after 16 to 18 h of milk accumulation in the udder, so that the longer the milking intervals, the more marked are the milk losses and carryover effects (Elliott et al., 1960; Wheelock et al., 1966; Stelwagen et al., 2008).

Studies describing the average effects of using a 24h-MI by omitting one milking per week reported an average decrease in milk yield of up to 7.5% over 2 lactations (Labussière and Coindet, 1968), 13% over the entire lactation (Roguinsky et al., 1972), 3.5% over 12 mo (Radcliffe et al., 1973), 10% over 8 wk (Pomiès and Rémond, 2000), and no significant variations over the last 10 wk of lactation (O'Brien et al., 2002). These decreases in milk yield are relatively low, but vary among studies. Wheelock et al. (1966) and Radcliffe et al. (1973) report an individual variability in cows' responses. This individual variability could depend on factors such as stage of lactation, parity, and milk yield potential. Radcliffe et al. (1973) reported greater milk yield losses for high-producing cows in early lactation. Accordingly, Elliott et al. (1960) reported that one of the main factors affecting the decline in the rate of milk secretion with increasing milking interval was the yield level of cows, independent of the stage of lactation.

However, these studies were performed on limited number of cows ($n < 50$), which prevented the authors from determining the influence of these factors. The aim of our study was thus to describe the average and individual responses in terms of loss and carryover effects of a 24h-MI on milk yield and composition using a larger data set (289 dairy cows). The influence of breeding factors, such as parity, stage of lactation, and milk yield potential were investigated, together with response repeatability.

MATERIALS AND METHODS

Experimental Design

To describe responses of dairy cows to a 24h-MI, 292 Holstein dairy cows from the INRA experimental farm of Méjussemaume (48.11°N, 1.71°W; Brittany, France) were used in compliance with the National Legislation on Animal Care (French Ministry of Agriculture certification No. C35-275-23).

A total of 775 24h-MI were performed, split into 10 cohorts ($32 < n < 159$), according to year, month, feeding, and housing conditions (Table 1).

Each 24h-MI consisted of 3 successive periods: 1 wk control, when cows were milked twice daily (**cTDM**), 1 d of 24h-MI (morning milking omitted), and 13 d of twice-daily milking (**TDM**) to examine milk recovery. These 13 d were divided into 3 sub-periods: **pTDM1** (d 1 after 24h-MI), **pTDM2** (d 2 to 6 after 24h-MI), and **pTDM3** (d 7 to 13 after 24h-MI). When milked twice daily, cows were milked at 0730 and 1630 h. On the day of 24h-MI, cows were milked at 1630 h.

Observations from cows that were dried off before the end of the experiment ($n = 20$), with DIM greater than 311 d on 24h-MI day ($n = 30$) or producing less than 10 kg/d on cTDM ($n = 1$) were removed from the data set. A total of 724 observations corresponding to 289 cows were kept for analysis.

A total of 216 cows underwent more than one 24h-MI, and 73 cows only one. When the 24h-MI was repeated, the number of observations per cow ranged from 2 to 9, with 101, 52, 40, 15, 3, 1, 3, and 1 cows having 2, 3, 4, 5, 6, 7, 8, and 9 observations, respectively, with no cow repeated inside a cohort. The number of observations per cow varied from 1 to 3 within lactation (no more than three 24h-MI per lactation per cow) and from 1 to 4 between lactations.

Cows differed in parity, stage of lactation, and age at first calving both within and among cohorts (Table 1). Calving (seasonal calving) occurred between September and January. Age at first calving was around 24 or 34 mo, and 76% cows had their first calf at around 24 mo.

Measurements, Sampling, and Analysis

Milk yield was recorded at every milking in the milking parlor (rotary milking parlor, milk meter MM25, DeLaval France, Elancourt, France). Milk fat, protein, and lactose contents were determined from milk samples collected at each milking, 2 or 3 d a week during cTDM, pTDM1, pTDM2, and pTDM3 and on the 24h-MI day. Somatic cell count was measured once a day on the same days. Milk fat, protein, and lactose contents were determined by infrared analysis (Milkoscan, Foss Electric, Hillerød, Denmark), and SCC with a Fossomatic cell counter (Foss Electric).

Calculations

For periods longer than 1 d, milk yield and composition were averaged over 5 d (pTDM2) or 1 wk (cTDM, pTDM3). Milk lactose content was transformed using a log scale due to the nonnormality of the data. The SCC was converted into SCS using the formula $SCS = \log_2(SCC/100,000) + 3$, where SCC is expressed in units of 1,000 cells/mL (Rupp and Boichard, 1997).

Milk yield loss (kg/d) was computed as the difference between 24h-MI and cTDM. Relative milk yield loss (%) was milk yield loss (kg/d) divided by cTDM milk yield, multiplied by 100. Milk yield recovery (kg/d) was computed as the difference between pTDM3 and 24h-MI. Milk recovery:loss ratio (%) was computed as milk yield recovery (kg/d) divided by milk yield loss (kg/d), multiplied by 100. The recovery:loss ratio was calculated for cows showing both a loss of milk yield when they switched to 24h-MI, and a gain of milk yield when they switched back to TDM, which occurred for 620 challenges.

The changes expected to occur during a 21-d period of normal twice-daily milking throughout lactation were estimated according to calving month, age at first calving, milk year, parity, and DIM from a reference data set of Holstein-Friesian dairy cows from herds of the west of France with official milk recording (reference data set based on 89,399,603 test-day milking with an average of 312 cows per level (minimum 24, maximum 848); H. Leclerc, 2014, personal communication). These provided a reference against which to compare the changes from 21-d periods including a 24h-MI, and

corrected daily milk yield, milk fat, protein, and SCS contents were calculated on this basis to estimate carryover effects of the 24h-MI.

Statistical Analyses

All statistical analyses were performed using R software (R Core Team, The R Foundation for Statistical Computing, 2014, R: A Language and Environment for Statistical Computing, Version 3.0.2, Vienna, Austria, <http://www.R-project.org>). Data were analyzed using linear mixed models (R package nlme, Pinheiro et al., 2013).

The evolution of milk yield and milk composition was analyzed with the following linear mixed model. Model 1 is

$$Y_{ijklmn} = \mu + \text{period}_i + \text{stage of lactation}_j + \text{parity}_k \\ + \text{age at first calving}_l + \text{milk year}_m \\ + \text{interactions} + \text{cow}_n + \varepsilon_{ijklmn},$$

where Y_{ijklmn} is the dependent variable (corrected and noncorrected daily milk yield, milk fat, protein, and SCS contents and noncorrected lactose content); μ is the mean; the fixed effects tested are the period i (cTDM, 24h-MI, pTDM1, pTDM2, pTDM3), the stage of lactation j , the parity k , the age at first calving l , the milk year m , and the 2-way interactions between the fixed effects; the random effect of the cow (assumed to be normally distributed) is n ; and ε_{ijklmn} is the residual error associated with each $ijklmn$ observation. The fixed effects other than period were coded as follows: primiparous ($n = 340$) were distinguished from cows in second lactation ($n = 162$) and third or more lactation ($n = 222$). Stage of lactation was divided into 4 classes: early lactation (24–50 DIM, $n = 59$), peak of lactation (51–100 DIM, $n = 119$), mid lactation (101–180 DIM, $n = 219$), and late lactation (181–311 DIM, $n = 327$). Age at first calving was divided into 2 classes: first calving at around 24 ± 5 mo ($n = 551$) and at 34 ± 5 mo ($n = 173$). The milk year effect was defined in 3 levels (2008–2010, $n = 287$; 2010–2011, $n = 306$; and 2011–2013, $n = 131$). In preliminary analyses, stage of gestation, feeding (access to pasture versus indoor feeding only), and initial levels of fat, protein and SCS contents were also included, but were not found to be significant.

To use the milk yield level as an explanatory variable for the response to 24h-MI, milk yield during period cTDM was adjusted for environmental factors using the following linear model. Model 2 is

$$\begin{aligned}
 Y_{jklm} = & \mu + \text{stage of lactation}_j + \text{parity}_k \\
 & + \text{age at first calving}_l + \text{milk year}_m \\
 & + \text{stage of lactation}_j \times \text{parity}_k + \text{parity}_k \\
 & \times \text{milk year}_m + \text{stage of lactation}_j \times \text{milk year}_m \\
 & + \varepsilon_{jklm},
 \end{aligned}$$

where Y_{jklm} is the milk yield during period cTDM and the other effects are as described above. Potential milk yield level was then defined as $\frac{Y_{jklm} - \hat{Y}_{jklm}}{\hat{Y}_{jklm}}$, where \hat{Y}_{jklm}

is the value predicted from model 2. These values were averaged for each lactation of the cow and coded in 4 levels using the limits: $[-0.38$ to -10%], $[-10\%$ to $0]$, $[0$ to 10%], and $[10$ to $36\%]$, which corresponds to the quartiles of a normal distribution.

Milk yield loss, relative milk yield loss, and milk yield recovery were analyzed according to the following linear mixed model. Model 3 is

$$\begin{aligned}
 Y_{jkmno} = & \mu + \text{stage of lactation}_j + \text{parity}_k \\
 & + \text{potential milk yield level}_o + \text{milk year}_m \\
 & + \text{stage of lactation}_j \times \text{parity}_k \\
 & + \text{stage of lactation}_j \times \text{milk year}_m + \text{parity}_k \\
 & \times \text{milk year}_m + \text{cow}_n + \varepsilon_{jkmno},
 \end{aligned}$$

where Y_{jkmno} is the dependent variable (milk yield absolute and relative loss and recovery); μ is the mean; the fixed effects are the stage of lactation j , the parity k , the potential milk yield level o , the milk year m , and the 2-way interactions between the fixed effects; the random effect of the cow (assumed to be normally distributed) is n ; and ε_{jkmno} is the residual error associated with each $jkmno$ observation.

The model built to analyze rate of milk recovery was identical to model 3, except for interactions. The interactions parity \times stage of lactation and parity \times milk year were not significant, but a significant potential milk yield level \times milk year interaction was found.

Results for fixed effects and interactions were expressed as least squares means and were computed using the lsmeans package (Lenth, 2014). Differences were considered significant at $P < 0.05$.

Repeatability of cows' response in terms of milk yield loss (kg/d and %) and recovery (kg/d) between each 24h-MI were computed by dividing the variance explained by the cow effect by total variance, multiplied by 100.

Pearson correlations were computed between milk yields at different experimental periods, milk losses

(kg/d, %), milk yield recovery (kg/d), and milk recovery:loss ratio (%).

RESULTS AND DISCUSSION

During the control week (cTDM), milk yield averaged 28.5 ± 6.33 kg/d, milk fat content averaged 36.9 ± 4.76 g/kg, milk protein content averaged 30.1 ± 2.4 g/kg, milk lactose content averaged 48.0 ± 2.02 g/kg, and SCS averaged 2.58 ± 1.63 units. These data showed marked individual variations, especially for milk yield, which varied from 12.9 to 52.3 kg/d, and milk fat content, which varied from 18.9 to 52.9 g/kg. Milk protein and lactose contents showed less between-cow variability: from 24.2 to 38.4 g/kg for protein content and from 32.2 to 53.1 g/kg for lactose content. Milk SCS varied widely, from -1.32 to 9.18 units (which corresponds to around 5,000 and more than 7 million cells/mL, respectively). This variability originated from the experimental design using 724 observations obtained over several years from 289 cows at different parity, stage of lactation, and age at first calving inside cohorts (Table 1). It remained steady over experimental periods except for milk fat and lactose content, whose coefficients of variation increased by 45% when one milking was omitted, and returned to their initial levels when cows resumed TDM.

Average Effects of a 24h-MI on Milk Yield and Composition

The omission of one milking led to an average decrease in milk yield of 6.3 kg/d (22.1%; Table 2). Milk yield and composition (except for milk lactose content) were corrected from the variations occurring in the course of lactation (according to model 1). In response to milking omission, least squares means of milk yield decreased by 7.8 kg/d (23.4%), and milk lactose content decreased by 2.6 g/kg, whereas milk fat and protein contents and milk SCS increased by 3.2 g/kg, 0.5 g/kg and 0.41 units, respectively (Table 3). The decrease in milk yield was greater than the 10% milk loss observed by Stelwagen et al. (2008) with one 24h-MI and the 14% losses observed in 7 cows by Wheelock et al. (1966). However, Wheelock et al. (1966) reported a high variability in responses between cows, milk yield losses varying between 1 and 31%. The decrease in milk lactose content and the increase in milk fat and protein contents and SCS support earlier findings (Labussière and Coindet, 1968; Pomiès and Rémond, 2000). Most changes in milk composition can be related to changes in mammary epithelial tissue permeability. Alveolar distension occurring in reaction to 18 to 24 h milk ac-

cumulation is known to impair tight junctions (**TJ**) between mammary epithelial cells (**MEC**; Stelwagen et al., 1994; Davis et al., 1999). Impaired TJ increases exchanges between the smaller components of milk and interstitial fluids, thereby leading to a leakage of milk lactose from milk to blood and an influx of proteins from blood into the milk compartment (Stelwagen et al., 1994; Stelwagen and Lacy-Hulbert, 1996; Auld-ist and Prosser, 1998). The increase in milk protein content observed with a 24h-MI could therefore be partly due to this influx. However, extended milking intervals stimulate multiple and complex physiological mechanisms, and changes in milk composition are not due solely to impaired TJ. An increase in milk fat content, for example, has been reported in extended milking intervals (Wheelock et al., 1966), and could be due to smaller changes in the regulation of milk fat globule secretion relative to that of milk aqueous phase components (Davis et al., 1999; Guinard-Flament et al., 2011b).

Average carryover effects of the 24h-MI on milk yield and composition were estimated 13 d after resuming TDM (pTDM3). Milk yield and fat and protein contents corrected from variations occurring in the course of lactation using data from official milk recording were not different from their control period levels (Table 3). In regard to milk lactose content, it was not possible to adjust for the trend with advancing lactation, because

routine milk recording does not automatically record this. However, the nonsignificance of the unadjusted difference between cTDM and pTDM2 milk lactose content suggests no carryover effects of 24h-MI on milk lactose. To our knowledge, no study has focused on the long-term carryover effects of omitting one milking. Most studies describing cows' responses to an extended milking interval aim to determine the length of the recovery period necessary to resume initial milk production. These studies report that the length of this recovery period is different for milk yield, milk fat, and milk protein contents, and that the length of the full recovery period could be more than 48 h (Wheelock et al., 1966; Radcliffe et al., 1973). The present study, reporting no carryover effect of a 24h-MI on milk yield and composition 2 to 6 d (pTDM2) and 7 to 13 d (pTDM3) thus agrees with previous studies, showing, on average, a full recovery of milk yield within the 2 to 3 d following the 24h-MI.

However, although the 24h-MI results in an average loss of 22.1% of milk yield with no carryover effects, this figure hides a high variability of responses.

Variability of Milk Yield Loss and Subsequent Milk Recovery Associated With a 24h-MI

The correlations between milk yields during experimental periods are given in Table 4. Milk yield correla-

tions between the 24h-MI and any given TDM period were lower than those between TDM periods, indicating that the 24h-MI induced variable responses among cows on both milk loss and milk recovery. The high correlation between cTDM and pTDM3 periods ($r = 0.95$) indicates that these responses were transient, and that most cows recovered their initial performance rank. These variable responses among cows on both milk loss and milk recovery suggest the presence of cows that are more tolerant toward this practice. Dairy cows that tolerate a 24h-MI could be defined by their ability to show a limited milk loss when undergoing a 24h-MI, to recover as much milk as they lost, or both. Milk losses, recovery, and recovery:loss ratio were therefore studied as indicators of the ability of the cow to tolerate a 24h-MI.

As indicated by standard deviation, most cows lost between 2 (-9.8%) and 10 kg/d (-32.8%) when undergoing a 24h-MI, with an average loss of 6.3 kg/d (-21.3%, Table 2). As illustrated in Figure 1, this loss was highly variable (CV = 62%), with cows losing as much as 21.6 kg/d (-52%) and some cows gaining up to 4.0 kg/d (21.6%). In pTDM3, cows on average recovered less milk yield (4.8 kg/d) than they had lost (6.3 kg/d). This average 1.5 kg/d difference between milk loss and recovery was mainly due to the variations occurring in the course of lactation, as previously shown by the correction of milk yield from changes occurring in the course of lactation (Table 3). As indicated by a negative correlation (Table 4), cows showing the highest milk losses were also those that had the highest milk recovery. However, the residual standard deviation of the regression of milk recovery on milk loss was 2.1

kg/d (Figure 1), indicating a significant variation in the relationship between loss and recovery: some late-lactation cows showed no positive recovery (Figure 1).

The present study showed a higher proportion of early lactation cows among those that recovered more than expected from the general regression (i.e., cows above the line in Figure 1), and a higher proportion of later-lactation cows among those that recovered less than expected (i.e., below the line in Figure 1). Cows in early lactation (24–50 DIM) recovered on average 0.95 kg/d more than expected, whereas cows in late lactation (181–311 DIM) recovered on average 0.23 kg/d less than expected.

Although significant, the correlation ($r = -0.10$) between recovery:loss ratio and milk loss (kg/d) was weak. Furthermore, recovery:loss ratio was not correlated with relative milk loss (%), thus indicating that recovery:loss ratio could be independent of the quantity of milk lost. To our knowledge, such observations have been reported only once in the literature, but using once-daily milking over 3 wk (Guinard-Flament et al., 2011a). Thus, to quantify cows' tolerance to 24h-MI, it seems necessary to describe the 2 abilities, namely the ability to show limited losses (kg/d and %) and the ability to recover as much milk as they lost (milk recovery:loss ratio, %).

Repeatability of Cows' Response between 24h-MI

Repeatability of the cow responses to a 24h-MI were 44% for milk loss (kg/d), 57% for relative milk loss (%), 33% for milk recovery (kg/d), and 0% for milk recovery:loss ratio (%). To our knowledge, repeatability

of cows' responses to a 24h-MI has not been studied to date. Repeatability of cows' responses in cases of extended milking intervals has been described only by Carruthers et al. (1993) in the case of cows milked once a day for three 1-wk periods. The absolute milk loss repeatability observed in the present study seems consistent with the 49% repeatability reported by Carruthers et al. (1993). However, the 57% relative milk loss (%) repeatability observed here was greater than the 41% they observed. As repeatability is known to constitute an upper limit of heritability, cow's milk loss when one milking is omitted could be a trait with a moderate heritability. Hence, the mammary gland's ability to tolerate disruption with 24h-MI could in part be genetically determined.

Effects of Cows' Potential Milk Yield Level, Stage of Lactation, and Parity on Cows' Ability to Tolerate a 24h-MI

Stage of gestation, feeding (access to pasture versus control feed), and initial levels of fat and protein contents and SCS did not significantly affect milk loss (kg/d and %) or milk recovery (kg/d) in the present study.

The estimation of the potential milk yield level of the cow expresses the part of the milk yield during the control period that was not accounted for by the effects of stage of lactation, parity, age at first calving, milk year, or the interaction of these effects. This milk potential was thus considered as being the sum of the milk genetic

potential of the cow and its permanent environment. As potential milk yield level was estimated as the residual from the model adjusting milk yield during the control period for breeding factors, it is assumed here that cows with the highest residuals had the highest milk potential. In the present study, higher potential milk yield level was associated with higher milk yield loss expressed in either absolute or relative value (3.6 kg/d and 6.3% difference between lowest 25% milk potential and highest 25% milk potential, respectively, Table 5). Milk recovery (kg/d) was also greater for cows with a higher potential milk yield (+2.8 kg/d). Consequently, no significant effect of potential milk yield was found on milk recovery:loss ratio. The ability to demonstrate a strong milk recovery:loss ratio after a 24h-MI was not linked to a higher estimated milk potential.

Cows in early lactation (24–50 DIM) lost more milk (in both kg/d and %), but recovered more milk than cows in late lactation (Tables 6 and 7). Their response also showed a different time course compared with cows at peak, mid, and late lactation (Figure 2). Cows in early lactation recovered the lost milk sooner. At pTDM1, these cows (24–50 DIM) had already reached 78% of the total milk yield they ultimately recovered (at the pTDM3 period), whereas cows at peak (51–100 DIM), mid (101–180 DIM) and late (181–311 DIM) lactation had respectively reached only 65, 44, and 41% of the total milk yield they ultimately recovered.

Milk yield loss measured on the first day of once-daily milking has been reported to be greater for cows having a smaller proportion of milk stored in the mam-

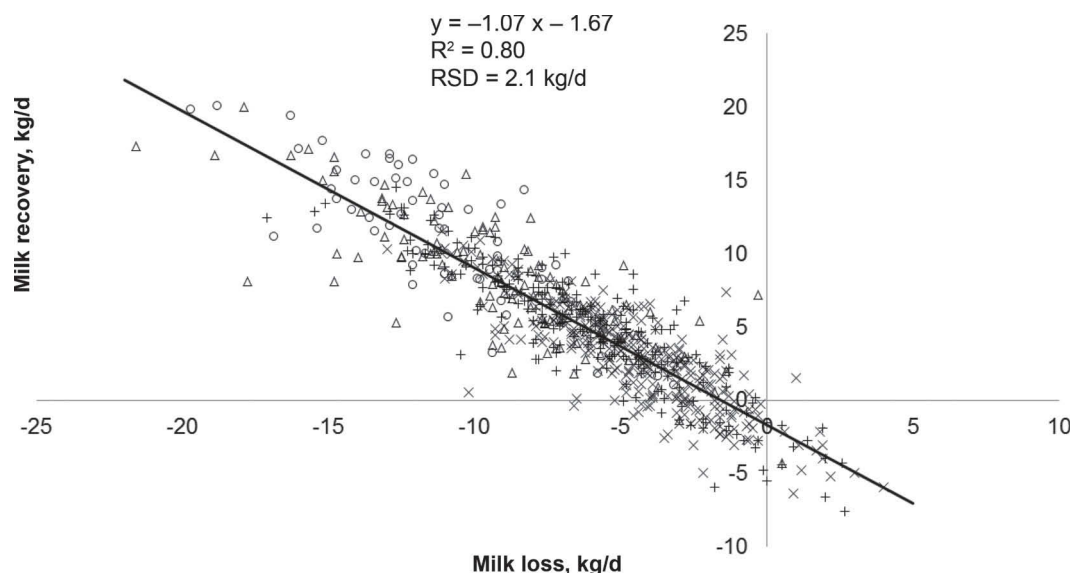

Figure 1. Individual milk yield loss and recovery of cows 2 wk after a 24-h milking interval (24h-MI). RSD = residual standard deviation. Symbols represent cows that on day of 24h-MI presented a stage of lactation between 24 and 50 DIM (○), 51 and 100 DIM (△), 101 and 180 DIM (+), and 181 and 311 DIM (×).

Table 5. Effects of cows' potential milk yield level on absolute and relative milk yield loss, milk recovery, and rate of milk recovery (means \pm SEM)¹

Item	Potential milk yield level			
	Lowest 25% (1st quartile)	2nd quartile	3rd quartile	Highest 25% (4th quartile)
Milk yield loss, kg/d	-6.6 \pm 0.30 ^a	-7.7 \pm 0.27 ^b	-9.0 \pm 0.24 ^c	-10.2 \pm 0.31 ^d
Relative milk yield loss, %	-22.1 \pm 1.0 ^a	-23.8 \pm 0.9 ^a	-26.9 \pm 0.8 ^b	-28.4 \pm 1.1 ^b
Milk yield recovery, kg/d	6.2 \pm 0.35 ^a	7.3 \pm 0.32 ^b	8.1 \pm 0.29 ^{bc}	9.0 \pm 0.36 ^c
Milk yield recovery:loss ratio, ² %	85.6 \pm 3.7 ^a	93.2 \pm 3.0 ^a	89.6 \pm 2.6 ^a	86.3 \pm 3.5 ^a

¹Potential was estimated as the residual from the model adjusting milk yield during the control period by the effects of stage of lactation, parity, age at first calving, and milk year (i.e., the median value of potential is set at zero).

²Computed on 620 cows.

mary cistern when milked twice daily on control period (Knight and Dewhurst, 1994). This proportion is lower in early lactation than in the rest of lactation (Stelwagen et al., 2013) and could explain why cows in early lactation tend to lose more milk when omitting one milking compared with cows in mid and late lactation.

The prompter milk yield recovery of cows in early lactation observed in this study is noteworthy. Milk production is known to be regulated by both number and activity of MEC (Capuco et al., 2001, 2003). Singh et al. (2005) and Tremblay et al. (2009) determined that MEC apoptosis does not increase in the first 24 h after milking, and so we assume that the 24h-MI is insufficient to induce a decrease in MEC numbers. Similar studies have also found that proliferative MEC are more numerous (Capuco et al., 2001) and that MEC secretory activity is still increasing in early lactation compared with the declining phase of lactation (Capuco et al., 2003). This is also associated with a higher milking release of prolactin, the lactogenic and galactopoietic hormone, in early lactation (Koprowski

and Tucker, 1973). All these early-lactation adaptive mechanisms could account for the faster recovery in milk yield observed in the present study for cows in early lactation.

Although parity did not significantly affect milk loss or recovery, primiparous cows showed greater relative losses in early and mid stages of lactation (Table 6). They also showed a greater milk recovery, leading to a greater recovery:loss ratio than cows in their second lactation (Table 7). To our knowledge, the influence of parity on cows' responses to a 24h-MI has not been reported in the literature. However, our finding of greater losses for primiparous cows is consistent with earlier findings using once-daily milking (Stelwagen et al., 2013). The effect of parity on recovery:loss ratio has not been studied to date. The higher recovery:loss ratio observed in primiparous cows in the present study might result from greater udder plasticity during the first months of lactation. A recent study showing similar results on milk losses on dairy ewes supports this hypothesis (Vanbergue et al., 2013).

Table 6. Effects of the interaction between stage of lactation and parity on absolute and relative milk yield loss and milk yield recovery (means \pm SEM)

^{a,b}Within each factor, values with different superscript letters differ significantly ($P < 0.05$).

CONCLUSIONS

The 24h-MI caused an average milk yield loss of 24%, higher than that reported in previous studies, with an average complete milk recovery after 2 d. However, the average responses for milk loss and recovery were associated with a significant variability among cows. Stage of lactation, potential milk yield level, and parity accounted for the cows' response to the 24h-MI, but not for all the individual variability. Other factors therefore also determine the ability of dairy cows to adapt to 24h-MI. The 57% relative milk loss (%) repeatability observed in the present study suggests that the ability of the mammary gland to tolerate an extended milking interval of 24 h could be to some degree genetically determined.

Figure 2. Time course of milk yield according to stage of lactation during experimental periods [twice daily milking control period (cTDM), a 24-h milking interval (24h-MI), d 1 after 24h-MI (pTDM1), d 2 to 6 after 24h-MI (pTDM2), and d 7 to 13 after 24h-MI (pTDM3)]. Values within the same stage of lactation with different letters differ at $P < 0.05$. Symbols represent cows that on 24h-MI presented a stage of lactation between 24 and 50 DIM (\circ), 51 and 100 DIM (Δ), 101 and 180 DIM (+), and 181 and 311 DIM (\times).

ACKNOWLEDGMENTS

The authors thank A. Mottin and all the staff at the INRA experimental farm of Méjusseume for help with animal care and handling. We are also grateful to G. Théaud and M. Fargetton for help in data collection. This study was funded by the INRA research unit PEGASE (St-Gilles, France).
