ABSTRACT: Triclinic calcium pyrophosphate dihydrate (t-CPPD) crystals are one of the two polymorphs of microcrystals that have been found in the joints of patients suffering from pseudogout. However, there is currently no treatment for inhibiting the formation of these crystals, which present a high inflammatory potential. In this context we studied *in vitro* the precipitation of t-CPPD in a stirred reactor under pH- and temperature-controlled conditions and determined the effect of selected biologically relevant ionic additives (Mg^{2+} , Cu^{2+} , Fe^{3+} , Zn^{2+} , $S_2O_3^{2-}$) on its formation. The results showed that 1 mM Fe^{3+} , Zn^{2+} , or Cu^{2+} induced the most significant changes by partly inhibiting the crystallization of t-CPPD and favoring the formation of an amorphous-CPP phase (98 wt %) in the presence of Fe^{3+} or a monoclinic-CPPD phase (78 or 71 wt %, respectively) in the presence of Zn^{2+} or Cu^{2+} . Correlations between ^{31}P solid-state NMR, XRD, and elemental analyses showed that the additive cations are inserted into the monoclinic-CPPD and/or amorphous-CPP phases. This study, which combines structural, morphological, and elemental analyses, paves the way toward a deeper comprehension of the role of ionic additives in preventing the formation of CPPD crystalline phases, and is a key step in long-term development of an effective therapeutic treatment.

1. INTRODUCTION

Osteoarthritis (OA) and pseudogout are forms of arthritis involving the deposition of microcrystals in the joints. Hydrated calcium pyrophosphates (CPP: $Ca_2P_2O_7 \cdot nH_2O$) have been identified among the deposited microcrystals in the joints of arthritic patients. More precisely, two polymorphs of CPP dihydrate (CPPD: $Ca_2P_2O_7 \cdot 2H_2O$) have been found in the joint tissues (cartilage, meniscus) or synovial fluids of patients suffering from pseudogout: the monoclinic (m-CPPD) and triclinic (t-CPPD) phases which both present a high inflammatory potential.^{1,2} The triclinic form is considered the most stable and is the most commonly found *in vitro* and *in vivo*.^{3–5} There is currently no treatment that inhibits the formation of these CPP crystals, but only treatment helping to limit the inflammatory response and relieve the patient's pain.^{6,7} Understanding the mechanisms of formation of CPP *in vitro* and *in vivo* and the influence of substances that could potentially inhibit the crystallization of the m-CPPD and t-CPPD phases is a key step in the medium- to long-term development of an effective therapeutic treatment.

Although only two dihydrated forms of CPPD crystals have been detected *in vivo* (m- and t-CPPD), investigations of other hydrated forms, such as the tetrahydrated CPP (m-CPPT β : $Ca_2P_2O_7 \cdot 4H_2O$) and especially amorphous CPP (a-CPP: $Ca_2P_2O_7 \cdot nH_2O$ with $n \cong 3$ to 4), have also been reported *in vitro*;^{8–10} these phases are also of interest as potential precursor phases for the crystalline t- and m-CPPD phases *in vitro* and *in vivo*.

There are few studies in the literature on CPP precipitation in the presence of additives.^{11–15} In addition, these experimental studies did not provide explanations of the mechanism by which the additives act on the crystallization of different CPP phases. However, the influence of additives or impurities on the crystallization of other compounds has been extensively studied in previous work.^{16,17} It is known that additives can act in different ways: they can favor the formation

of one phase at the expense of another,¹⁸ they can increase the nucleation rate at the expense of the growth step, or they can selectively inhibit or promote the growth of particular crystal faces.¹⁹

In the case of CPP precipitation, one can classify the potential additives into different categories: (i) additives having a chemical resemblance to pyrophosphate or orthophosphate ions, such as phosphocitrates²⁰ and bisphosphonates;²¹ (ii) proteins of biological interest, such as osteopontin, a negatively charged bone sialoprotein²² and fetuin A, a blood protein;²³ and (iii) cationic additives corresponding to ions already found in the body, such as Mg²⁺ or Fe³⁺.

These additives may act according to the modes of action described by Mullin²⁴ and Nyvlt and Ulrich.²⁵ Different adsorption sites exist on the crystal surface (kinks, steps, and edges) and the additive can be adsorbed on one or more of these sites, to create a complex compound with entities/ions at the surface of the crystal or included in the crystal lattice. This can be facilitated if there is a similarity of ionic or molecular structure between the additive and the ions or molecules constituting the crystal (i.e., P₂O₇⁴⁻ and/or Ca²⁺ in the case of CPPD compounds). In the present study, only ionic additives will be considered.

Cheng and Pritzker¹⁴ showed that magnesium ions promote the production of crystals of the m-CPPD phase rather than t-CPPD in a laboratory study where the concentrations of Ca²⁺ and Mg²⁺ were varied simultaneously during the synthesis of CPP. These authors performed their tests with three different concentrations of sodium pyrophosphate high enough to obtain sufficient CPP precipitate for analysis. Mandel et al. reported a synthesis protocol of m-CPPD involving magnesium ions which were not present in the synthesis of t-CPPD.²⁶

In our study, besides Mg²⁺, four other types of biologically relevant ions (Zn²⁺, Cu²⁺, Fe³⁺, and S₂O₃²⁻) were selected as additives. In human metabolism, iron is present in two different ionic forms: Fe²⁺ (ferrous) and Fe³⁺ (ferric). Fe²⁺ is transported in the blood by ferroportin, but the element is taken up in tissues and cells as Fe³⁺, using transferrin (a plasmatic carrier) and ferritin (an intracellular storage protein).²⁷ In addition, it is known that iron and magnesium are associated with hypomagnesaemia and hemochromatosis diseases which are related to premature osteoarthritis.^{28,29} In hemochromatosis joint disease, measurements of serum ferritin have proven to be useful in disease detection.³⁰ Furthermore, previous studies on crystal growth have shown that the higher the charge state of the ion is, the more pronounced is the effect of this ion on crystallization.²⁴ Indeed, if Fe²⁺ were used in this study, it would be difficult to stabilize and to prevent its oxidization in solution at high temperature (e.g., 90 °C) and acidic pH. Therefore, Fe³⁺ was chosen in the present study.

Among the other ions of interest, thiosulfate (S₂O₃²⁻) was previously studied and displayed a reasonable efficiency in the treatment of renal or vascular calcifications.^{31–33} This ion was selected to determine its influence, if any, on the formation of CPP involved in osteoarthritis.

The objective of this study is to synthesize t-CPPD *in vitro* through a precipitation process in a stirred reactor under pH- and temperature-controlled conditions and to determine the effect of the selected ionic additives on its precipitation. We do not intend on mimicking *in vivo* conditions for CPPD polymorph precipitation (it seems difficult at this stage, owing to the lack of information we have on these systems at the onset of CPPD formation) but we aim to evaluate and

compare the effect of various biologically relevant ionic additives while keeping all the other synthesis parameters identical to the t-CPPD reference synthesis (without additive).

The effect of these different ions will be thoroughly investigated by means of a set of complementary characterization techniques: X-ray diffraction, Fourier-transform infrared (FTIR) spectroscopy, Raman spectroscopy, solid-state nuclear magnetic resonance (solid-state NMR), scanning electron microscopy, and elemental analysis by inductively coupled plasma spectrometry.

2. MATERIALS AND METHODS

2.1. Materials. Anhydrous potassium pyrophosphate (K₄P₂O₇) was obtained by heating potassium hydrogen phosphate dihydrate (K₂HPO₄·2H₂O, VWR, purity: 100%) at 400 °C for 4 h, and was used to prepare the pyrophosphate reagent solution (rs). The other precipitating reagents, i.e., calcium nitrate tetrahydrate (Ca(NO₃)₂·4H₂O, Carlo Erba, purity: 97%), acetic acid (VWR, purity: 100%), and ammonia aqueous solution (VWR, 30%), were used without undergoing further purification.

Commercial salts of zinc acetate dihydrate (Zn(CH₃COO)₂·2H₂O, Fisher Scientific, purity: 99.5%), iron chloride hexahydrate (FeCl₃·6H₂O, VWR, purity: 98%), magnesium chloride hexahydrate (MgCl₂·6H₂O, VWR, purity: 100%), copper nitrate hydrate (Cu(NO₃)₂·2.5H₂O, Alfa Aesar, purity: 98%), and sodium thiosulfate pentahydrate (Na₂S₂O₃·5H₂O, VWR Prolabo, purity: 99.5%) were used as additives.

All the solutions used for performing precipitation by the double decomposition method were prepared by dissolving the salts in ultrapure water (18.2 MΩ·cm).

2.2. Experimental Setup for Precipitation in the Absence or Presence of Ionic Additive. Pure t-CPPD, m-CPPD, and a-CPP reference samples for this study, i.e., without any additive, were synthesized by double decomposition precipitation by simultaneously adding, at controlled flow rate (2.25 mL·min⁻¹), a potassium pyrophosphate reagent solution (rs) and a calcium nitrate reagent solution (rs) into an ammonium acetate buffer solution (b) at controlled temperature and pH. This method of synthesis was adapted from that published by Gras et al.¹⁰ and implemented in a stirred reactor in order to study the effect of the ionic additives under improved control of conditions (pH, temperature, and stirring/mixing). The pure CPP phase obtained by this method depends on the chosen combination of pH and temperature as reported in Table 1.

Table 1. Selected Temperature and pH Conditions for the Synthesis of the Various Pure Reference CPP Phases According to Gras et al.¹⁰

CPP phase synthesized	t-CPPD	m-CPPD	a-CPP
Temperature	90 °C	90 °C	25 °C
pH	3.6	5.8	5.8

The precipitation reaction involved in the precipitation of the t-CPPD or m-CPPD phase is

Reagent solutions were prepared at room temperature by dissolving K₄P₂O₇ (8.70 × 10⁻³ mol) or Ca(NO₃)₂·4H₂O (1.74 × 10⁻² mol) in 115 mL of ultrapure water to respectively prepare the pyrophosphate and calcium reagent solutions (rs). A buffer solution (b) of ammonium acetate was prepared from a mixture of acetic acid and ammonia in water: ammonia solution was poured into the acetic acid solution to reach the desired pH (i.e., 3.6 for t-CPPD and 5.8 for m-CPPD or a-CPP).

The experiments were carried out in a 500 mL double-jacketed Pyrex glass round-bottomed crystallizer. This tank was equipped with four baffles, a lid, and a pH probe (PHC3001–8 Radiometer Analytical) connected to a pH-meter (PHM220 Radiometer

Analytical). Temperature control was provided by a cryostat (AD15R-30, VWR) connected to an external temperature sensor (PT100, VWR). A stirrer (Propeller Stirrer Shafts, Bola) fixed to a motor (RW 20 digital, IKA) was used to ensure a homogeneous mixture. 100 mL of the cationic and anionic reagent solutions were simultaneously added at a constant flow rate ($2.25 \text{ mL}\cdot\text{min}^{-1}$) in the buffer solution (200 mL) by means of two syringe pumps (Harvard Apparatus PHD 2000) (Figure 1). At the end of the addition of the reagent solutions,

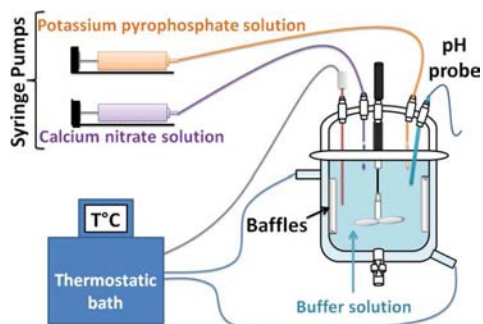

Figure 1. Standard experimental setup for the precipitation in a stirred tank at controlled temperature, pH, flow rate, and mixing.

an aging step was performed at the selected temperature ($90 \text{ }^\circ\text{C}$ for m-CPPD and t-CPPD or $25 \text{ }^\circ\text{C}$ for a-CPP precipitation) for 10 min under stirring. The precipitate was then filtered on a Buchner funnel and washed with 1200 mL of deionized water before being dried in an oven at $37 \text{ }^\circ\text{C}$ for at least 12 h. Finally, the samples obtained were stored at ambient temperature in a sealed container to avoid any contamination.

The effect of various ionic additives (A) on t-CPPD precipitation was investigated at $90 \text{ }^\circ\text{C}$ and pH 3.6, i.e., the combination of temperature and pH corresponding to the formation of the t-CPPD phase.¹⁰ The ionic additive was introduced into the reactor via two

routes: (i) the additive salt was dissolved at different concentrations in the buffer solution (b, placed in the reactor), or (ii) it was dissolved into one of the reagent solutions (rs, placed in a syringe pump): in the pyrophosphate reagent solution for experiments with the anionic additive ($\text{S}_2\text{O}_3^{2-}$) or in the calcium reagent solution for experiments with cationic additives (Mg^{2+} , Cu^{2+} , Fe^{3+} , Zn^{2+}).

The concentrations tested for each ionic additive were chosen to be in the range of those found in human blood plasma (1 mM of dissociated Mg^{2+} , 0.002 to 0.04 mM Fe^{3+})^{34–37} or in blood components (0.020 to 0.030 mM Zn^{2+} in blood plasma),³⁸ except for sodium thiosulfate, which is not naturally present in the human body. It is important to note that for some of these ions, their concentrations can vary in the human body, such as Cu^{2+} , the concentration of which is different in sweat ($18.10 \pm 3.90 \text{ } \mu\text{M}$ Cu^{2+} in sweat from the arm), in serum ($0.00 \text{ } \mu\text{M}$ Cu^{2+} for a healthy patient, $0.64 \pm 1.10 \text{ } \mu\text{M}$ Cu^{2+} for an osteoarthritic patient), and in synovial fluid ($1.10 \pm 1.65 \text{ } \mu\text{M}$ Cu^{2+} for an osteoarthritic patient).³⁹

The quantities of ionic additives to be introduced into the buffer (b) or a reagent solution (rs) placed in a syringe pump were calculated with respect to the total volume of the solution within the reactor at the end of the precipitation: 0.10 and 1.00 mM for Zn^{2+} , Mg^{2+} , or Cu^{2+} ; 0.03, 0.10, and 1.00 mM for Fe^{3+} ; and 1.00 and 5.00 mM for $\text{S}_2\text{O}_3^{2-}$ when the additive was introduced into the buffer (b). When the additive was introduced into one of the reagent solutions (rs), the concentrations tested for each ionic additive were 0.10 and 1.00 mM.

All experiments were performed at least in duplicate.

2.3. Characterization of the Synthesized Powders. Each synthesized sample was characterized by powder X-ray diffraction (XRD), FTIR and Raman spectroscopy, and scanning electron microscopy (SEM). In addition, elemental analyses were performed by inductively coupled plasma optical emission spectrometry (ICP-OES) on a solution of each sample.

The powder X-ray diffraction data were collected with a Bruker D8 Advance diffractometer equipped with a Bragg–Brentano θ – θ geometry and a copper anode ($\lambda(\text{Cu } K_{\alpha 1}) = 1.54060 \text{ \AA}$ and $\lambda(\text{Cu } K_{\alpha 2}) = 1.54439 \text{ \AA}$). The X-ray diffraction patterns were obtained for a range of 2θ angles from 5 to 50° with a step of 0.2° .

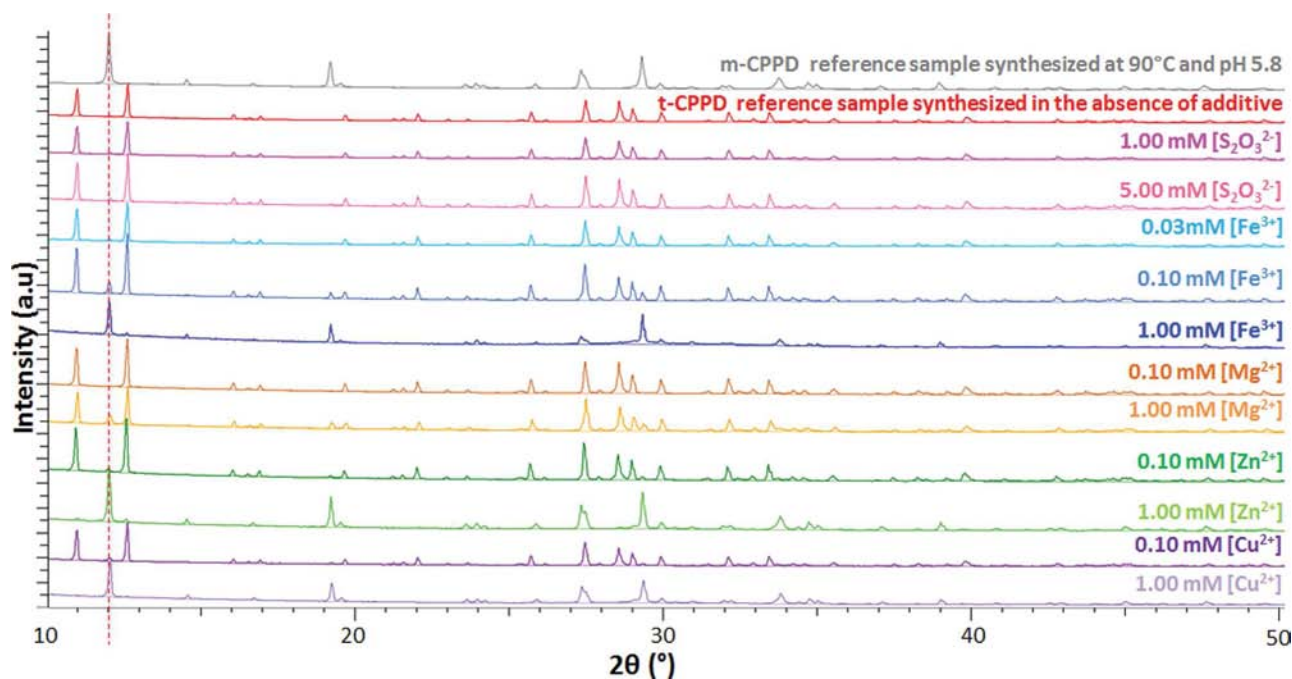

Figure 2. XRD patterns of m-CPPD and t-CPPD reference phases and of samples synthesized in the presence of additives at various concentrations (0.10 or 1.00 mM for Mg^{2+} , Zn^{2+} , or Cu^{2+} ; 0.03, 0.10, or 1.00 mM for Fe^{3+} ; and 1.00 or 5.00 mM for $\text{S}_2\text{O}_3^{2-}$) initially present in the buffer solution (b).

A semiquantitative study was performed on the XRD data obtained for each synthesized sample using the TOPAS software according to the methods of Scarlett and Madsen⁴⁰ and Madsen et al.⁴¹ which allowed the determination of the relative proportion (wt %) of m-CPPD, t-CPPD, and a-CPP phases. This method, named the Partial or No Known Crystal Structure method (PONKCS), is a direct approach, where the amorphous contribution to the pattern is used to directly estimate its proportion. A ± 1 wt % accuracy for the relative weight proportion can be expected with the PONKCS method.⁴¹

FTIR spectra were recorded with a ThermoNicolet 5700 Fourier-transform infrared spectrometer in the 4000–400 cm^{-1} range with 64-scan accumulation in transmission mode and a ± 4 cm^{-1} resolution using powder samples in KBr pellets (2 mg of sample in 300 mg of KBr).

Elemental analyses were performed on aqueous solutions of the dissolved samples using ICP-OES (Ultima2 spectrometer, HORIBA Jobin Yvon). Each sample was analyzed in triplicate.

Scanning electron microscopy (SEM) micrographs were obtained using a Leo 435 VP microscope. The samples were silver-plated with an evaporator (Scancoat Six, Edwards) before observation.

Thermogravimetric analyses (TGA-DTA) were performed on some of the samples using a Setaram Setsys Evolution instrument, with a heating rate of 5 °C per minute, starting at 25 °C up to 1000 °C.

Complementarily to the XRD analyses, for some of the synthesized samples, further structural investigations were performed using ³¹P magic-angle spinning (MAS) NMR. Data were recorded using a 700 MHz Bruker AVANCE III spectrometer, equipped with a 4 mm Bruker MAS probe. A MAS frequency of 14 kHz was used. The chemical shifts were referenced to H₃PO₄. The main purposes of these experiments were (i) to measure the T₁(³¹P) relaxation times in order to evaluate the impact of the cations added in the precipitating medium, and (ii) to record fully relaxed ³¹P NMR spectra in order to quantify the involved phases. Briefly, a saturation-recovery experiment under fast MAS was implemented as follows: saturation ³¹P pulses were followed by a delay ranging from 0.25 to 720 s, and a final ³¹P 90° pulse of 5 μ s. Spinal-64 ¹H decoupling (70 kHz) was applied during acquisition.⁴² Prior to all experiments, the magic angle was carefully set in order to obtain the best ³¹P MAS resolution, avoiding the reintroduction of any CSA (chemical shift anisotropy) or dipolar interaction which would broaden the spectra. Four scans were usually used.

3. RESULTS AND DISCUSSION

3.1. Influence of Ionic Additives Initially Present within the Buffer (b) Solution: Qualitative and Semiquantitative XRD Study. The X-ray patterns of the CPP reference sample (prepared in the absence of additive) and of the CPP samples synthesized in the presence of Mg²⁺, Zn²⁺, Fe³⁺, Cu²⁺, or S₂O₃²⁻ ions initially present at different concentrations in the buffer solution within the reactor are shown in Figure 2. The results of the semiquantitative analysis (relative weight proportion of m-CPPD, t-CPPD, and a-CPP phases for all synthesized samples) of these XRD data are reported in Table 2. We observed that the method of synthesis in a stirred reactor at pH 3.6 and 90 °C and without additives led to the precipitation of the t-CPPD phase (reference compound) and that no additional crystalline phase could be detected using XRD (as compared with the JCPDS No. 00–041–0488 XRD reference data for the t-CPPD phase). However, it appeared that this reference t-CPPD sample was not fully crystallized (93 wt % of t-CPPD) and that it included a small proportion (7 \pm 1 wt %) of the a-CPP phase (Table 2). The effect of maturation time during the synthesis of t-CPPD and m-CPPD phases has yet been investigated; the characterization of the precipitates formed during the synthesis from 3 min up to the end of the precipitation (about 1 h) showed that the phases were formed from the beginning and did not evolve

Table 2. Relative Weight Proportion (wt %) of the CPP Phases (m-CPPD, t-CPPD, and a-CPP) Determined from the XRD Data for the Samples Precipitated in the Presence or Absence of Ionic Additives Initially Introduced in the Buffer Solution (Denoted (b) in the Main Text)^s

ionic additive concentration in the precipitation medium	m-CPPD (wt %)	t-CPPD (wt %)	a-CPP (wt %)
without additive (reference)	0 \pm 1	93 \pm 1	7 \pm 1
[S ₂ O ₃ ²⁻] = 1.00 mM	3 \pm 2	90 \pm 1	7 \pm 1
[S ₂ O ₃ ²⁻] = 5.00 mM	3 \pm 1	89 \pm 1	8 \pm 1
[Mg ²⁺] = 0.10 mM	1 \pm 1	94 \pm 1	5 \pm 1
[Mg ²⁺] = 1.00 mM	26 \pm 1	69 \pm 1	5 \pm 1
[Fe ³⁺] = 0.03 mM	4 \pm 1	89 \pm 1	7 \pm 1
[Fe ³⁺] = 0.10 mM	14 \pm 1	80 \pm 1	6 \pm 1
[Fe ³⁺] = 1.00 mM	37 \pm 1	1 \pm 1	62 \pm 1

[Zn ²⁺] = 1.00 mM	75 \pm 1	5 \pm 1	20 \pm 1
[Cu ²⁺] = 0.10 mM	4 \pm 2	93 \pm 1	3 \pm 1
[Cu ²⁺] = 1.00 mM	60 \pm 1	4 \pm 1	36 \pm 1

^sAll experiments were performed in duplicate.

(unpublished results). Additional evolution tests have been made at 37 °C, in solution, for 1 month for t-CPPD and m-CPPD phases, and no alteration was detected.

The composition of the samples synthesized in the presence of ionic additives showed the characteristic peaks of t-CPPD (especially at 10.96° \pm 0.02 and 12.59° \pm 0.02) and a more or less intense additional diffraction peak at about 2 θ = 12.03° \pm 0.02 characteristic of the m-CPPD phase ((110) Bragg peak⁴³), indicating that this latter phase also formed when the ionic additives tested were present, except in the case of a low concentration of Mg²⁺ (0.10 mM) (Figure 2). The relative weight percentage of m-CPPD was approximately 0% in the absence of ionic additive, but increased from 3 \pm 1 wt % up to 75 \pm 1 wt % in the presence of 1.00 mM of S₂O₃²⁻ or Zn²⁺, respectively (Table 2). We can also clearly observe a dose-dependent effect (by comparison of the relative peak intensities for 0.10 and 1.00 mM of additive) for each ionic additive except for S₂O₃²⁻: in the case of a higher concentration (1.00 mM) of Fe³⁺, Zn²⁺, or Cu²⁺ we observed that the diffraction peaks for the t-CPPD phase were almost absent, indicating that the major crystalline phase in these samples was m-CPPD (37, 75, and 60 wt %, respectively). The dose-dependent effect appeared to be less pronounced in the presence of Mg²⁺ than in the presence of Fe³⁺, Zn²⁺, or Cu²⁺ and was negligible for S₂O₃²⁻: in both cases (Mg²⁺ and S₂O₃²⁻) the major crystalline phase observed remained t-CPPD (from 69 up to 90 wt %).

Furthermore, it can be noted that the relative proportion of the amorphous phase increased significantly in the presence of 1.00 mM of Zn²⁺ (20 \pm 1 wt %) or Cu²⁺ (36 \pm 1 wt %). The greatest effect was observed for 1.00 mM of Fe³⁺ (62 \pm 1 wt %). The presence of an amorphous phase from 5 up to 62 \pm 1 wt % depending on the ionic additive present in the precipitating medium, is supporting the observation of a more or less important diffuse halo on the XRD pattern (Figure 3). Like the pure a-CPP reference compound, the fraction of a-CPP phase detected is probably associated with around 3 to 4 water molecules.^{8–10}

These results showed that 1.00 mM Fe³⁺, Zn²⁺, or Cu²⁺ induced the most significant changes related to the presence of the m-CPPD and a-CPP phases: the presence of 1.00 mM of Zn²⁺, Cu²⁺, or Fe³⁺ ions partly inhibited the crystallization of t-

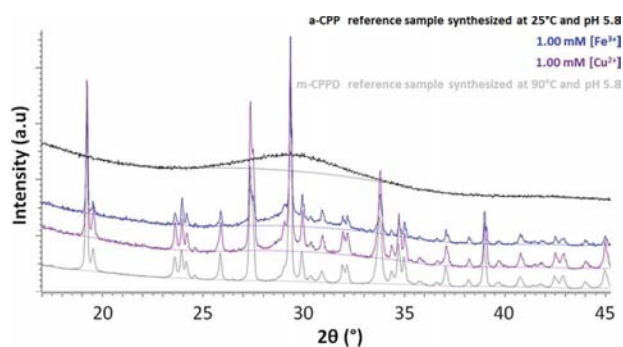

Figure 3. XRD patterns (for $2\theta = 17\text{--}45^\circ$) of the m-CPPD and a-CPPD reference compounds and the samples synthesized in the presence of 1.00 mM Cu^{2+} or Fe^{3+} initially present in the buffer (b) solution. Solid line: halo corresponding to a-CPPD.

CPPD and favored the formation of (i) a-CPPD phase (62 ± 1 wt %) in the presence of Fe^{3+} , and (ii) m-CPPD phase (75 ± 1 wt %) in the presence of Zn^{2+} . For the lowest concentrations of Zn^{2+} , Cu^{2+} , or Fe^{3+} ions (0.10 mM), t-CPPD remained the major phase in the precipitated samples.

All these results demonstrated a major effect of 1.00 mM of Cu^{2+} , Zn^{2+} , and Fe^{3+} on t-CPPD crystallization, but did not allow the detection of pure crystalline phases of magnesium, zinc, iron, or copper pyrophosphate that may have precipitated, considering the limit of detection (2%) of the XRD analysis. Assuming that all the cationic additives (A) involved in the synthesis had precipitated as A-pyrophosphate salts, we would have expected a contribution of 2.6% (molar) or 2.0 to 3.1 wt % of this compound depending on the additives (Zn^{2+} , Cu^{2+} , or Mg^{2+}) or 4.0% (molar) or 3.9 wt % of iron pyrophosphate (with Fe/Pyro = 4/3 for electrical neutrality of the solid), which would have been detectable by XRD.

Moreover, after carefully checking the unit-cell parameters calculated from the XRD pattern data, we can confirm that there is no significant difference from the unit-cell parameters of the reference CPPD phases already published.¹⁰

Further structural investigations were performed by ^{31}P solid-state NMR analysis to provide more information on the phases that precipitated in the presence of additives via the chemical

shift ^{31}P and relaxation time $T_1(^{31}\text{P})$ data (see Section 3.3). Indeed T_1 (the longitudinal relaxation time) is a parameter, which is sensitive to the potential presence of paramagnetic ions, such as Cu^{2+} and Fe^{3+} , in the precipitated CPPs.

3.2. Influence of Ionic Additives Initially Present in One of the Reagent Solutions (rs): Qualitative and Semiquantitative XRD Study. Figure 4 shows the XRD patterns of CPP samples synthesized with 1.00 mM of the selected ionic additives initially present within the cationic or anionic reagent solution (rs). The results of the semi-quantitative analysis (relative weight proportion of m-CPPD, t-CPPD, and a-CPP phases for all synthesized samples) of these XRD data are reported in Table 3.

Table 3. Relative Weight Percentage of the CPP Phases (m-CPPD, t-CPPD, and a-CPP) Present in the Samples Synthesized in the Presence or Absence of Ionic Additives Initially Introduced into the Reagent Solution (rs)

ionic additive concentration in the medium of precipitation	m-CPPD (wt %)	t-CPPD (wt %)	a-CPP (wt %)
without additive (reference)	0 ± 1	93 ± 1	7 ± 1
$[\text{S}_2\text{O}_3^{2-}] = 1.00$ mM	3 ± 1	91 ± 1	6 ± 1
$[\text{Mg}^{2+}] = 1.00$ mM	4 ± 2	90 ± 1	6 ± 1
$[\text{Fe}^{3+}] = 1.00$ mM	2 ± 1	0 ± 1	98 ± 1
$[\text{Zn}^{2+}] = 1.00$ mM	71 ± 1	4 ± 1	25 ± 1
$[\text{Cu}^{2+}] = 1.00$ mM	78 ± 1	2 ± 1	20 ± 1

We can observe that the presence of 1.00 mM of Mg^{2+} or $\text{S}_2\text{O}_3^{2-}$ ions did not lead to significant changes in the sample composition, which contained mainly t-CPPD (91 wt %), a-CPP (6 wt %), and m-CPPD (3 wt %). The results reported in Table 3 indicate the determinant effect of the presence of 1.00 mM of Fe^{3+} , Zn^{2+} , or Cu^{2+} ions on the composition of the synthesized samples: Zn^{2+} or Cu^{2+} both favored the formation of m-CPPD (71 and 78 wt %, respectively), a smaller amount of a-CPP (25 and 20 wt %, respectively) and a very low proportion of t-CPPD (4 and 2 wt %, respectively). On the other hand, Fe^{3+} completely inhibited the crystallization of the t-CPPD and m-CPPD phases: the samples synthesized in the presence of 1 mM of Fe^{3+} were mostly amorphous (98 wt %). The number of water molecules associated with this amorphous

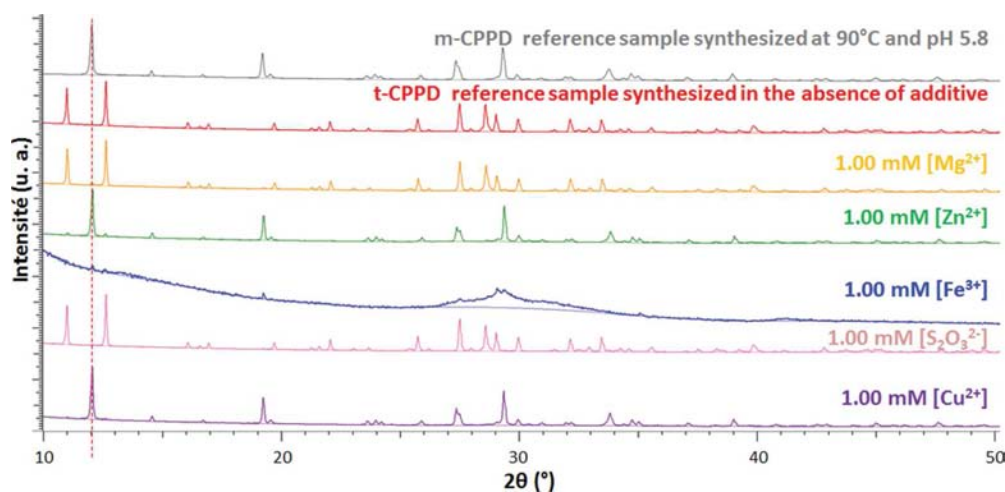

Figure 4. XRD patterns of m-CPPD and t-CPPD reference phases, and of samples synthesized in the initial presence of ionic additives in one of the reagent solutions (rs), leading to a 1 mM ionic additive concentration in the buffer solution at the end of the experiment.

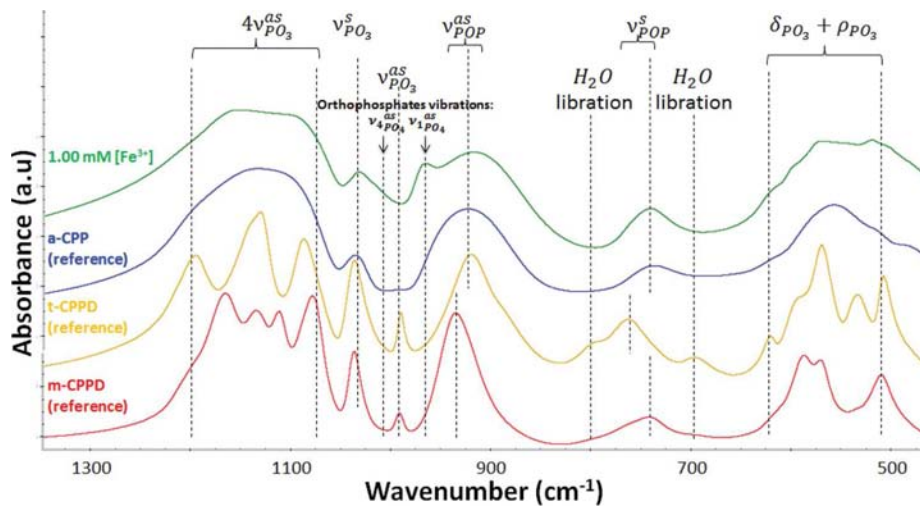

Figure 5. FTIR spectra of reference m-CPPD, t-CPPD, and a-CPP phases and of the sample synthesized in the presence of 1 mM Fe^{3+} present initially in the calcium reagent solution, denoted (rs) in the main text. The different vibrational modes of the molecules, stretching (ν), bending (δ), and rocking (ρ), respectively, symmetric (s) or antisymmetric (as), are indicated.

Table 4. A/Ca, A/P, Ca/P, and (Ca+A)/P or Ca/(P+A) Molar Ratios Calculated with Concentrations of Ca, P, and Ionic Additives (A) Determined by ICP-OES Analyses of the Samples Synthesized in the Presence or Absence of the Ionic Additive Initially Present in the Reagent Solution (rs) or in the Buffer Solution (b)

ionic additive concentration in the precipitation medium	A/Ca	A/P	Ca/P	(Ca+A)/P	Ca/(P+A)

CPP phase (3.2 ± 0.1 , for 1 mM of Fe^{3+} (rs) sample), determined by ATG analysis, was lower than those reported for pure a-CPP reference compound,^{8–10} but they were still in the range 3–4.

In addition, we observed that no crystalline phases of magnesium, zinc, iron, or copper pyrophosphates coprecipitated. As previously indicated for the samples precipitated using the (b) protocol, if present in the samples the A-pyrophosphate phases would have been detectable.

As in the case of ionic additives initially present in the buffer solution, presented in Figure 3, the presence of a more or less prominent diffuse halo around $2\theta = 30^\circ$, especially for samples prepared in the presence of Zn^{2+} , Cu^{2+} , or Fe^{3+} in the calcium reagent solution (data not shown) testifies to the presence of an amorphous phase.

Complementary FTIR spectroscopic analysis of the samples formed in the presence of 1.00 mM Fe^{3+} was performed to further investigate their composition. The spectra of this sample and that of reference a-CPP¹⁰ are presented in Figure 5. All in all, the spectra were quite comparable. The presence of the $\nu_{\text{POP}}^{\text{as}}$ and the $\nu_{\text{POP}}^{\text{s}}$ vibration modes confirmed the presence of pyrophosphate groups in an amorphous phase. A slight increase of the absorbance at 960 cm^{-1} ($\nu_{\text{IP}_4}^{\text{as}}$) and 1010 cm^{-1} ($\nu_{\text{4PO}_4}^{\text{as}}$)

seems to indicate the presence of a small proportion of poorly or noncrystalline calcium orthophosphate.^{44,45} Furthermore, the splitting of the peaks corresponding to the $4\nu_{\text{PO}_3}^{\text{as}}$, $\nu_{\text{PO}_3}^{\text{as}}$, and $\delta_{\text{PO}_3} + \rho_{\text{PO}_3}$ vibration modes confirms the presence of a small amount of a crystalline phase of CPPD without the possibility to clearly identify which CPPD phase (triclinic or monoclinic) is present due to the low proportion of this crystalline phase in this sample (2 wt % of m-CPPD evaluated by XRD, see Table 3), and also due to important band broadening characteristic of the presence of the a-CPP phase. Complementary analysis by Raman spectroscopy was performed and also confirms this result (data not shown).

3.3. Complementary Elemental, Morphological, and Structural Analyses.

3.3.1. Elemental Analyses. The results of the elemental analysis of samples precipitated in the absence or presence of ionic additives (A) are reported in Table 4. We note that whatever the mode of introduction (b or rs) of the cationic additive, the lowest A/Ca and A/P ratios (for 1 mM Mg^{2+} (rs): 6.7×10^{-3} and 7.0×10^{-3} , respectively) were obtained for samples precipitated in the presence of Mg^{2+} . These ratios were the lowest in the case of anionic additives (A/Ca = 5.8×10^{-3} and A/P = 5.9×10^{-3} for 1.00 mM $\text{S}_2\text{O}_3^{2-}$

(rs)). For the other cationic additives, this ratio ranged between 1.9% and 3.9%, indicating a quite high introduction of the additive into the samples, including 100% for 1 mM of Cu^{2+} and Fe^{3+} introduced in the buffer or Zn^{2+} introduced in the reagent solution. These three samples had a-CPP compositions of 36, 62, and 25 wt %, respectively, the highest proportions of a-CPP found in the studied samples. Indeed, if the totality of the additive ions involved in synthesis had precipitated in pure CPP phases in which $\text{Ca}/\text{P} = 1$, we would obtain 2.6% (molar) of additive-pyrophosphate for Zn^{2+} , Cu^{2+} , and Mg^{2+} or 4.0% (molar) of iron pyrophosphate (with $\text{Fe}/\text{Pyro} = 4/3$ for electrical neutrality of the solid).

We also observed that except in the case of Zn^{2+} for which the difference in sample compositions between both protocols (b and rs) was not significant, for all the other additives the A/Ca and A/P ratios were higher when the additive was introduced in the buffer solution (b), which corresponded to higher initial concentration of additives (high A/Ca or A/P initially in the buffer solution, which then decreased as precipitation occurred) (Table 4). Comparing the ionic radii (in picometer: pm) of the cationic additives (Mg^{2+} (72 pm), Cu^{2+} (73 pm), Fe^{3+} (55 pm), or Zn^{2+} (74 pm)) with those of Ca^{2+} (100 pm), they are all smaller than calcium ions, indicating that we should expect fairly similar behavior for these ions upon CPP precipitation, as well as no significant variation in their cell parameters by XRD analysis in the case of a limited amount of additive ions incorporated in the crystals. A Ca/P ratio lower than 1 can be expected if the cationic additives are incorporated into the CPP precipitate and this was observed, except in the cases of 1.00 mM Mg^{2+} or Fe^{3+} initially introduced in the reagent solution (Table 4). This observation may be explained by the low influence of the presence of 1.00 mM Mg^{2+} (rs) on the sample composition (90 wt % of t-CPPD, 6 wt % of a-CPP, and 4 wt % of m-CPPD) compared with the reference sample (without additive: 93 wt % of t-CPPD and 7 wt % of a-CPP) leading thus to a similar Ca/P ratio for both samples (1.04 and 1.03, respectively). On the contrary, the strongest effect on CPPD crystallization was observed in the presence of 1 mM of Fe^{3+} (rs) (98 wt % of a-CPP and 2 wt % of m-CPPD) and it has been reported that some orthophosphates can be associated with a-CPP phase,⁸ which could in this case explain a Ca/P ratio slightly higher than 1.

3.3.2. Observations by Scanning Electron Microscopy. Scanning electron micrographs of the samples precipitated in presence of the various additives initially introduced in the buffer (b) or reagent solution (rs) are presented in Figure 6. We can observe that whatever the ionic additive involved, except in the case of Fe^{3+} which will be discussed in the next paragraph, the crystals appear to keep their acicular shapes, with a large heterogeneity in particle sizes and agglomeration states. Indeed, in the presence of additives, except in the case of Fe^{3+} , we observed finer particles and more needle-like crystals, which is a morphology characteristic of the m-CPPD phase, compared with the reference t-CPPD phase, the crystals of which appear thicker (parallelepipedic crystals). This feature is a general characteristic of CPPD crystals as observed in previous works by Gras et al.¹⁰ These observations are consistent with the m-CPPD/t-CPPD weight ratio determined by XRD, which was found to increase rapidly with the concentration of Mg^{2+} , Zn^{2+} , or Cu^{2+} (Table 2 and Table 3). We also notice that the presence of Zn^{2+} ions causes a marked agglomeration of the particles of the precipitate (Figure 6). A less pronounced effect seems to appear in the presence of Cu^{2+} . These observations

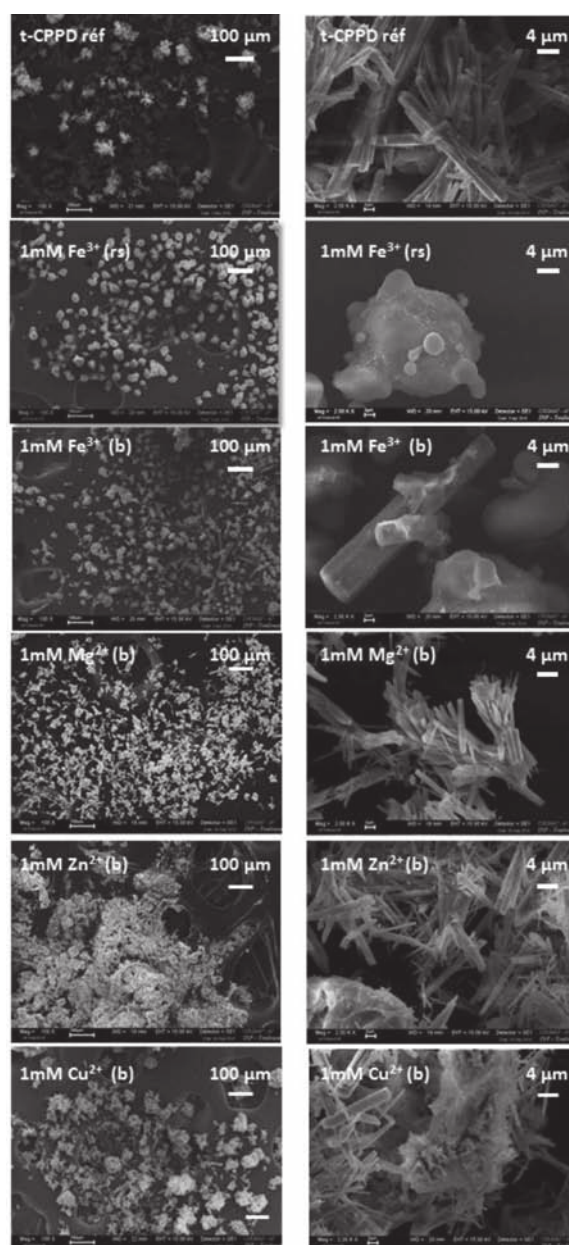

Figure 6. SEM micrographs of the crystals of the reference t-CPPD phase and of samples precipitated in the presence of 1.00 mM Mg^{2+} , 1.00 mM Zn^{2+} , 1.00 mM Cu^{2+} , or 1.00 mM Fe^{3+} introduced in the buffer (b) or in the reagent solution (rs).

can be linked to the XRD semiquantitative results (Table 2): high agglomeration is visible for samples with a high proportion of a-CPP even if it was not the major phase (in presence of 1 mM of Zn^{2+} and 1 mM of Cu^{2+} initially introduced in the buffer solution).

The case of samples precipitated in the presence of 1 mM Fe^{3+} is considered separately, as the a-CPP phase was the major phase in these samples (Table 2 and Table 3). In agreement with the XRD data, we can see on Figure 6 that the acicular morphology of the CPPD crystals was no longer visible for samples precipitated in the presence of 1.00 mM Fe^{3+} introduced in the calcium reagent solution (rs; 98 wt % of a-CPP), whereas a few particles with the acicular morphology

were still visible for samples precipitated in the presence of 1.00 mM of Fe^{3+} introduced in the buffer solution (b; 62 wt % of a-CPP) (Figure 6 and Tables 2 and 3). The a-CPP phase showed quite well dispersed and smooth, round particles with a diameter of about 20 μm . This a-CPP phase morphology was different from that described by Gras et al.¹⁰ which contained smaller (less than 1 μm) round, agglomerated particles.

Further structural investigations using solid-state NMR were performed to shed some light on the possible mechanism of action of some of these ionic additives.

3.3.3. Structural Analyses by ^{31}P Solid-State NMR Spectroscopy. As explained previously, none of the characterization methods used so far allowed a clear identification of the dopants (cationic additives) in one or the other of the mineral phases identified, due principally to the low amount of dopant species. The determination of $T_1(^{31}\text{P})$ (spin–lattice) relaxation times could give an answer to this important question. Generally speaking, the observed T_1 in solid-state NMR are strongly dependent on the presence of paramagnetic species, which has been shown to considerably reduce their values. Thus, this method is especially useful for paramagnetic dopants like Cu^{2+} and Fe^{3+} , whereas diamagnetic species such as Zn^{2+} and Mg^{2+} are expected to produce no noticeable effect (such cations are introduced in very small amounts, and the natural abundances of ^{25}Mg and ^{67}Zn , which are quadrupolar nuclei, are <10%).

The ^{31}P MAS spectrum of the t-CPPD reference phase is presented in Figure 7. As previously observed by Gras et al.,⁹ t-CPPD (labeled t in Figure 7) is characterized by two sharp peaks located at -5.14 and -6.24 ppm. The observation of two ^{31}P resonances is in full agreement with the crystallographic data as reported in previous publications.⁹ Studying the spectrum in detail, one can observe the presence of two very minor components at -7.5 and -9.96 ppm. They correspond to a-CPP (labeled a in Figure 7) and m-CPPD (labeled m in Figure 7), respectively (m-CPPD is also characterized by a second resonance at -6.30 ppm, which here is superimposed onto one of the peaks of the t-CPPD phase). These side phases were considered here as negligible. $T_1(^{31}\text{P}) = 76.3$ s for t-CPPD (Table 5). m-CPPD is characterized by two resonance peaks centered at -5.91 and -9.68 ppm. $T_1(^{31}\text{P}) = 96.0$ s for m-CPPD. In the case of a-CPP, a featureless broadened component is observed at ~ -5 ppm, exhibiting $T_1(^{31}\text{P}) = 29.5$ s.

The ^{31}P MAS NMR spectra of the samples obtained in the presence of 1.00 mM Cu^{2+} initially present in the buffer (b) or in the reagent solution (rs) are reported in Figure 8. When comparing these spectra with those of the t-CPPD, m-CPPD, and a-CPP reference samples, it is obvious that the spectra of the Cu^{2+} -doped samples exhibit m-CPPD as the major phase, confirming the XRD data (Table 2 and Table 3). The ^{31}P isotropic chemical shifts are centered at -6.44 and -10.24 ppm, slightly shielded when compared with the m-CPPD reference (Table 5). This variation may be attributable to the presence of Cu^{2+} cations in the sample, which was confirmed by ICP-OES elemental analysis: Cu/Ca (rs) and Cu/P (rs) are both around 2×10^{-2} ; Cu/Ca (b) and Cu/P (b) are both around 3×10^{-2} (Table 4). A deconvolution of the spectra is also presented in Figure 8. t-CPPD was present as a minor component, as well as a much broader component, which could be safely assigned to an amorphous phase. This amorphous component is rather nonsymmetric in contrast to the one observed for nondoped a-CPP (consequently, two components

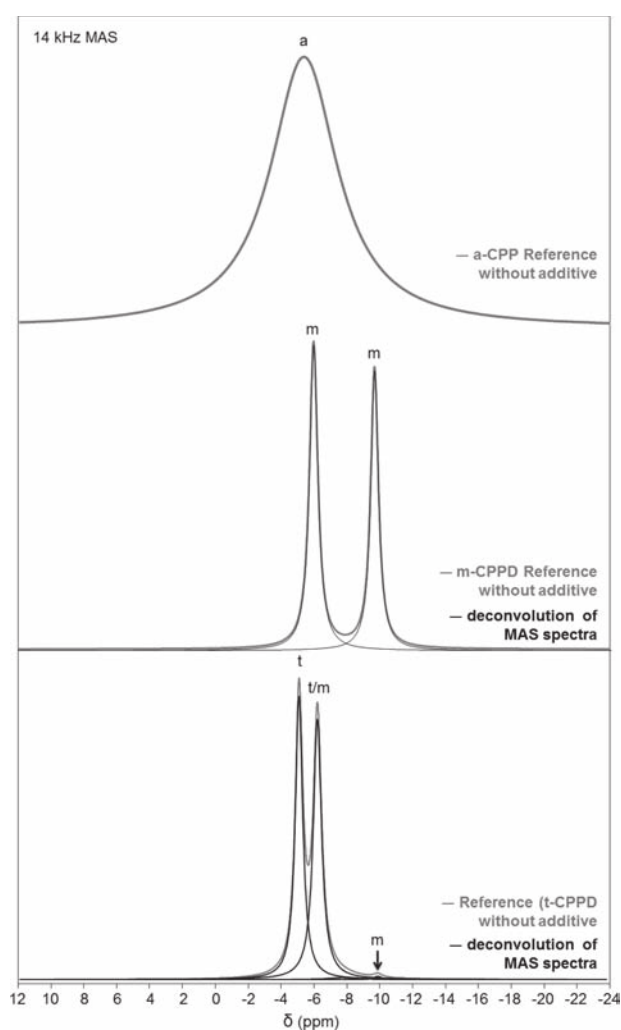

Figure 7. ^{31}P MAS NMR spectra (decoupled from ^1H during the acquisition) of the reference samples t-CPPD, m-CPPD, and a-CPP (synthesized without additives). The different components of the MAS spectra are labeled as follows: t (t-CPPD), m (m-CPPD), and a (a-CPP).

were used in the final deconvolution—they are both indicated by the notation “a” in Figure 8). We did not attempt to further analyze the shape of this particular resonance, but used it as a fixed model for spectral deconvolution and quantitative analyses (Table 5). The resulting data are in good agreement with the results obtained by semiquantitative XRD analysis (Table 2 and Table 3). Even if the semiquantitative XRD data provide results in wt % and those of solid-state NMR in molar % of the CPP phases, we can globally compare both data, as the CPP phases involved in all samples have the same or quite the same molecular weight (2 water molecules for t-CPPD and m-CPPD and between 3 and 4 associated with a-CPP phase).

Finally, we note the presence of a broad component centered at ~ -2.0 ppm. The intensity of this particular component is small but measurable. It was even broader when Cu^{2+} was introduced in the buffer ((b) protocol). At this stage, two distinct assignments can be proposed for this broadened component: (i) orthophosphates, such as those that can be obtained as side products of the partial hydrolysis of pyrophosphates,⁹ or (ii) pyrophosphates exhibiting shifted

^aIsotropic chemical shifts, line widths, and relative molar % are given as well. t: t-CPPD, m: m-CPPD, a: a-CPP, sPP: shifted calcium pyrophosphates.

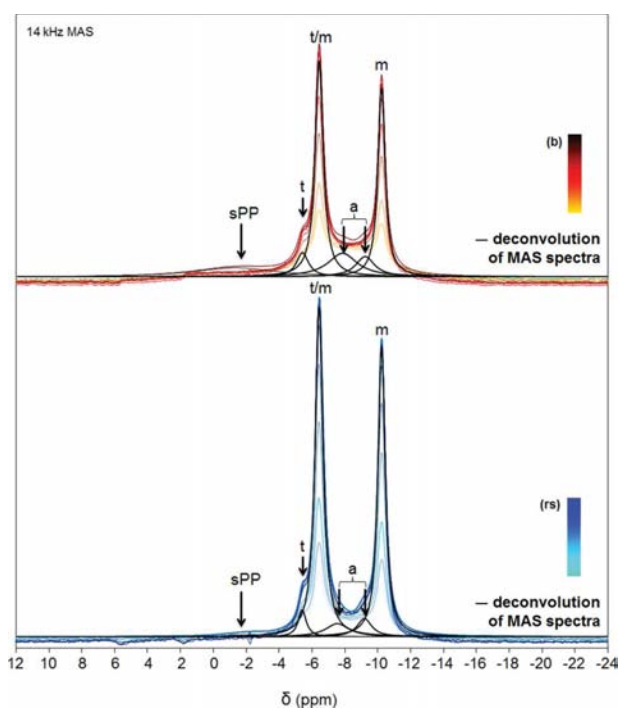

Figure 8. ^{31}P MAS NMR spectra (decoupled from ^1H during the acquisition) of samples synthesized in the presence of 1.00 mM Cu^{2+} introduced in the buffer (b) or in the calcium reagent solution (rs). The relaxation delay after the train saturation of the ^{31}P channel was incremented from the bottom to the top of the spectra (saturation–recovery). The different components of MAS spectra are labeled as follows: t (t-CPPD), m (m-CPPD), a (a-CPP), and sPP (shifted calcium pyrophosphates).

$\delta_{\text{iso}}(^{31}\text{P})$ due to the paramagnetic effect of Cu^{2+} cations. From the NMR point of view, ^{31}P INADEQUATE MAS experiments should allow definite assignments,⁸ as this double quantum (DQ)-based experiment is sensitive to pyrophosphate groups only. We did not attempt to implement this sequence, as the intensity of the involved resonance was very small. However, such a broad component was not observed at all in the case of diamagnetic cations, namely, Zn^{2+} and Mg^{2+} (Figures 10 and 11, respectively). Moreover, it is clear from Figure 8 that the broadening is more pronounced in the (b) protocol than in the (rs) protocol. We recall here that Cu/P (rs) < Cu/P (b). In summary, we suggest that the broad component centered at ~ -2.0 ppm can be assigned safely to pyrophosphate groups in relatively close vicinity to the paramagnetic centers.⁴⁶ Indeed, such a component is observed on the ^{31}P MAS NMR spectra.

Even if FTIR spectroscopy was able to distinguish orthophosphate from pyrophosphate groups (for instance, in the case of Fe^{3+} ; see Figure 5), the broadening and overlapping of the vibrational bands would exclude definite assignments at this stage. The complementary roles of solid state NMR spectroscopy, X-ray diffraction and vibrational spectroscopies characterization techniques are demonstrated here.

Considering the $T_1(^{31}\text{P})$ data, we focused here only on the major m-CPPD phase, and found that $T_1(^{31}\text{P}) \cong 2.3$ s for both samples (on average). When compared with the reference m-CPPD phase, one observes a drastic reduction of the ^{31}P longitudinal relaxation time. This can be safely attributed to the presence of the paramagnetic Cu^{2+} cations within the m-CPPD structure. Indeed, it is well established that paramagnetic ions

usually lead to a very efficient pathway for nuclear relaxation.^{46–50} Two relaxation mechanisms can be considered, namely, a through-space dipolar coupling between electrons and nuclei and a through-bond electronic interaction (Fermi contact). Both are usually present. The effect of paramagnetism on the NMR resonances can be summarized as the following: (i) a loss of signal is observed for those nuclei in close vicinity to the paramagnetic centers, (ii) line widths can broaden significantly, (iii) nuclear longitudinal T_1 values are usually strongly shortened, and (iv) paramagnetic shifted peaks can be observed directly on the NMR spectrum. Very recently, McCarty and Stebbins⁵¹ performed an in-depth study of the effect of paramagnetic cations such as Ni^{2+} and Co^{2+} on the ^{17}O , ^{25}Mg , and ^{43}Ca MAS NMR spectra of CaO , MgO , and CaO .

Though present as a minor component, $T_1(^{31}\text{P}) \cong 4$ s was estimated for the a-CPP component. No attempt was made to derive the $T_1(^{31}\text{P})$ data for t-CPPD (t) and the shifted pyrophosphates (sPP) as the corresponding intensities were intrinsically small.

The ^{31}P MAS NMR spectra of the samples obtained in the presence of 1 mM Fe^{3+} initially present in the buffer (b) or in the reagent solution (rs) are reported in Figure 9. All relevant isotropic chemical shifts and $T_1(^{31}\text{P})$ data are reported in Table 5. In the case of the (b) protocol, there are similarities with the results for the Cu^{2+} -doped samples. Indeed, m-CPPD and a-CPP were clearly obtained as major phases, but with a different molar ratio compared with the Cu^{2+} case. This result is in good agreement with the XRD data (Table 2 and Table 3).

In the case of the (rs) protocol, a broad spectrum was obtained, exhibiting two main components: shifted pyrophosphates, sPP; and amorphous pyrophosphates, a (Figure 9). A very small amount ($\sim 4\%$) of another phase (~ -9.9 ppm) was faintly detected.

This ^{31}P isotropic chemical shift is in agreement with the presence of m-CPPD as a minor phase, as shown by powder XRD (Table 3).

In other words, Fe^{3+} is able to inhibit almost completely the crystallization of CPPD phases (m and t) when using the (rs) protocol. As already observed in the case of Cu^{2+} -doped samples, a drastic reduction of $T_1(^{31}\text{P})$ was observed for both m-CPPD and a-CPP phases. This shows again that Fe^{3+} cations are inserted into the m-CPPD and a-CPP phases.

In the case of Fe^{3+} ((b) protocol), we further observe that the content of a-CPP is much larger than in the case of Cu^{2+} (Figure 8). This observation is in full agreement with the semiquantitative XRD data mentioned above (62 wt % of a-CPP phase in the case of Fe^{3+}).

The ^{31}P MAS NMR spectra of the samples obtained in the presence of 1.00 mM Zn^{2+} and Mg^{2+} (diamagnetic species) initially present in the buffer (b) or in the calcium reagent solution (rs) are reported in Figures 10 and 11, respectively. All relevant isotropic chemical shifts and $T_1(^{31}\text{P})$ data are reported in Table 5. In the case of Zn^{2+} (Figure 10), there are similarities with the results of the Cu^{2+} -doped samples. Indeed, m-CPPD and a-CPP were clearly obtained as the major phases but with a different molar ratio when compared with the Cu^{2+} case. This result is in good agreement with the XRD data (Table 2 and Table 3). Furthermore, the molar proportions of the different phases reported in Table 5 are in good agreement with the XRD data (Table 2 and Table 3) and confirm that m-CPPD and a-CPP are indeed obtained as the major phases.

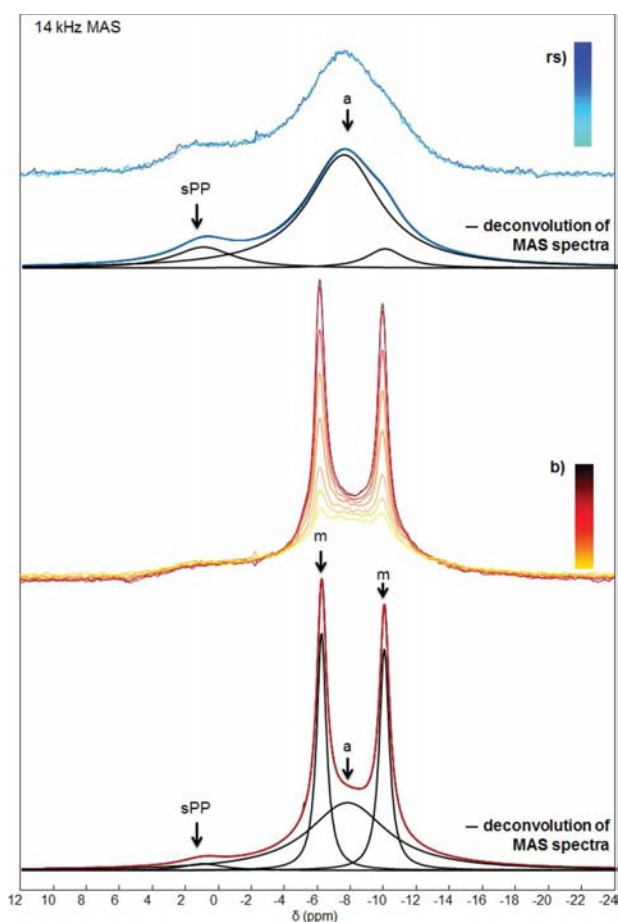

Figure 9. ^{31}P MAS NMR spectra (decoupled from ^1H during the acquisition) of samples synthesized in the presence of 1.00 mM Fe^{3+} introduced in the buffer (b) or in the calcium reagent solution (rs). The relaxation delay after the train saturation of the ^{31}P channel was incremented from the bottom to the top of the spectra (saturation–recovery). The different components of MAS spectra are labeled as follows: m (m-CPPD), a (a-CPP), and sPP (shifted pyrophosphates).

In the case of the (rs) protocol (Zn^{2+}), the amorphous (a) contribution is characterized by two components as observed above (Figure 10). Furthermore, a small contribution of t-CPPD is evidenced as well. Finally, a negligible resonance is observed at ~ 0 ppm.

As already observed in the case of Cu^{2+} doped samples, a significant reduction of $T_1(^{31}\text{P})$ was observed for both the m-CPPD (~ 45.0 s) and a-CPP (~ 12.0 s) phases (we mention here that $T_1(^{31}\text{P}) = 96.0$ and 29.5 s for reference m-CPPD and a-CPP, respectively). However, this reduction is not as pronounced as in the case of the paramagnetic ions of Cu^{2+} . In this case, any effect of paramagnetic relaxation is excluded. We believe that Zn^{2+} cations enter the m-CPPD structure as well as a-CPP, leading to local defects and consequently to the subsequent decrease of $T_1(^{31}\text{P})$.

When comparing the spectra obtained in the case of Mg^{2+} with the t-CPPD, m-CPPD, and a-CPP references (Figure 11), it is obvious that the spectra of the Mg^{2+} -doped samples exhibit t-CPPD as the major phase and m-CPPD as a minor one in the case of the (b) protocol. This result is in good agreement with the XRD data (Tables 2 and 3), and the molar proportions of the different phases reported in Table 5 are in good agreement

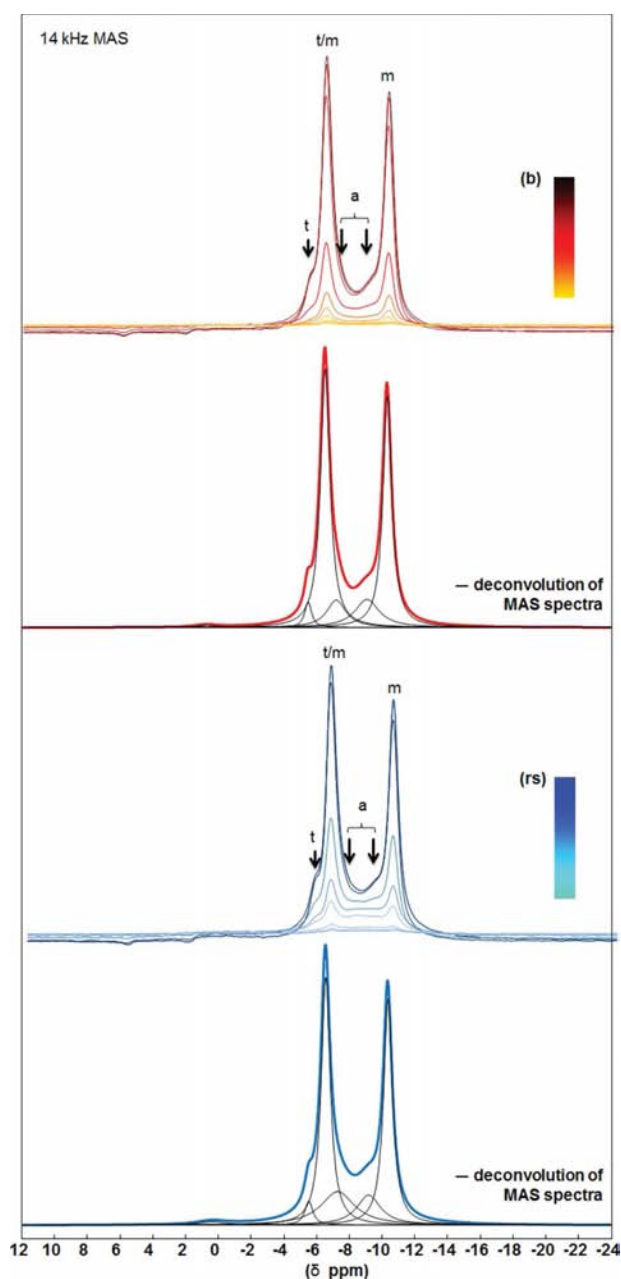

Figure 10. ^{31}P MAS NMR spectra (decoupled from ^1H during the acquisition) of samples synthesized in the presence of 1.00 mM Zn^{2+} introduced in the buffer (b) or in the calcium reagent solution (rs). t (t-CPPD), m (m-CPPD), a (a-CPP).

with XRD as well. The ^{31}P isotropic chemical shifts are centered at -5.70 , -6.50 , and -10.34 ppm, slightly shielded when compared with the reference phases. This variation may be attributable to the presence of Mg^{2+} cations which was confirmed by ICP-OES elemental analysis: Mg/P (rs) = $(7.0 \pm 0.6) \times 10^{-3}$; Cu/P (b) = $(9.1 \pm 1.9) \times 10^{-3}$ (Table 4). As already observed in the case of the Zn^{2+} -doped samples, a reduction of $T_1(^{31}\text{P})$ (in the presence of Mg^{2+}) was observed for t-CPPD in the (rs) protocol and m-CPPD in the (b) protocol as well. Recently, Gras et al.⁴³ reported some similarities between the m-CPPD and t-CPPD phase structures and those of other dihydrated pyrophosphate phases involving

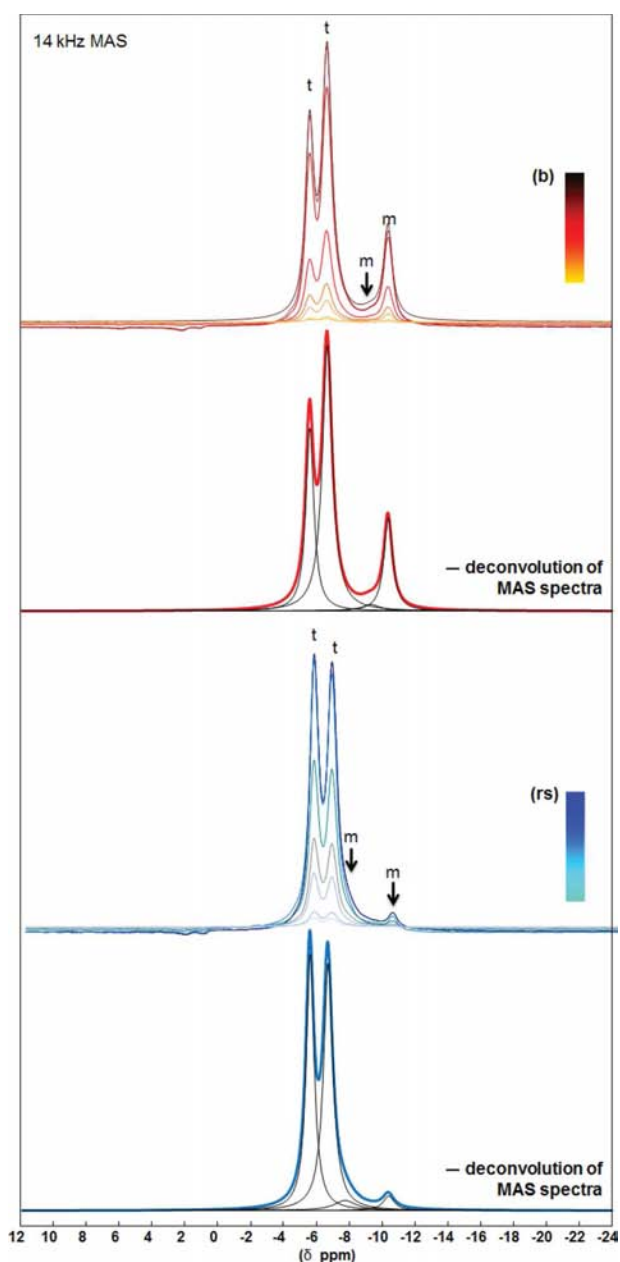

Figure 11. ^{31}P MAS NMR spectra (decoupled from ^1H during the acquisition) of samples synthesized in the presence of 1.00 mM Mg^{2+} introduced in the buffer (b) or in the calcium reagent solution (rs). t (t-CPPD), m (m-CPPD).

other divalent metal cations, such as Mg^{2+} , Mn^{2+} , Fe^{2+} , or Co^{2+} , which support our results suggesting the introduction of magnesium in the CPPD phase structures.

These experiments using the same ionic additive introduced in the buffer or in the reagent solution demonstrate that the initial concentration of the additive and its distribution in the reactor combined with the supersaturation level are crucial parameters.

Concerning the inhibition of the t-CPPD crystallization by Fe^{3+} ions, there may be a competition between iron pyrophosphate and calcium pyrophosphate precipitation, or Fe^{3+} may be adsorbed on the crystal and block some of the

growth sites (the Fe/Ca atomic ratio ranged between 2.7% and 4.9%; Table 4).

The use of $\text{S}_2\text{O}_3^{2-}$ ion as an additive has no notable effect on the t-CPPD formation.

At this stage, it is important to recall that the m- and t-CPPD phases are those that have been identified *in vivo*, while we are attempting to explain some of their behaviors observed *in vitro*. The medium of precipitation is highly supersaturated at the beginning of the synthesis. In the presence of additives, it is possible that the most unstable phase (a-CPP) is formed first, then evolves into m- or t-CPPD. The formation of a dihydrate phase instead of another may be due to kinetics, potentially modified by the presence of additives in the precipitation medium. This seems to be consistent with the fact that *in vitro*, the a-CPP phase could be a precursor of the m- and t-CPPD phases. Another hypothesis is that the less stable crystalline dihydrated phase (m-CPPD) could be formed first, and then evolve into t-CPPD. In this case, the ionic additives studied here would stabilize the m-CPPD phase and therefore prevent it from evolving toward the t-CPPD phase. This assumption is consistent with the effect identified in this study for Mg^{2+} , Zn^{2+} , and Cu^{2+} cations. These ions promote the formation of m-CPPD instead of t-CPPD by replacing Ca^{2+} in the structure. That effect is especially strong for high initial concentrations of these ions at the beginning of the precipitation of CPP ((b) protocol). A potential excess of certain ions in arthritic joints could be a precursor and/or aggravating factor for the formation of CPPD crystals and the inflammatory response. To explore this assumption, it could be interesting to correlate medical analyses of the osteoarticular fluid compositions in osteoarthritic patients who also suffer from diseases caused by ionic imbalance, such as Menke's or Wilson's disease affecting copper levels in the body.⁵² Furthermore, the use of Fe^{3+} ions to prevent the precipitation of CPPD crystals has yet to be explored in physiological conditions.

CONCLUSION

Calcium pyrophosphate dihydrate polymorphs (m-CPPD and t-CPPD: $\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$) detected in the joints of arthritic patients are known to be highly inflammatory. Understanding their formation and trying to minimize their development are routes to reduce the pain caused or even to cure the disease.

Two main steps were analyzed in this study to achieve this goal: the ability to produce these crystals *in vitro*, outside the human body, to study their nucleation and growth phenomena on the one hand, and testing ionic additives likely to have an inhibitory action on CPPD formation on the other hand.

A stirred-batch reactor under controlled pH and temperature was implemented to prepare almost pure t-CPPD, m-CPPD, and a-CPP (amorphous) phases by simultaneously adding, at controlled flow rates, a potassium pyrophosphate reagent solution, and a calcium nitrate reagent solution into an ammonium acetate buffer solution. This method is fast and reproducible and produces adequate quantities of pure products *in vitro*.

These phases were characterized in detail by using X-ray diffraction, FTIR spectrometry, ^{31}P solid-state nuclear magnetic resonance, scanning electron microscopy, and elemental analysis by inductively coupled plasma spectrometry. The addition of one type of ionic additives (ionic additives (Mg^{2+} , Cu^{2+} , Fe^{3+} , Zn^{2+} , and $\text{S}_2\text{O}_3^{2-}$) in the reactor during the precipitation of CPPD was tested. These additives can influence the obtained phase.

When the t-CPPD phase was synthesized in the presence of ionic additives, the results showed that instead of pure t-CPPD, the m-CPPD phase formed simultaneously for all the tested ionic additives, except in the case of low concentrations of Mg^{2+} . We also observed a dose-dependent effect: the higher the amount of additives, the higher the proportion of m-CPPD in the obtained mixture. Furthermore, for some additives, like Zn^{2+} , Cu^{2+} , and Fe^{3+} , the relative proportion of the amorphous phase increased significantly in the mixture. The additive can also change the morphology of the obtained particles, leading to more or less agglomerated crystals. The use of $S_2O_3^{2-}$ ions as an additive has no notable effect on the formation of t-CPPD.

NMR analysis has allowed us to advance some interpretation of the modes of action of the cationic additives tested that can be adsorbed or inserted in the crystal lattice. In vitro, the a-CPPD phase may be a precursor of the m- and t-CPPD phases. Another hypothesis is that the less stable crystalline dihydrated phase (m-CPPD) may be formed first, and then evolve into t-CPPD. In this case, the ionic additives studied here would stabilize the m-CPPD phase and therefore prevent it from evolving toward the t-CPPD phase. As ionic additives may change the CPPD nucleation and crystal growth processes, we recently engaged to study CPPD crystallization at constant supersaturation with different CPPD seeds to understand better these effects.

This study contributes to understanding the role some trace elements can have in CPP crystal formation occurring in pseudogout and in associated diseases like hypomagnesaemia (low magnesium), Wilson's disease (copper excess), and hemochromatosis (iron excess).
