ABSTRACT

Polycrystalline CeNiZn (ZrNiAl type, $P\bar{6}2m$, $a = 715.6(4)$, $c = 388.4(2)$ pm) forms a new hydride CeNiZnH_{1.2(1)} under hydrogen exposure (10 bar) at 423 K. The resulting hydride crystallizes in a hexagonal structure ($P6/mmm$) with the unit cell parameters $a = 433.19(2)$ and $c = 424.37(2)$ pm. Thus, hydrogen atom insertion yields a structural

transition from a ZrNiAl- to an AlB₂-type structure with a high volume cell expansion of +20.1 %. The magnetic, thermal and transport properties of CeNiZnH_{1.2(1)} were investigated. Susceptibility and specific heat measurements do not reveal magnetic order down to 1.8 K but most likely the presence of ferromagnetic correlations due to the proximity of a ferromagnetic order or a nonmagnetic atom disorder spin-glass state. Moreover, the cerium valence is modified from an intermediate to a trivalent state, a change that results from the decrease of the hybridization strength between conduction and Ce(4f) electrons upon hydrogenation. Transport measurements also evidence a deviation from the typical resistivity behavior of metallic systems. Several scenarios are conceived to explain this change, in particular weak localization effect, knowing that it rarely occurs upon hydrogenation of intermetallics.

1. Introduction

The equiatomic cerium intermetallics Ce*TX* (*T* = transition metal; *X* = element of the 3rd, 4th, or 5th main group) cover more than 100 representatives with different crystal structures and broadly varying magnetic and electrical properties [1-3]. The physical properties of these materials depend on the valence electron concentration and the structure type. Several Ce*TX* phases show pressure and / or temperature driven structural phase transitions along with distinct changes in the physical properties. These structure property relationships have recently been reviewed [1-3].

An interesting subgroup of the Ce*TX* intermetallics concerns the Ce*TZn* compounds. Zinc occupies the position typical for a *p* element, underlining the covalent bonding within the two- or three-dimensional [*TZn*] networks. CeCuZn and CeAgZn [4] crystallize with the KHg₂ type structure with random occupancy of the copper (silver) and zinc atoms on the mercury site. In contrast, CePtZn [5, 6] and CeAuZn [7, 8] show complete Pt (Au) / Zn ordering. Both compounds order antiferromagnetically below $T_N = 1.7$ K [5-9].

CeNiZn [7, 10] and CePdZn [10, 11] crystallize with the hexagonal ZrNiAl type. The nickel compound shows intermediate cerium valence. CePdZn is dimorphic. The high-temperature modification adopts the orthorhombic TiNiSi type. This has consequences on the magnetic ground state. The low-temperature modification shows no magnetic ordering down to 2 K while the high-temperature modification orders antiferromagnetically at $T_N = 3.2$ K [11]. Electronic structure calculations and the magnetic data point to larger Ce(4*f*)–Pd(4*d*) hybridization for the low-temperature type phase.

CeRhZn (orthorhombic LaNiAl type) [12] is one of the remarkable Ce*T*Zn compounds. Its crystal structure contains two crystallographically independent cerium sites and temperature dependent magnetic susceptibility measurements indicate Pauli paramagnetism, in line with an almost tetravalent state for both sites.

The magnetic ground state of Ce*TX* intermetallics can be effectively influenced through hydrogenation. The studies on Ce*TX*H_{*x*} phases with *X* = *p* element of the 3rd, 4th or 5th main group are summarized in [1-3]. We have now included the zinc compounds into these systematic studies. Herein we report on the hydrogenation behavior of intermediate valent CeNiZn and describe the structural, magnetic, thermal and transport properties of the CeNiZnH_{*x*} phase.

2. Experimental

2.1. Synthesis

Starting materials for the preparation of the CeNiZn precursor were cerium pieces (Sigma-Aldrich, > 99.9 %), nickel powder (Merck, 99+) and zinc granules (Merck, > 99.9 %). Pieces of the cerium ingot were first arc-melted [13] to a small button under an atmosphere of ca. 700 mbar. The argon was purified over titanium sponge (900 K), silica gel and molecular sieves. The cerium button, nickel powder and pieces of the zinc granules (36 : 32 : 32 molar ratio) were then arc-welded in a tantalum ampoule. The latter was sealed in an evacuated quartz tube for oxidation protection, placed in a chamber furnace (Nabertherm P330) and heated to 1590 K within 6 h. This high temperature was kept for 10 min, followed by cooling to 920 K at a rate of 6 K min⁻¹. The temperature was kept for another 6 h followed by cooling to room temperature within 2 h. The

polycrystalline sample could easily be separated from the container by mechanical fragmentation. CeNiZn is highly brittle and shows bright metallic lustre.

Hydrogen absorption experiments were performed by solid-gas reaction. An ingot of the CeNiZn precursor was crushed in small pieces prior to being introduced into a stainless steel container. The sample was activated under vacuum at 423 K for 2 hours and then exposed to a pressure of 10 bar of hydrogen gas at the same temperature for 1 day. The amount of hydrogen absorbed was determined volumetrically by monitoring pressure changes in a calibrated volume. After hydrogenation, we observe the decrepitation of the pieces into fine powder. The hydride is stable in air over months.

2.2. X-Ray diffraction

The polycrystalline CeNiZn precursor sample was checked by powder X-ray diffraction (XRD) (Enraf-Nonius FR552 Guinier camera) using $\text{CuK}\alpha_1$ radiation and α -quartz ($a = 491.30$ and $c = 540.46$ pm) as an internal reference substance. The refined lattice parameters ($a = 715.6(4)$, $c = 388.4(2)$ pm) are in good agreement with earlier literature data [7, 10]. The hydride CeNiZnH_x was analysed by X-ray powder diffraction with a Philips1050-diffractometer using Bragg-Brentano geometry with $\text{CuK}\alpha$ radiation. The crystal structure was refined by the Rietveld method using the FullProf program [14].

2.3. Physical property studies

Magnetic properties of the samples were investigated using a MPMS-XL Squid magnetometer from Quantum Design. Measurements were performed on free powder in the temperature range 1.8-300 K and under magnetic fields up to 7 T.

For the heat capacity measurements, one piece of the crushed pellet was fixed to a pre-calibrated heat capacity puck using Apiezon N grease to ensure thermal conductivity. Measurements were realized with a PPMS from Quantum design in the temperature range of 2.0 to 300 K under applied external fields of 0, 0.1, 1 and 5 T.

Resistivity measurements were carried out with a PPMS from 2 to 325 K using a ac four probe method. Powder of CeNiZn and CeNiZnH_x was cold pressed to form pellets on which electrical contacts were glued with silver paint.

3. Results and discussion

3.1. Structural aspects

At 423 K and exposed to 10 bars of H₂ gas, CeNiZn uptakes hydrogen till reaching a pressure plateau in around 35 min corresponding to an absorbed H amount of 1.2(1) H/f.u. (formula unit). Thus, this indicates the potential formation of the hydride CeNiZnH_{1.2(1)}. The X-ray powder diffractograms of the precursor CeNiZn and the compound obtained after hydrogenation are shown in Fig. 1. The XRD pattern of CeNiZn is well indexed on the basis of the hexagonal ZrNiAl-type structure (space group $P\bar{6}2m$), in agreement with data reported earlier in the literature [7, 10]. In this structure, Ce atoms occupy the $3f$ (0.41576 0 0) site, Ni atoms $1a$ (0 0 0) and $2d$ ($2/3$ $1/3$ $1/2$) sites and Zn the $3g$ (0.76498 0 $1/2$) site, as determined from single crystal data. After hydrogen exposure, the compound displays a completely different pattern, confirming the effective hydrogen uptake in CeNiZn without any sign of decomposition. The diffractogram of the resulting hydride CeNiZnH_{1.2} is perfectly indexed with the hexagonal space group $P6/mmm$, with the unit cell parameters $a = 433.19(2)$ and $c = 424.37(2)$ pm. The small extra peaks correspond to the presence of the Ce₂Ni₂Zn impurity already observed in the pristine compound as well as residual non-hydrogenated CeNiZn. A Rietveld refinement of the data was performed on the basis of the AlB₂-type structure by analogy with the CeNiXH_x hydrides ($X = \text{Al, Ga}$) that show similar X-ray patterns [15-17]. This Rietveld refinement ($R_{\text{Bragg}} = 5.0\%$) is depicted in Fig. 1. The Ce atoms are located in the $1a$ (0 0 0) site whereas the Ni and Zn atoms are statistically distributed on the $2d$ ($1/3$ $2/3$ $1/2$) site. However, it is noteworthy that the refinement of the structure considering an alternation of the Ni and Zn atoms within the (ab)-plane, i.e. with the LiBaSi-type structure ($P\bar{6}m2$), is only slightly worse since both elements have close x-ray scattering factors. The simple AlB₂-type structure is built up of face-sharing trigonal prisms of Ce atoms [Ce₆] filled either by Ni or Zn atoms in their centre. Thus, this structure contains [Ce₃Ni] or [Ce₃Zn] tetrahedra as potential interstitial sites for hydrogen atoms. It is noteworthy that [Ce₃Ni] tetrahedra are also found in the ZrNiAl-type precursor CeNiZn. The positions of the hydrogen atoms could not be refined from X-ray data but we can assume that they are preferentially located in the $4h$ sites [Ce₃Ni] (or [Ce₃Zn]) tetrahedra. This hypothesis is based on neutron diffraction results obtained for the CeNiInD_{1.24} deuteride that report D atoms location in this position inducing short D–D interatomic distances of around 160 pm [18]. However,

Shashikala *et al.* also mentioned the additional sites $6k$ and $6i$ for deuterium atoms in the $\text{CeNiAlD}_{3.2}$ deuteride crystallizing in the AlB_2 type structure [19]. These tetrahedral interstices are formed by 2 atoms of Ce and 2 atoms of Ni/Zn and are filled with a lower occupancy than the $4h$ one. Thus, we can assume that the $4h$ site is filled first, and then the $6k$ and $6i$ positions are occupied for higher H/D insertion rate. Neutron powder diffraction measurements will be needed to check this hypothesis for $\text{CeNiZnH}_{1.2}$ and to determine more accurately the hydrogen composition within the structure.

The hydrogenation of CeNiZn induces a drastic increase of the molar volume from 0.0574 to 0.0690 nm^3 , i.e. an increase of $+20.1 \%$. Additionally, it yields a structural transition from the ZrNiAl to the AlB_2 -type structure. Interestingly, similar high volume expansion and structural change upon hydrogenation ($+19.7\%$) was also evidenced in the isotopic intermetallic uranium compound UNiZn [20]. In this case, the crystal structure of the resulting hydride $\text{UNiZnH}_{2.3}$ was not unambiguously solved between the AlB_2 -type structure and a derivative of this structure with an ordering of the Ni and Zn atoms. But, the survival of the ZrNiAl -type structure was clearly ruled out from x-ray diffraction analysis. In both U and Ce compounds, the observed structural modification is coherent with the high volume expansion. Indeed, the unit cell expansion exceeding $10\text{-}15\%$ induces this type of structural transition as for CeNiGa (low-temperature form) or CeNiAl , whereas lower volume increase ($<10\text{-}15\%$) keeps the initial ZrNiAl structure type as for CeNiIn [15-17].

The high volume expansion in the sequence $\text{CeNiZn} \rightarrow \text{CeNiZnH}_{1.2}$ results in increasing the interatomic distances in the structure, except for the shortest M–M distance of 250 pm , M being Ni or Zn (see Table 1). In the precursor CeNiZn , the shortest distances, found between the Ni and Zn atoms, were equal to 257 pm . However, in the hydride, these distances still remain slightly longer than the sum of the covalent radii (240 pm for Ni+Zn). A spectacular effect concerns the strong augmentation of the Ce–Ce distances from $371\text{-}389$ to $424\text{-}433 \text{ pm}$. All these distances are much longer than those found in Ce metal (365 pm [21]) or in cerium hydride CeH_2 (394 pm [22]). The Ce–M distances between Ce and M atoms also strongly increase upon hydrogenation, going from $289\text{-}322 \text{ pm}$ in CeNiZn to 328 pm in the hydride. These distances variations suggest

that f electrons could be more localized and the Ce valence state modified after hydrogen absorption.

3.2. Magnetic, thermal and transport properties

The temperature dependence of the magnetic susceptibility of CeNiZn and CeNiZnH_{1.2} measured in the field of 3 T is presented in Fig. 2. The curve of CeNiZn shows a rather temperature-independent behavior as reported earlier for this intermediate-valent cerium compound [7]. The small bump around 25 K, not observed in ref [7], could be due to the presence of a small amount of the Ce₂Ni₂Zn impurity observed in XRD. On the contrary, the hydride displays much higher values of the susceptibility and follows a Curie-Weiss behavior above 30 K (see inset of Fig. 2). The downward curvature in inverse susceptibility below 30 K might be due to crystal-field effects. The linear fit of data in the temperature range 25-200 K gives an effective moment $\mu_{\text{eff}} = 2.49 \mu_{\text{B}}/\text{Ce}$ atom and a paramagnetic Curie temperature $\theta_{\text{p}} = -15$ K (Table 2). The effective moment close to that of the free Ce³⁺ ion (2.54 μ_{B}) suggests that the cerium is trivalent and that Ni atoms do not carry magnetic moments. This means that hydrogenation induces a cerium valence change from intermediate-valent to a trivalent state, which is coherent with the strong increase of the Ce–Ni and Ce–Zn interatomic distances from CeNiZn to CeNiZnH_{1.2}.

For CeNiZnH_{1.2}, the susceptibility measurement at 0.05 T (Fig. 3) shows an enhancement of $\chi(T)$ below 5 K but without clear evidence of any magnetic ordering down to 1.8 K. The small anomaly around 8 K may be attributed to some impurity since no peak is visible at this temperature on the specific heat measurement (Fig. 4). However, the negative curvature of the magnetic isotherm $M(H)$ at 1.8 K (inset of Fig. 3) may indicate the existence of ferromagnetic correlations. It is noteworthy that this behavior cannot be accounted for the presence of a small quantity of a ferromagnetic impurity. The magnetization at 1.8 K reaches almost 1 μ_{B}/Ce atom at 7 T. At higher temperatures the negative curvature of the $M(H)$ isotherms progressively disappears and at 15 K the curve is linear. These observations suggest that, at low temperature, CeNiZnH_{1.2} could be close to a long-range ferromagnetic order or to a nonmagnetic atom disorder spin glass state. A spin glass behavior could arise from the atomic disorder on the Ni/Zn site and on the H site that would yield a random exchange interaction between the Ce atoms. This was

observed in the AlB₂-type germanides Ce₂NiGe₃ and Ce₂CuGe₃ in which a random distribution of the Ge and Ni or Cu atoms on the 2*d* crystallographic site is also reported [23, 24]. The M(H) isotherms at low temperatures for these two germanides are very similar to those measured on CeNiZnH_{1.2}. However, the absence of a peak in the ZFC curve of the hydride at 20 Oe (*not shown here*) does not allow us defining a freezing temperature T_f as for Ce₂NiGe₃ (T_f = 3.5 K [23]) or Ce₂CuGe₃ (T_f = 3 K [24]).

The specific heat measurement in zero magnetic field shown in Fig. 4 clearly indicates the absence of a λ -peak characteristic of a magnetic order down to 2 K. However, the C_p(T) curve reveals a small upturn below 8 K which seems to reach a maximum around 2 K. This maximum becomes more visible with increasing fields, especially at 5 T. This behavior suggests the existence of a nonmagnetic atom disorder spin glass state or a ferromagnetic state. On the plot of the C_p/T versus T², we observe a linear region above approximately 12 K. The fit of the data with the formula C_p/T = γ + β T² between 12 and 24 K at zero field gives the values γ = 44 mJ.mol⁻¹K⁻² and β = 0.478 mJ.mol⁻¹K⁻⁴ (Table 2). The β coefficient, associated to the phonon contribution to the specific heat, gives an estimation of the Debye temperature θ_D of 230 K (considering only the 3 non-hydrogen atoms since hydrogen atoms are usually involved in higher energy optical phonons modes). The moderate γ value suggests that the Kondo effect is weak in the hydride, in agreement with the small paramagnetic Curie temperature θ_p . Nevertheless, below 12 K, the C_p/T curve strongly increases, reaching a value of 1120 mJ.mol⁻¹K⁻² at 2 K. Such apparently large electronic coefficients γ are usually found in heavy-fermions or in spin glass systems [25] as for example in the Ce₂NiGe₃ and Ce₂CuGe₃ spin glasses in which C_p/T even attains a maximum [23, 24]. It was also observed in the hydrides Ce₂Ni₂MgH_{7.7} [26] and CeNiGaH_{1.1} [17], the last one crystallizing also in the AlB₂-type structure. The rather high γ value was associated to the existence of a strongly correlated system at low temperature in the former hydride and of a spin glass state in the latter one. However, in CeNiZnH_{1.2}, this γ value depends on the magnetic field since it is well reduced to 800 mJ.mol⁻¹K⁻² at 5 T (see inset of Fig 4). Therefore, it is reasonable to consider that this high γ value is not ascribed to a heavy-fermion character manifestation since, usually, γ is rather insensitive to the magnetic fields in heavy-fermion systems.

The resistivity measurements of the precursor CeNiZn and of the hydride are displayed on Fig. 5. The data were normalized to the value at 325 K because the use of

compacted pellets for the measurements yields the presence of porosities and microcracks that hamper the accurate determination of $\rho(T)$. The resistivity of CeNiZn behaves as a normal metal as typically expected for an intermediate-valent Ce compound with a high spin fluctuations temperature T_{sf} . On the contrary, the electrical resistivity of CeNiZnH_{1.2} presents different characteristics: $\rho(T)$ rises continuously with decreasing temperature in the whole temperature range 1.8-325 K with a more pronounced augmentation below 25 K. This behavior is not typical to that of a classical metal but more similar to that of a disordered Kondo system or a Kondo insulator as CeNiSn for example [27]. However, by plotting $\ln(\rho)$ versus $1/T$ we do not clearly observe a linear region at low temperature allowing us to define a band gap E_g (maybe due to the lack of pellet densification). Besides, a Kondo insulator state implies the absence of structural disorder and of a long-range magnetic order ground state [28], ground state which is not ruled out in our hydride. Thus, it is more likely that the drastic change in the transport properties originates from structural disorder. This could arise from the random distribution on the Ni/Zn atoms on the $2d$ site and on the partial filling of the H site. This hypothesis includes the case of a disordered Kondo lattice in which disorder hampers the establishment of the low-temperature coherent regime, regime below the Kondo temperature T_K where the resistivity drops with decreasing temperature. In contrast, in the incoherent regime, the magnetic part of the resistivity diverges logarithmically as the temperature decreases. A similar resistivity curve as that of CeNiZnH_{1.2} was observed in the hydride Ce₂Ni₂MgH_{7.7} [26]. But as such a behavior was also reported for the isotypic compound La₂Ni₂MgH₈ [29], this suggests that the Kondo effect is not directly responsible for the non-metallic character of Ce₂Ni₂MgH_{7.7}. Another possibility to consider is the weak localization of electron waves induced by atomic disorder. In this case, the electron motion experiences numerous random scatterings on scattering centers. The resulting “circle-like manner” scattering paths give rise to interference phenomena which leads to an increase in the resistivity. This effect can be well reduced by the application of an external magnetic field. Therefore, further resistivity measurements under magnetic fields are planned in order to provide more evidences of weak localization effect in CeNiZnH_{1.2}.

It is important to note that metal to non-metal transitions induced by hydrogenation occur rarely. Interestingly, such a transition was evidenced in the hydrides MAiSiH [30]

and $MGaXH$ [31] ($M = \text{Ca, Sr, Ba}$; $X = \text{Si, Ge, Sn}$) which crystallize in a structure closely related to the AlB_2 -type. In those systems, the calculated density of states (DOS) clearly revealed an indirect band gap opening upon hydrogenation with E_g values between 0.1 and 0.8 eV. It was ascribed to the removal of the partly filled antibonding π^* band in the metal having a predominantly Ga or Al p orbital character that yields an energetically low Ga(Al)–H bonding band. Thus, it turns out that hydrogen captures electron density, leading to hydride formation with covalent Ga(Al)–H bonding. However, it is unlikely that a similar scenario takes place in $CeNiZnH_{1.2}$ since the Sommerfeld coefficient suggests a significant density of state at the Fermi level and thus the conservation of a metallic state.

4. Conclusions

The intermetallic $CeNiZn$ forms the new hydride $CeNiZnH_{1.2}$ upon exposure to 10 bar of H_2 gas at 423 K. The hydrogenation of $CeNiZn$ induces a structural transition from a $ZrNiAl$ -type to an AlB_2 -type structure that goes along with a drastic unit cell volume expansion (+20.1 %) and a strong increase of the interatomic distances within the structure. As a result, the $Ce(4f)$ electrons are more localized, the hybridization strength between conduction and f electrons decreases and the Ce valence changes from an intermediate to a trivalent state. According to magnetic and specific heat measurements, the hydride does not display magnetic order down to 2 K but is most likely close to a ferromagnetic order or to a spin-glass behavior as ground state. This second option could arise from the random distribution of the Ni and Zn atoms on the same Wyckoff position and on the partial filling of the H site inducing crystallographic disorder in the structure and thus the presence of competitive indirect RKKY (Rudermann-Kittel-Kasuya-Yosida) interactions between Ce atoms. Further magnetic and specific heat measurements at lower temperatures would be helpful to elucidate the ground state of $CeNiZnH_{1.2}$.

Interestingly, hydrogen insertion also provokes a deviation from the classical metallic behaviour of the resistivity. In $CeNiZnH_{1.2}$ it most likely results in atomic structural disorder leading to disordered Kondo lattice effect or weak localization of the electrons, as possible scenario. Further resistivity measurements under magnetic fields are planned in order to provide more evidences of weak localization effect in $CeNiZnH_{1.2}$. Besides, it would be fruitful to better evidence the role of the structural disorder on the resistivity

behavior notably. One possible way would be to modify the hydrogen amount in CeNiZnH_x via different hydrogenation conditions. Such modifications of the transport properties, which are not often observed upon hydrogen insertion, can be interesting for applications as optical mirrors or hydrogen detector if they are reversible around room temperature.

Table 1. Interatomic distances (pm) of CeNiZn and CeNiZnH_{1.2}. For CeNiZn, Ni1 and Ni2 atoms are in positions 1*a* (0 0 0) and 2*d* (2/3 1/3 1/2) respectively.

CeNiZn				CeNiZnH _{1.2}			
Ce	Ni2	x4	289.45(6)	Ce	Ni/Zn	x12	327.98(1)
	Ni1	x1	296.6(1)		Ce	x2	424.37(2)
	Zn	x2	315.95(9)		Ce	x6	433.19(2)
	Zn	x4	322.66(9)	Ni/Zn	Ni/Zn	x3	250.10(1)
	Ce	x4	371.5(1)		Ce	x6	327.98(1)
	Ce	x2	388.7(1)		Ni/Zn	x2	424.37(2)
Ni1	Zn	x6	256.66(6)		Ni/Zn	x6	433.19(1)
	Ce	x3	296.56(9)		Ni/Zn	x6	492.59(2)
Ni2	Ni1	x2	388.7(1)				
	Zn	x3	279.5(1)				
Zn	Ce	x6	289.45(8)				
	Ni2	x2	388.7(1)				
	Ni1	x2	256.66(6)				
	Ni2	x2	279.51(9)				
	Zn	x2	290.4(1)				
	Ce	x2	315.95(9)				
	Ce	x4	322.66(9)				
	Zn	x2	388.7(1)				

Table 2. μ_{eff} , θ_p , γ and β fitting values of CeNiZn and CeNiZnH_{1.2} obtained as explained in the text from the Curie-Weiss fit of the susceptibility curve and from the low-temperature specific heat measurement. The data for CeNiZn are taken from ref [5].

	μ_{eff} (μ_B)	θ_p (K)	γ ($\text{mJ}\cdot\text{mol}^{-1}\cdot\text{K}^{-2}$)	β ($\text{mJ}\cdot\text{mol}^{-1}\cdot\text{K}^{-4}$)
CeNiZn	0.29	-2.8	-	-
CeNiZnH _{1.2}	2.49	-15	44	0.478

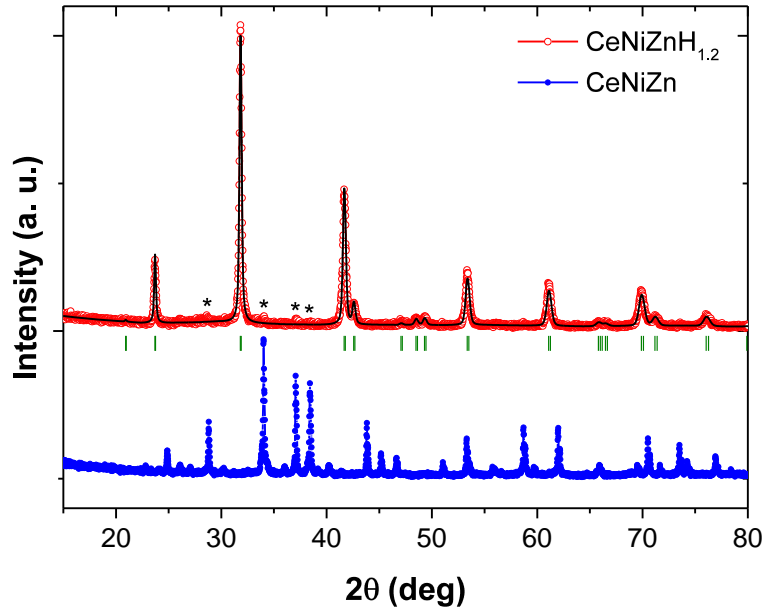

Fig. 1. X-ray powder diffraction patterns of CeNiZn and CeNiZnH_{1.2}. Indexation of the pattern on the basis of the AlB₂-type structure is indicated for the hydride and Rietveld refinement is shown by a solid line. Stars symbols indicate the main visible peaks of the residual pristine compound.

Fig. 2. Temperature dependence of the magnetic susceptibility of CeNiZn and CeNiZnH_{1.2} measured at 3 T. Inset: Temperature dependence of the inverse of the magnetic susceptibility of the hydride with the Curie-Weiss fit in dotted line.

Fig. 3. Temperature dependence of the susceptibility of $\text{CeNiZnH}_{1.2}$ measured at 0.05 T. Inset: Magnetization isotherms of $\text{CeNiZnH}_{1.2}$ at various temperatures.

Fig. 4. Temperature dependence of the specific heat of $\text{CeNiZnH}_{1.2}$ measured at 0, 0.1, 1 and 5 T. The inset presents the C_p/T versus T^2 curve at 0 and 5 T with the linear fit $C_p/T = \gamma + \beta T^2$ in dotted line for zero magnetic field as mentioned in the text.

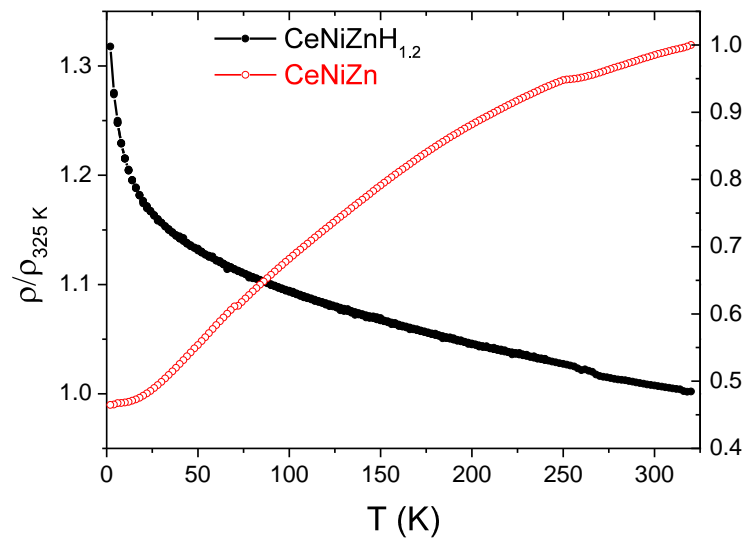

Fig. 5. Temperature dependence of the electrical resistivity of CeNiZn and CeNiZnH_{1.2}, normalized to the value at 325 K.
