**Abstract:** This paper presents a method that automatically decides which system configuration should be used to process a query. This method is developed for the case of repeated queries and implements a new kind of meta-system. It is based on a training process: the meta-system learns the best system configuration to use on a per query basis. After training, the meta-search system knows which configuration should treat a given query.

The Learning to Choose method we developed selects the best configurations among many. This selective process rests on data analytics applied to system parameter values and their link with system effectiveness. Moreover, we optimize the parameters on a per-query basis. The training phase uses a limited amount of document relevance judgment. When the query is repeated or when an equal-query is submitted to the system, the meta-system automatically knows which parameters it should use to treat the query. This method fits the case of changing collections since what is learned is the relationship between a query and the best parameters to use to process it, rather than the relationship between a query and documents to retrieve.

In this paper, we describe how data analysis can help to select among various configurations the ones that will be useful. The “Learning to choose” method is presented and evaluated using simulated data from TREC campaigns. We show that system performance highly increases in terms of precision, specifically for the queries that are difficult or medium difficult to answer. The other parameters of the method are also studied.

**Category:** H.3.3 Information Search and Retrieval

## 1 Introduction

In information retrieval (IR), a ranking function is used to decide the documents to retrieve according to a query and their order. Document and query similarity is

a key component of the ranking function in which many parameters are involved: the way documents are indexed, the possible query expansion, the similarity function itself, ... Systems vary because they use different parameters.

Over queries, systems do not behave homogeneously and a system that answers well a query  $Q_1$  can answer query  $Q_2$  poorly, while another system does oppositely. As a result, it is impossible to define the best parameter values that fit any query. Rather, most of the approaches optimize the parameters so the results are best in average over queries. Alternatively, it is possible to consider methods which are query-based. We propose such a method. It chooses among a set of system configurations the one that fits the best, on a per query basis.

This principle implies to learn a link between queries and systems. It can be done by learning the association between query features and system features or parameters. This is done in selective query expansion for example [Amati et al., 2004], [Zhao and Callan, 2012], [Chifu and Mothe, 2014]. In that case, queries are represented by features and the meta-system learns in which cases query expansion should be applied. A new query can then be compared to learned queries on the basis of its features and the expansion decision can be applied.

We consider an alternative process in which learning is applied to individual query: in that case the training consists in associating the best system to each query. In practice, this latest principle is possible if the queries are known in advance only; which is indeed the case for repeated queries.

Several studies have shown repeated queries occur frequently in real applications. Teevan *et al.* [Teevan et al., 2007] have shown that 33% of queries are exact repeats of a query issued by the same user (equal-query queries) and 25% leads to the same single user click. Sanderson and Dumais studied 3.3 million queries and showed more than 50% of them were repeated queries [Sanderson and Dumais, 2007]. These studies show that it is worth improving system results for repeated queries.

Our method is a selective approach we call “learning to choose” and which has this aim. The learning to choose method implements a meta system that makes use of systems variability. It aims at deciding which system configuration should be used to treat a given query. To do so, the learning to choose method learns the best query-system association: it learns the system configuration to be used for a given query in order to optimize the results. This training phase uses a subset of documents for which the document relevance is known. After training, whenever equal-query queries occur, the learned system configuration will treat the query over the entire document collection.

The main results of this work are:

- The best configuration to use for a query can be learned over a subset of documents for which relevance is known.

- The number of system configurations that are useful can be relatively small: less than 10 configurations are needed to improve Mean Average Precision (MAP) of about 20%.
- Learning to choose improves the results the most on medium hard queries.

The paper is organized as follows. In Section 2, we report related works. Section 3 presents the learning to choose method. Section 4 describes the evaluation framework. In Section 5 we report and discuss the results. Finally, the last section concludes the paper and draw some future works.

## 2 Related Works

Our method aims at taking advantage of system variability. Other methods rely on system variability to improve retrieval. Without being exhaustive, this section presents the different types of methods. This section also includes related work on how repeated queries are handled and on selective information retrieval.

### 2.1 Data Fusion

Data fusion takes advantage of system variability by combining the ranked lists retrieved by different systems for a given information need [Fox and Shaw, 1994]. The issues of data fusion are to decide both the ranked lists to fuse and the fusing function. Fox and Shaw [Fox and Shaw, 1994] suggested several methods to fuse retrieved document lists and show that the resulting meta-system outperforms any of the combined system when considered separately. CombMNZ is the most popular among these measures [Lee, 1997]; it combines the scores the documents obtained using the various systems and favors the documents which are retrieved by a larger number of individual systems.

Some works have shown that the systems to fuse should be independent [Croft, 2000], [Wu et al., 2009]. Some studies have also been carried on the various parameters that may have an influence on the fusion such as the number of systems to fuse, their performance, and their diversity [Liu et al., 2012]. Liu *et al.* take into account the ranks the systems obtained and show that effectiveness does not necessarily increases with the number of systems but rather that the systems to be fused have to be effective and enough different one from the other considering the RSC (Rank-score characteristics) feature. One of the issues in data fusion is to assign weights to each component. Wu [Wu, 2012] uses the multiple linear regression technique to learn the best weights, considering both estimated relevance scores and judged scores.

The same fusing function is generally applied whatever the queries are. However, the fusing model can also be learned on a per query basis; in that case, the fusing function is query dependent [Wilkins et al., 2006].

Unlike data fusion which fuse various system results, learning to choose selects the best system configuration that should treat a query among several.

## 2.2 Learning to Rank

Variability and learning are also core elements of learning to rank methods [Liu et al., 2010]. The main goal of learning to rank is to learn a ranking function that optimizes the ranking of web pages or documents.

Various algorithms have been developed that make use of a range of features to be used during learning. Learning to rank relies on machine learning. In the training phase of learning to rank, the examples to learn consist of ranked lists of relevant documents associated with the corresponding information needs. The ranking function is trained on these examples. The testing phase uses the single learned ranking function on new queries [Cao et al., 2007]. Recent work in this domain focus on feature selection [Laporte et al., 2014], [Lai et al., 2013].

Unlike learning to rank, learning to choose does not learn a general function that would work whatever the query is. Rather, the principle of the method is to select the best system configuration on a per query basis by analyzing the performance on a subset of documents; the learned system configuration is then used on the entire set of documents.

## 2.3 Repeated Queries

Several studies shown that repeated queries occurs frequently in real applications [Smyth et al., 2005], [Sanderson and Dumais, 2007], [Teevan et al., 2007], and [Tyler and Teevan, 2010]. In addition, Zhang suggested a method to predict repeated queries [Zhang and Lu, 2009]. Thus, improving performance for repeated queries is an important track.

Some approaches process repeated queries by storing documents that should be retrieved. This is done for frequently asked queries for which the results are cached [Baeza-Yates et al., 2007], mainly to answer time response issue. In that case, one assumes that the relevant documents remain the same. In addition, because new documents are continuously added or deleted, index updates lead to cache invalidation: cached results correspond to entries whose results have changed [Blanco et al., 2010]. The cache method can also be used to answer queries that are close to previous queries [Baeza-Yates et al., 2007]. Alternatively [Mothe and Tanguy, 2007], some specific treatments can be done on a per query basis.

In our approach we associate the best system parameters to each query; it thus fits the case of repeated queries. Moreover, since learning to choose does not store the results but rather the best way to obtain them, it can be applied in the context of highly dynamic collections.

## 2.4 Selective Approach

The literature also investigates selective information retrieval, mainly considering selective query expansion (QE). The basic idea is that, even though query expansion (e.g. pseudo relevance feedback query expansion) improves system effectiveness in average, some queries are degraded by query expansion. Thus, query expansion should not be applied when it may degrade the results [Amati et al., 2004, Cronen-Townsend et al., 2004, Chen et al., 2012]. Rather than deciding whether the query should be expand or not, more adaptive methods are used to learn the functions according to query features. For example, [He and Ounis, 2004] suggest a method to select among several term-weighting models depending on the query. Queries are described by features that are used to cluster them. Training associates the best term-weighting to each query cluster. When a new query is submitted to the system, it decides which cluster the query belongs to and process it by the corresponding system. Chifu *et al.* [Chifu and Mothe, 2014] presents a selective QE method that relies on a combination of query difficulty predictors. The method combines statistically and linguistically-based predictors. The QE method is learned by a SVM (Support Vector Machine). Other per-query techniques [Cao et al., 2008] and [Lv and Zhai, 2009] have been developed.

In previous work, we also suggest three methods that aim at deciding which system(s) would be the best to process a given query considering TREC participant systems as system candidates [Bigot et al., 2011]. Compared to He and Ounis' technique that learns some queries over the entire collection, Bigot *et al.* learns all the queries on a sample of documents. In Bigot *et al.*, the three methods are based on a training stage in which the decision is learned for each query using a sub-set of the document collection and the maximization of a performance measure (e.g. precision). Once trained the meta-system knows which system should process the query ; this system will then process the query over the entire document collection. The first method we called OneT2OneS (for One Topic to One System) selects the best retrieval system for each query. The two other variants are based on a first stage that clusters the systems prior to the training phase, then choose an ambassador for each cluster. Finally the best cluster is selected by choosing the ambassador that maximizes the performance measure. The two approaches that use system clustering are OneT2ClusterS (for One Topic to System Cluster) and ClusterT2ClusterS (for Cluster Topic to Cluster Systems). They differ in that ClusterT2ClusterS clusters topics (queries) according to their difficulty.

In this paper we reconsider the OneT2OneS method and analyse in deep the various parameters of the method to draw more useful conclusions. In addition, in this paper, we target repeated queries. In that context, queries are known and the problem is to choose the best system configuration to apply. Compared to

[He and Ounis, 2004] and [Bigot et al., 2011] we do not use various systems but rather various retrieval configurations that do not imply various indexing. We think that our method is easier to use in real systems because of this. Moreover, we evaluate the method and show that a limited number of configurations are needed to improve results, specifically on difficult or medium difficult queries.

### 3 Learning to Choose System Configurations

#### 3.1 Principle of the Method

In our method, we make the hypothesis that system parameters lead to different system performances depending on the queries. Moreover, the method is based on the fact that for a given query, it is possible to optimize the results in terms of effectiveness by optimizing the system parameters or by using the relevant system parameter values. Following this idea, our method aims at deciding which system parameter values should be used for a given query. In the rest of the paper, a given set of parameter values is called a system configuration.

Our method implements a meta-system that chooses among pre-defined system configurations on a per-query basis. It is based on a simple learning process or association process.

The training query set consists on all the queries that have been identified as repeated and for which the meta-system should learn the best configuration. The training phase of the learning to choose method is applied to a subset of documents (training set). On this document subset, the various system configurations are used to process the queries using a sample of annotated documents. For these documents, we know whether they are relevant to the query or not. Each system configuration treats the training document set over the query set. From the retrieved document lists we compute the evaluation measure for each query and each system configuration. The best configuration is then chosen for each query. After training, the meta-system knows which system configuration should process each query (over the entire and possibly dynamic collection). Whenever an equal-query is submitted to the meta-system, it processes it using the learned system configuration.

The set of system configurations is an important parameter of our method.

#### 3.2 Defining and Selecting the Set of System Configurations

Defining the set of system configurations is not obvious.

First, some IR parameters are more resource demanding than other when making them varying. For example, making indexing parameters varying implies to index several times the collection which can be costly in terms of time and storage. For this reason, in the evaluation process, to be more realistic on

the usability of the method for real applications, we only consider retrieval parameters to be variable, while indexing parameters are set once for all.

Second, some parameters have more influence on the result than others [Chifu et al., 2016]. It does not make sense to consider two configurations that does not change the results; rather, it is useful to take advantage of system variability. Moreover, the set of system configurations should be composed of configurations that perform well on average over queries.

In our approach, to be kept, a system configuration should (a) obtain good results on average over the queries (b) obtain better results than the average on a subset of queries. Moreover, it is not mandatory that a given query is treated effectively by several system configurations; one being enough to ensure users satisfaction. As a matter of fact, we do not need to consider all possible system configurations; what is needed is to ensure that at least one available system configuration is effective on each query.

Considering the example given in Table 1, we would like to select either system configuration  $S_1$  or  $S_2$  to ensure query  $Q_1$  is well processed by at least one system configuration. This is also true for system configuration  $S_3$  or  $S_4$  for query  $Q_2$ .

Table 1: Exemplification- Performances of 4 system configurations on two queries.

	$S_1$	$S_2$	$S_3$	$S_4$
$Q_1$	0.8	0.9	0.2	0.1
$Q_2$	0.2	0.1	0.9	0.8

More concretely, to select among system configuration candidates we dispose the corresponding performance over the query set on the training document set. For defining the configurations to keep, we iteratively select the most useful configuration as follows:

1. For each query, we compute the value of the performance measure that corresponds to the highest percentile; the system configuration that gets this value becomes a candidate. For example, if we consider the average precision (AP) as the performance measure, we calculate the AP value  $AP_{001}$  for which 1% of the AP values are higher and 99% of the AP values is lower for this query, whatever the system configuration is. Let us consider that the processed query is an easy one and that over system configurations, the best system  $S_b$  got a MAP of 0.85,  $MAP_{001}$  for this query is set to 0.85;  $S_b$  becomes a candidate.

2. System configurations that have been selected in step 1 constitute the set of candidates for this first iteration.
3. For each candidate, we compute the number of times it has been selected; that is to say the number of queries that selected each configuration. We keep the system configuration which is the most frequent. An additional condition to keep the system configuration is that its frequency is higher than a threshold. For example,  $S_b$  has been selected in step 1 by 10 queries and is the most selected configuration and given a threshold of  $Q_{min}$  queries 6 for instance,  $S_b$  is definitively kept.
4. The queries that selected this configuration are removed from the query set. Considering our example, the 10 queries that choose configuration  $S_b$  are removed.
5. We go back to step 1 considering all system configurations and the remaining queries (in our example using *Number of queries* – 10).

If there is no system configuration selected the process is iterated considering the second percentile (the performance value for which 98% of the values are higher than it), third percentile, ... If less than  $T$  queries remain unmatched, they have to all be selected at once (the percentile criteria is relaxed); this results in selecting the best system in average on the remaining topics. This rule is used to avoid selecting hardest topics one by one while percentile is decreasing.

## 4 Evaluation Framework

### 4.1 TREC Collection to Simulate Data

Evaluating our method in a real context implies to have access to real data (repeated queries, documents, document relevance); such a collection is not freely available. For this reason, we simulated the environment by evaluating our method on data from TREC (Text Retrieval Conference<sup>1</sup>). The collection we used (TREC7 and TREC8 adhoc sets) is composed of approximately 528, 155 documents (2 gigabytes), a set of 100 natural language topic statements and the associated relevance judgments. In our experiment, any TREC topics are considered as repeated information needs. Topics are composed of a title, a description and a narrative part and correspond to information needs. Notice that, since the methods are evaluated on TREC, we distinguish topics and queries in the rest of the paper: topic is used to refer to a TREC topic; a query is the internal representation used by the search system and is built from a topic. QRel consists of document relevance judgements for each topic. By confronting them to the

<sup>1</sup> <http://trec.nist.gov/>

list of retrieved documents, it is possible to compute performance measures to evaluate system configuration performance.

## 4.2 Evaluation Measures and Methods

We use the TREC evaluation software `trec_eval`<sup>2</sup>, version 9.0 that computes many measures. Evaluation measures have been shown to be highly correlated [Baccini et al., 2011]. In this work, we only consider average precision (AP) for each topic and mean average precision (MAP) over topics. AP is the result of averaging precision (number of relevant retrieved documents over retrieved documents) each time a relevant document is retrieved. MAP characterises a system configuration by averaging AP over topics.

Using AP to evaluate the system configurations, we store AP in a table in which lines correspond to topics and columns to system configurations as illustrated in Table 2.

Table 2: Extract of the AP data - TREC Ad-hoc.

	Sys1	Sys2	...	Sys99	Sys100
T351	0.5819	0.5722	...	0.5432	0.5135
T352	0.0001	0.0011	...	0.0016	0.0005
...	...	...	...	...	...
T449	0.0528	0.0275	...	0.1324	0.0117
T450	0.3353	0.1699	...	0.3067	0.2959

In our experiments, we partition the document collection according to a training part of  $\frac{2}{3}$  and a test part of  $\frac{1}{3}$ ; 10 random selections are performed then we average the results over the 10 collections [Freund et al., 1996]. The repetition of queries is simulated by treating the same topic on test documents. Evaluation uses the QRel after removing the training documents from it.

The performance of our approach is compared to a baseline. The baseline is defined as the result of the best system configuration over the queries. The mean of all ten baselines (from cross-validation) is the general baseline. It was mandatory since the set of documents varies and thus the MAP varies as well depending on the draw.

## 4.3 Building System Configurations

We use the Terrier platform [Ounis et al., 2006] in our experiments. Terrier allows to choose modules from the three steps of the IR process:

<sup>2</sup> [http://trec.nist.gov/trec\\_eval/](http://trec.nist.gov/trec_eval/)

- Indexing: stemmer, size of blocks, empty documents ignored or not;
- Matching: retrieving model, topic fields to use, low idf terms ignored or not;
- Query expansion (QE): QE model, number of terms to add to the query, number of top documents to consider for QE, number of top documents a term should appear in to be used during QE.

Concretely, we built different runs using Terrier. We used a specific tool we developed on top of Terrier [Louedec and Mothe, 2013] in order to generate massive numbers of runs using the various models and parameters available in Terrier. Rather than having to re-write a program that requests Terrier many times in its command mode (e.g. *trec\_terrier.sh -r -Dtrec.model = BB2*), this interface allows deciding which parameters one wishes to vary, in which range, etc. The interface is based on Terrier 3.5 and written in Java.

Not all the parameters are equal in terms of resource needed. For example, using different indexing implies to re-index the entire collection and to store twice the inverted files. Once the index is built, it is also less resource demanding to process a simple search than a pseudo-relevance feedback (the latter implies two searches, one with the initial query and a second with the expanded query).

To be more realistic with regard to applicability, we considered a single indexing. Indeed, indexing is costly in terms of time processing, disk space and updates when creating an IR stream. For that reason, we consider a single index and thus indexing parameters are set once. The only parameters that we make varying are matching and query expansion parameters. The indexing phase uses the default Terrier stopword list, Porter stemmer algorithm, a block size of 1 and ignores empty documents. Indeed using different stopword lists does not have significant impact on the results but using one (rather than none) does significantly improve the results [Dolamic and Savoy, 2010]. Fuller *et al.* [Fuller and Zobel, 1998] showed Porter stemmer is the most accurate. Also Compaore *et al.* [Compaore *et al.*, 2011] showed that block size different from 1 and empty documents do not change the results significantly.

From this single indexing, we then run various system configurations making the other parameters varying. Table 3 presents the modalities of the different parameters we used to generate the runs. The detailed description of these parameters can be found on Terrier web site<sup>3</sup>. These runs correspond to candidate system configurations.

We then select the 100 best configurations. More precisely, we kept only the 100 ones that get an AP over 0.2 for at least 50% of the topics. This threshold of 0.2 is set to ensure that the performance of the selected system configurations is good enough.

<sup>3</sup> <http://terrier.org/>

Table 3: System parameters with the corresponding values

System Parameter Name	Modalities
Retrieving Model	TFIDF, DPH, IFB2, DFRee, InexpC2, HiemstraLM, XSqrAM, DLH, DFRBM25, DirichletLM, InexpB2, LGD, PL2, JsKLS, DF10, InL2, InB2, BM25, DLH13, LemurTFIDF, BB2
Trec Query Tags Process	"TITLE,DESC", "TITLE", "NARR", "TITLE,NARR", "TITLE,DESC,NARR", "DESC", "DESC,NARR"
Parameter Free Expansion	TRUE, FALSE
Query Expansion (QE) Model	KL, Info, KLCp, Bo2, Bo1, KLCt
Number of Documents for QE	2, 5, 10, 20
Number of terms for QE	2, 5, 10, 20
Minimum number of documents in which terms should occur	2, 5, 10, 20, 50

These 100 configurations can then be used directly in the learning to choose process or be filtered out to decrease their number. We considered two ways of filtering them out: using a clustering method (see Section 5.1) and using a more sophisticated method (see Section 5.2).

## 5 Results and Discussions

### 5.1 Impact of the Number of System Configurations

In real applications, using 100 system configurations can be costly. For that reason, we study the impact of the number of system configurations to use. We consider various selection thresholds (10, 20, 30...100 configurations). One solution could be to randomly select the systems. However this solution would not take advantage of system variability. For this reason, we prefer to select system configurations that behave differently on the topics. To do so, an hybrid clustering (hierarchical clustering combined to K-means) is applied so system configurations of each cluster lead to close performance in terms of AP for each topic of the cluster on the training document set. For each cluster the best configuration is selected to be used in the learning to choose process. This method insures that the selected configurations are different enough. We then consider several thresholds: we analyse the results when 100% of the configurations are used (no clustering), when 90% of the initial configurations are used, 80% ... until 10% (meaning that only 10 configurations are used, corresponding to 10 different clusters or configuration profiles).

Figure 1 shows the results of this experiment.

Figure 1: Analysis of the number of different system configurations. Grey lines corresponds to the training phase, and black lines to the testing phase. Dashed line is the baseline and plain line with dots correspond to the average over all ten sub-collections. Dotted lines represent the result of a random selection.

Results presented in Figure 1 show that using only 10 different system configurations, improves the results from 0.28 to 0.34 which corresponds to an increase of 22%. Using more than 10 system configuration (10%) candidates does not improve the results very much specifically on the testing phase.

From this preliminary study, we conclude that 10 configurations are enough to significantly improve the performance but less could also be enough.

In the following, we select a minimal set of system configurations (less than 10) to make further analysis on the behaviour of the selection technique on a small sample of configurations.

## 5.2 Defining a Minimal Set of System Configurations

To select a minimal and optimal set of systems, we apply the method presented in Section 3.2 to the previous set of 100 system configurations.

One parameter of the method is the minimum number of topics a system is effective for to be selected. Figure 2 shows the lower the number of topics  $T$  is, the more specific the selection is, and the better the results are. However, we do not want to be too specific because that leads to selecting too many system configurations; for that reason we consider 10 configurations or less.

Figure 3 displays the average MAP in function of the number of system configurations; 10 being the maximum number of system configurations we allow to be selected by the algorithm. As a compromise between effectiveness and the number of selected system configurations, we choose 7 possible configurations.

Figure 2: Number of selected system configurations (right axis) & performance (left axis) according to T.

This corresponds to 3 different possibilities of the number of topics T (see the dots hovered by horizontal dashed line in Figure 2) and the best MAP (0.528) is obtained for T=13 (vertical dashed line).

The 7 configurations are detailed in Table 4.

Table 4: Most useful system configurations. In the third column, the parameters are given in the following order: Retrieving Model, Topic field, Query expansion model, Number of documents, Number of terms.

Configuration name	MAP	System parameters value
Run1	0.2429	DFRee; T; Bo2; 20; 5
Run2	0.2487	BB2; T; Bo1; 20; 15
Run3	0.2196	BM25; T; Bo2; 5; 2
Run4	0.2366	InL2; TD; Bo2; 5; 20
Run5	0.2172	InB2; T; Bo2; 10; 2
Run6	0.2245	InL2; TD; Bo2; 2; 5
Run7	0.1907	InB2; TDN; Bo1; 10; 20

Within these 7 configurations, different search models have been selected (DFRee, BB2, BM25, InL2 and InB2). Moreover, in the majority of cases, the topic field used is the title (T); Title + Descriptive (TD) is chosen twice and the full topic (TDN) once; we could have restricted ourselves to runs where title only was used, but we decided differently considering that descriptive and narrative fields could be captured in real applications using past queries or users profiles. The query expansion models are either Bo1 or Bo2 for any of the 7 configurations. Finally, the number of documents used in the pseudo relevance feedback and the number of terms used to expand the queries vary from 2 to 20.

Figure 3: Average performance according to the number of selected system configurations. The black line is the number of selected system configurations and the grey line is the MAP; MAP averages the AP of the systems selected for each topic during the selection.

Table 5 provides additional features about the 7 selected configurations. The best AP varies from one run at the other as well as the topic for which the best AP is obtained. Although the method aims at selecting configurations that best fit for some of the topics, the results show that the selected configurations perform well on common topics: when considering the best 10 topics over the 7 configurations, we get a total of 18 different topics.

Interestingly, Figure 4 (left part) shows for each topic (x-axis) the difference between the maximum and the minimum AP over the 7 configurations; these differences are sorted in decreasing order. For half the queries (see right side of Figure 4), this difference is higher than 0.18; given the fact that for the best run (Run2) MAP is of 0.2487 and that half of the queries get an AP lower than 0.17; this difference is important. This means that by choosing the relevant configuration of systems for each query, one can largely improve the overall performance.

Figure 4: Difference between the Max and Min AP over the 7 configurations for the 100 topics, sorted in decreasing order on the left; boxplot of the same values on the right.

Table 5: Features about the 7 selected configurations

Config.	Best AP	Worst AP	Best 10 topics
Run1	T365 0.8847	T432 0.012	T351 T365 T368 T403 T410 T423 T425 T430 T441 T444
Run2	T410 0.8859	T433 0.0000	T351 T365 T368 T390 T403 T410 T415 T431 T441 T444
Run3	T410 0.8668	T433 T432 0.0000	T351 T365 T382 T403 T410 T423 T429 T430 T431 T444
Run4	T365 0.8553	T389 T397 T397 0.0000	T351 T365 T382 T403 T410 T423 T430 T441 T447 T450
Run5	T410 0.8731	T433 0.0000	T351 T365 T368 T382 T403 T410 T430 T431 T441 T444
Run6	T365 0.8172	T397 T442 0.0000	T351 T365 T382 T403 T410 T423 T430 T441 T444 T450
Run7	T447 0.7100	8 topics 0.0000	T351 T361 T365 T368 T382 T410 T423 T444 T447 T450

Table 5 presents some features of the 7 selected configurations.

Figure 5: Hierarchical clustering on data computed with the full collection of documents.

### 5.3 Impact of the Topic Difficulty

In this section we evaluate the performance of learning to choose using the selection of systems (the 7 previous configurations) using levels of topic difficulty. Again, to avoid randomness effect that could lead to one lucky or unlucky experiment, we proceed a cross validation on ten different splits of the document collection.

As we ran 10 experiments, the number of topic clusters may change from one experiment to another. To be able to merge the results, we need to keep the same number of clusters for all 10 experiments. Each cluster is characterised by a difficulty label according to AP systems obtained. Among the 10 experiments, we observed that 4 to 6 levels of topic difficulty would be optimal for the learning to choose method. To set the number of difficulty levels to consider, we run the hierarchical clustering on data computed with the full collection of documents. The resulting dendrogram is shown in Figure 5. The top right corner of the figure displays the inertia loss of the last 15 steps of the clustering. The first optimal cut is 5 clusters so we run the 10 cross validation experiments with 5 topic clusters. Indeed, from the clustering, it can be concluded that 5 difficulty levels is a reasonable choice.

As the number of topics in a difficulty level varies along the 10 experiments, the overall average MAP by cluster is weighted with the number of topics included in the considered level. This is done for both the meta-system and the baseline. Figure 6 displays the average mean of MAP by topic difficulty level during the test phase. Topics on which systems performed poorly are qualified

Figure 6: Fusion Results according to topic difficulty. Black dots correspond to the MAP of the meta-system and grey dash show the baseline MAP and are read on the left axis (with black guidelines). Grey squares show the relative difference between the meta-system and the baseline and are read on the right axis (with grey guidelines).

“hard”, those on which they performed less poorly are qualified “medium hard” and so on for “medium easy” level, “easy” level and finally the “easiest” level on which systems performed greatly.

We show that performances are poorly increased on easy topics; that can be explained by the fact it is hard to improve system performances when they already are really high. At least, performances are not degraded. Performances on medium easy topics are improved by 12%; according to the t-test, the increase is significant for 6 experiments out of 10.

The best improvement is observed for the medium hard topics with an increase of 44% (increase is significant for 9 experiments). Finally, the hardest topics are improved by 43%. However the absolute increase is little (0.04), it is still significant for 8 experiments.

## 6 Conclusion and Future Works

This work has been possible thanks to the French ANR agency through their support of the CAAS-Contextual Analysis and Adaptive Search project (ANR-10-CORD-001 01).

In our work, we proposed a method easy to reproduce to select a subset of systems that are then used in a query-based selective process. Systems are selected on the base that whether or not their performances belong to the highest percentile for a defined number of topics. Matched topics are successively deleted from the selection until no topics remain. The analysis of this selection method leads to select seven systems in order to balance performances and real conditions. Even if the last matched topics are poorly performed by the selected systems, due to the selection method itself, the evaluation is not degraded.

Learning to choose has been then evaluated on the seven systems and clusters of topics are defined according to system performances: the better system performances are, the easier the topic are. The evaluation shows that, based on a given set of systems, a fusion method is able to improve retrieval performances from 12% on medium difficulty topic to 44% on hard topics. Since results of the information retrieval process are not stored, the method is able to deal with dynamic collections. Learning to choose focuses on the case of repeated queries; for unseen queries, the meta-search system would use the best system in average.

In this study, query clusters are defined after queries have been processed at least once. This is possible in the context of repeated queries. However, such a method is not able to deal with queries submitted for the first time. Actually, future works should focus on applying difficulty prediction techniques. Such techniques can be based on linguistic predictors [Mothe and Tanguy, 2007] or on different predictors such as query ambiguity [Chifu, 2013].
