HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Twisting Induces Ferromagnetism in Homometallic Clusters

Ghenadie Novitchi, Sergi Vela, Guillaume Pilet, Cyrille Train, Vincent Robert

A helical chiral cluster bridging two sets of Cu₂ units is reported. The two double-strand ligands induce a distorted tetrahedral environment for one of the two copper(II) ions whereas the second one remains in a standard octahedral environment. Magnetic measurements and wavefunction calculations demonstrate that the copper(II) centres are ferromagnetically coupled (\(J = 7.7 \text{ cm}^{-1}\)). This ligand-driven ferromagnetic interaction thus appears as a proof-of-concept of an innovative strategy towards high-spin clusters.

Increasing the spin value in the ground state (GS) of polymetallic coordination clusters was and remains one of the major concerns in molecular magnetism. The ferrimagnetic strategy, that is an antiferromagnetic (AFM) exchange interaction with uncompensated up and down spins, is the most widely used strategy because AFM exchange interaction occurs as soon as the so-called magnetic orbitals (MOs) overlap insuring the domination of superexchange and kinetic exchange mechanisms over potential exchange mechanisms. Nonetheless, a ferromagnetic (FM) exchange interaction leads to the highest possible GS spin value and can therefore appear as the most natural route towards high spin clusters. The first and still most common strategy to achieve orthogonality of the magnetic orbitals (FM coupling) is to use heterospin pairs. Architectures based on homospin units are more scarce in such dinuclear complexes or cubanes, the ferromagnetic interaction arises from M-O-M angles close to 90°, ensuring the orthogonality of the magnetic orbitals in much the same way as in divalent metal oxides governed by Goodenough-Kanamori rules.

Moreover, since the discovery of DNA double-stranded helical structure, chemists have made many efforts to design and synthesize helical systems. From the early days of A. Werner, coordination complexes are known to favour helical structures. This possibility has been extended to polynuclear helical complexes (helicates) and, more recently, to Metal-Organic Frameworks. In the present contribution, the ligand is indeed designed to form upon its expected twisting a helical shaped tetranuclear copper(II) cluster \([\text{Cu}_4(\text{L}_4)_2]^{-}\). Single-crystal X-ray diffraction demonstrates that the cluster has a double-strand helical structure where the copper(II) ions are in two complementary environments. A FM exchange interaction between the magnetic centres is demonstrated by magnetometry. The origin of this interaction is thoroughly studied by ab initio calculations.

The synthesis (details in SI) of the cluster is a three-step process: i) The grafting of a proline moiety onto 3-(methylchloride)-1-carboxaldehydephen-2-ol to yield 2-hydroxy-3-methyl-(S)-pyrrolidine-2-carboxylate-5-methylbenzaldehyde (H₂L₄); ii) the complexation of this tridentate chiral proligand to copper(II) ions; iii) taking advantage of the free aldehyde of \([\text{Cu}_4(\text{H}_2\text{O})_2]^{-}\), this complex is reacted with di(4-aminophenyl)methane in a 2:1 stoichiometry (Fig. 1) to yield the tetranuclear cluster \([\text{Cu}_4(\text{L}_4)_2]^{-}\).

According to single crystal X-ray diffraction, \([\text{Cu}_4(\text{L}_4)(\text{H}_2\text{O})_2]^{-}\) is chiral (Flack parameter equals to 0.05(2)) and has a mononuclear structure with a square-pyramidal (SP) copper \([\text{Cu}(\text{NO}_3)]^{-}\) centre. The three coordinating atoms of the tridentate ligand \(\text{L}_4^{-}\) are in the basal plane of the pyramid and the apical position is occupied by a water molecule located at 2.443 Å. This contrasts with the situation observed for cobalt(II) (Fig. S1). In this latter case, the preference of cobalt(II) for hexacoordinated environment leads to a 1D coordination polymer. The insolubility of this polymer prevented its use in the third step of the synthesis. The copper(II) derivative \([\text{Cu}_4(\text{L}_4)_2]^{-}\) obtained after this third step crystallizes in the non-centrosymmetric space group P2₁ (Flack parameter equals to 0.045(7)). The compound consists in phenoxy-bridged dicopper(II) units held together by two fully deprotonated \(\text{L}_4^{-}\) polytopic Schiff base ligands that are formed during the condensation reaction (Fig. 2). The separation distance between the two copper(II) dimers is \(\approx 11.9\) Å. The diphenylmethylene fragments (PPhCH₂PPh) are twisted yielding a metalhelicate.
indicates that chiral metalhelicates are present in solution, absorption bands related to 550 nm with negative similar shapes and are stable in time. The two signals at 660 nm centre, one obtains two six copper(II) ions and, from four five coordinated in a bis(tridentate) manner by the proline/phenoxo moieties of two L₄⁺ ligands: two nitrogen and two oxygen atoms from the carboxylate groups of the L-proline fragments and two oxygen atoms from the phenolate groups located further away from the copper(II) centres (Cu₂ and Cu₄ in Fig. 2) are coordinated in a bis(bidentate) manner: two oxygen atoms from the phenolate groups and two nitrogen ones from the imine functions. The corresponding (N₂O₄) environment can be seen as a flattened tetrahedron (Td), the angles between the imine functions.

The generation of such helical structure is typical of Schiff-base complexes containing a diphenylmethane fragment. Moreover, guided by the enantiopurity of the proline, only one type of helices is present in the crystals. The environment of the metal ions is deeply modified during the last step of the synthesis. The outer copper(II) centres (Cu₂ and Cu₄ in Fig. 2) are coordinated in a bis(tridentate) manner by the proline/phenoxo moieties of two L₄⁺ ligands: two nitrogen and two oxygen atoms from the carboxylate groups of the L-proline fragments and two oxygen atoms from the phenolate groups located further away from the copper(II) centres (dCu₂-O = 2.384 Å; dCu₄-O = 2.441 Å). The corresponding (N₂O₄) distorted octahedral (Oh) environment has a symmetry close to Cᵥ. In contrast, the inner copper(II) centres (Cu₁ and Cu₃ in Fig. 2) are coordinated in a bis(bidentate) manner: two oxygen atoms from the phenolate groups and two nitrogen ones from the imine functions. The corresponding (N₂O₄) environment can be seen as a flattened tetrahedron (Td), the angles between the N-Cu-N and O-Cu-O planes being 42.71(2)° and 47.96(2)°. From the structure resolution, it appears that the condensation reaction deeply influences the coordination of the copper(II) ions: the newly formed bidentate part of L₄⁺ have replaced the two coordinated water molecules initially present around copper(II) ions and, from four five-coordinated copper(II) centres, one obtains two six- and two four-coordinated metal centres. Most importantly, the expected twist of the L₄⁺ ligands leads to an original tetrahedral environment for Cu₁ and Cu₃.

The Circular Dichroism (CD) spectra of H₂L₄, [CuL₂(H₂O)₂] and [Cu₂L₄] recorded in solution confirm the stereoregularity of the whole synthetic process. The CD spectra of [Cu₂L₄] in CHCl₃ and methanol (see Fig. S12) have similar shapes and are stable in time. The two signals at 660 and 550 nm with negative Cotton effect can be associated to absorption bands related to d-d transitions for tetrahedral and octahedral copper(II) centres, respectively. This evidence indicates that chiral metalhelicates are present in solution, mainly in one of its enantiomeric form. The molar magnetic susceptibility χₑ of tetranuclear copper(II) cluster [Cu₂L₄] was investigated in the 2-300K temperature range. The temperature dependence of the χₑ product is shown in Fig. 3. At room temperature, the χₑ product is equal to 1.84 cm³ mol⁻¹ K⁻¹ and increases upon cooling to reach 2.28 cm³ mol⁻¹ K⁻¹ at 7K. Below 7K, the χₑ value decreases down to 2.02 cm³ mol⁻¹ K⁻¹ at 2K. At room temperature, the χₑ product is higher than the theoretically expected for four isolated $S = 1/2$ with $g = 2$ (1.5 cm³ mol⁻¹ K⁻¹). Associated with the progressive increase of χₑ when the temperature is lowered, this is indicative of dominant FM interactions between the metal centres in [Cu₂L₄]. The decrease of the χₑ product at low temperature is associated to weaker AFM interactions also present in the system. Based on the X-ray analysis, the tetranuclear core in [Cu₂L₄] can be separated in two magnetically independent dicopper(II) systems. Moreover, given the similarities of the coordination environments in both ends of [Cu₂L₄], the two dinuclear units are assumed to display the same magnetic behaviour. Accordingly, the magnetic properties of [Cu₂L₄] were analysed with the isotropic spin-Hamiltonian $H = -2J(S_S + S_T)$ where $J$ is the exchange interaction parameter between two neighbouring copper(II) ions and $S_S$, $S_T$ are the spins operators associated with $S_S$, $S_T$ is $\frac{1}{2}$ spin value. The model has been complemented with an additional parameter $zJ'$ to take into account the AFM interaction between the dinuclear units. The best set of parameters obtained using this model is $J = +7.7 ± 0.4$ cm⁻¹; $g = 2.200 ± 0.005$, $zJ' = -0.10 ± 0.01$ cm⁻¹. The presence of FM exchange interactions is supported by magneto-transport data (see inset in Fig. S4) which was analysed as a sum of two Brillouin functions with $S = 1$ and $g = 2.185 ± 0.015$. In both cases, the $g$-factor is the mean value for the four Cu²⁺ centres. Finding a FM exchange interaction between two copper(II) centres is rather uncommon in the literature. Based on Kahn’s model, this must be related to the different coordination environments of the two copper(II) centres that leads to the orthogonality of the MOs.

Table 1. Calculated exchange coupling constant values (in cm⁻¹) and amplitudes of the leading contributions in the triplet wavefunctions of subunit A. The subscripts Oh and Td refer to the copper(II) centre implied in the LMCTs.

| $J$ | $\psi_{CAS}$ | $|LMCT_{(Td)}|\geq$ | $|LMCT_{(Td)}|\geq$ | $|LMCT_{(Oh)}|\leq$ |
|---|---|---|---|---|
| CAS-Cl | +1.4 | 1.0 | 0.0 | 0.0 |
| CAS+S | +2.5 | =1.0 | ... | ... |
| CAS+DDCI | +6.7 | 0.954 | 0.036 | 0.022 | 0.046 |
The magnetism of \([\text{Cu}_2(\text{L}_4)\text{]}\)] can be described as two nearly independent dicopper(II) units referred to as A and B. DDCl calculations on pairs A and B confirm the FM character of the exchange interaction within the dinuclear units (\(J = 6.7\) and 8.1 cm\(^{-1}\) for A and B, respectively). The mean computed value (7.4 cm\(^{-1}\)) is in excellent agreement with the fitted J value (7.7 cm\(^{-1}\), see above). Interestingly, the calculations are able to distinguish two exchange interaction parameters in A and B despite the similar metrics in both subunits.

Moreover, these calculations allow us to investigate the different contributions to the singlet-triplet energy-difference; the ligand imposes electronic configurations \(t_{2g} e_{g}\) and \(e_{g} t_{2g}\) on the Oh and flattened Td sites, respectively. Based on Kahn’s model, the ligand is thus expected to favour FM behaviour by driving the orthogonality of the magnetic orbitals. Indeed, the singly-occupied \(e_g d_{z^2}\) - and \(t_{2g} d_{xy}\)-type orbitals (localized on the Oh and Td moieties, respectively) are quasi-perpendicular (see Fig. 4). This analysis is consistent with the positive J value obtained at the CAS-CI level for dimer A (+1.4 cm\(^{-1}\) in Table 1).

However, this scenario can be deeply modified as soon as electron correlation effects (charge distributions and spin polarization) are included. In particular, the contributions of the so-called ionic forms (e.g. \(t_{2g} e_{g}^2 e_{g}^{-2} t_{2g}^{-5}\)) entering the singlet CAS-CI wavefunction are likely to be enhanced by the CAS+S dynamical response. In contrast, the sign of the spin polarization contribution is difficult to predict. Such contributions are known to be dominant for bridging ligands (LMCT(Td) entry in Table 1). Spin polarization slightly stabilizes the triplet state over the singlet. Interestingly, the enhancement of FM is more pronounced at the DDCl level (+6.7 cm\(^{-1}\)): from Table 1, the LMCT forms which are almost absent at the CAS+S level become important and their stabilization in the triplet state give rise to a complementary FM contribution.

It thus appears that \textit{ab initio} calculations not only reproduce quantitatively the FM exchange interaction parameter found experimentally in the dicopper(II) units but dig out more complex exchange mechanisms. This latter result underlines that a valence-only vision of exchange interaction is not sufficient to conclude on the origin of FM behaviour for medium-range exchange interaction parameter.

In summary, following a three-step synthesis, a new chiral tetranuclear helical copper cluster [\(\text{Cu}_2(\text{L}_4)\)] has been obtained. Upon the expected twisting of the chiral polytopic Schiff-base ligand \(\text{L}_4\), the copper(II) ions seat in complementary distorted octahedral and tetrahedral coordination sites. This unique Oh-Td pair favours a FM exchange interaction (\(J_{\text{exp}} = +7.7\) cm\(^{-1}\)) between the copper(II) ions. Wavefunction-based calculations reproduce quantitatively the experimental magnetic behaviour and indicate that the FM character is due not only to the orthogonality of the magnetic orbitals in such architecture but also to the presence of spin polarization effects and the stabilization of the LMCT forms. The synthetic strategy presented herein extends the scope of existing routes for high-spin clusters generation. The twisting ability of Schiff-base complexes containing a diphenylmethane fragment calls for the insertion of other metal ions in such metalhelicates. Moreover, the controlled chirality of these objects combined with their magnetic properties are an open door towards the observation of magneto-chiral effects given that ions with high spin-orbit coupling are introduced in the molecular architecture.

Methods. The synthetic procedures of synthesis are reported in the SI. The FTIR spectra were obtained using the Nicolet Fourier Transform Infra-Red (FTIR) spectrophotometer IS 50 IR. The FTIR spectra were recorded in KBr pellets with 32 scans per spectrum at a resolution of 4 cm\(^{-1}\). UV-vis absorption spectra were recorded on JASCO V770 spectrophotometer, while CD spectra on JASCO J-500 spectrometer. The spectra were measured at room temperature in a cuvette with 10 mm path length. The \(\text{H}\) and \(\text{D}\) NMR spectra were recorded on Bruker Advance II spectrometers at 300 \(\text{MHz}\) and 75.4 \(\text{MHz}\), respectively. The \(\text{H}\) and \(\text{D}\) chemical shifts were referred to the residual signals from the solvent as reference. Deuterated solvent DMso-\(d_6\) was bought from Sigma-Aldrich. Variable-temperature (2.0–300 K) direct current (dc) and magnetic susceptibility and magnetization measurements were carried out on slightly crushed polycrystalline sample with a Quantum Design SQUID magnetometer. The dc susceptibility was measured using an applied field of 0.1 T. The magnetic susceptibility data were corrected for the diamagnetism of the constituent atoms and the sample holder contribution. Single-crystal XRD studies of \([\text{Cu}_2(\text{H}_2\text{O})]_2\), \([\text{Cu}_2(\text{L}_4)]\), and \([\text{Cu}_2(\text{L}_4)]\) were performed with a Gemini diffractometer and the related analysis software. Absorption corrections based on the crystal faces (analytical, \([\text{Cu}_2(\text{L}_4)]\), and \([\text{Cu}_2(\text{L}_4)]\)) and semi-empirical (multi-scan, H$_2$L$_4$, Cu$_2$(H$_2$O)$_2$) were applied to the data set. Structures were solved by direct methods with the SIR97 program combined with Fourier difference syntheses and refined against F with the CRYSTALS program. All atomic displacement parameters for non-hydrogen atoms were refined with anisotropic terms. The hydrogen atoms were located theoretically on the basis of the correction of the supporting atom and refined by using a riding model. All details are summarized in Table S1.
