# Is phylogeography helpful for invasive species risk assessment? The case study of the bark beetle genus *Dendroctonus*

Martin Godefroid, Jean-Yves Rasplus and Jean-Pierre Rossi

M. Godefroid ([martin.godefroid@gmail.com](mailto:martin.godefroid@gmail.com)), J.-Y. Rasplus and J.-P. Rossi, INRA, UMR1062 CBGP (Centre de Biologie pour la Gestion des Populations) – Avenue du Campus Agropolis, Montpellier sur Lez, CS30016, FR-34988, France.

Despite evidence that conspecific lineages may display different climatic tolerances, most invasion risk assessment tools are calibrated without considering phylogeographic information. This study aims to investigate the existence of intraspecific niche divergence within a group of insect pests and to explore how the inclusion of phylogeographic information into species distribution models may alter the estimation of the potential distribution of a species. We studied North American bark beetles belonging to the genus *Dendroctonus*, a group of pests of conifers that are listed as quarantine species in numerous countries. Most *Dendroctonus* species exhibit strong genetic divergence that appears to be geographically structured and shaped by historical events and biotic factors. We modeled all lineage distributions within five species, using MaxEnt and Boosted Regression Trees, and compared the results with the models fitted at the species scale. Multivariate analysis and niche similarity and equivalency tests were additionally performed to investigate the existence and magnitude of climatic niche divergence between conspecific lineages. We also tested the ability of lineage-based models to predict the region invaded by *D. valens* in China. Conspecific lineages showed a climatic niche more similar than expected by chance, but displayed different climatic envelopes in their native range and, consequently, different estimates of potential distributions. We also observed that classical models calibrated using the entire range of the species could potentially under- or overestimate the potential range of the species when compared to a global prediction built by aggregating lineage-based projections. This study showed that the invasive phylogeographic lineage of *D. valens* has invaded regions characterized by climatic conditions highly similar to those encountered in its native range suggesting that preadaptations to environment might have played a role in this invasion. This study highlights how our perception of the invasion risk of pests may be altered when integrating phylogeographic information.

Most species exhibit phylogeographic structure in the form of discrete genetic units within their distribution range. Considerable attention has been paid to describe these patterns and to identify the underlying processes that may involve historical events, dispersal limits, geographic barriers, biotic interactions or ecological niche evolution (Avisé et al. 1987, Marske et al. 2013). Because they share a recent common ancestor, conspecific lineages often display similar climatic tolerances (Peterson et al. 1999, Martínez-Meyer et al. 2004, Kozak and Wiens 2006, Peterson 2011, Araújo et al. 2013). However, in some cases, the observed intraspecific genetic differentiation is associated to adaptations to local environments with subsequent divergence of the fundamental niche sensu Hutchinson (1957) (Rehfeldt et al. 1999, Michalak et al. 2001, Grout and Stoltz 2007). Understanding how phylogeographic structures correspond to different climatic tolerances has consequently received increasing attention especially in the context of invasion biology and climate change (Lachmuth et al. 2010, Pearman et al. 2010, Thompson et al. 2011, Rey et al. 2012, Schulte et al. 2012, D'Amen et al. 2013, Guisan et al. 2014, Godefroid et al. 2015, Strubbe et al. 2015).

When intraspecific lineages differ in terms of climatic tolerances, their invasion capacity in a given habitat may differ. Consequently, these lineages address contrasted biosecurity threats to areas they may invade hence deserving different management plans. As underlined by Peterson and Holt (2003), integrating phylogeographic information into pest risk assessment allows to limit the overestimation of invasion risk when only a population subset finds suitable conditions in a considered area. For example, Rey et al. (2012) showed how populations of the ant *Wasmannia auropunctata* located at the southern limit of its native area, were pre-adapted to the cold conditions found in an invaded area (Israel). Similarly, Lachmuth et al. (2010) showed that different intraspecific units within the South African ragwort *Senecio inaequidens* displayed contrasted invasiveness in northern Europe because they exhibit different climatic preferences. However, relatively little attention has been paid to explore how considering within-species variation of the realized niche sensu Hutchinson (1957) could valuably improve risk assessment of invasive species (Peterson and Holt 2003) although more information is available regarding conservation planning (Rissler et al. 2006, Pearman et al. 2010,

Benito Garzón et al. 2011, D'Amen et al. 2013, Fitzpatrick and Keller 2014).

Estimating the full extent of environmental damages caused by invasive species has proved to be a difficult task but most estimates indicate that the costs associated to prevention and control must be extremely high (Pimentel et al. 2001, 2005). A current debate concerns the better cost-effectiveness of investments in prevention over investments in control although the social consequences of such a strategy may result in a greater probability of future invasions and lower social welfare (Finnoff et al. 2007). Prevention largely relies on pest risk analysis (PRA; Devorshak 2012) that consider various aspects of the biology and ecology of species and include species distribution models (SDMs) as tools to assess their potential geographical distributions. In PRA, SDMs are generally based on climate data and are usually fitted with no consideration of the phylogeographic structure of the considered species. Consequently, most predictions assume that species are homogeneous entities and that intraspecific variation in climatic tolerances is weak. However, contrasted environmental tolerances have been shown either between populations inside species native range (Grout and Stoltz 2007, Rey et al. 2012) or between native and invasive populations (Broennimann et al. 2007, Hill et al. 2013) suggesting that climatic niche preferences may evolve over reduced evolutionary timescales i.e. those involved in biological invasions. Nevertheless, this point is currently a matter of debate (Peterson 2011, Petitpierre et al. 2012, Strubbe et al. 2013) since discrepancies in the realized niche may be explained by true changes in the fundamental niche as well as changes in the patterns of fundamental niche occupancy due to biotic interactions or dispersal constraints (Araújo and Peterson 2012).

The present study considers the impact of accounting for phylogeographic structures in the outputs of SDMs in the framework of PRA. How our estimate of the invasion risk associated to a species is changed when considering the realized climatic niche of the phylogeographic lineages separately rather than the species as a whole? To do so, we retained the bark beetle genus *Dendroctonus* as our biological model (see Methods). It comprises several species that are serious pests of conifer forests (Wood 1982, Six and Bracewell 2015) and many species are listed as quarantine species in numerous temperate countries of the world including European Union. We combined phylogeographic data and SDMs to specifically address the following questions: 1) do conspecific lineages of several *Dendroctonus* species exhibit differences in their realized climatic niche? 2) To which extent accounting for species phylogeography in SDM alter our perception of the risk of biological invasion? 3) How the realized climatic niche of *D. valens* has been conserved during its invasion of Chinese forests? Which role has played the phylogeographic structure of *D. valens* during its invasion of China?

## Methods

The genus *Dendroctonus* (Coleoptera: Curculionidae: Scolytinae) comprises 19 species, 17 of which are native to Central and North America, where they are considered

important pests of conifers (*Pinus*, *Picea*, *Pseudotsuga* and *Larix*; Wood 1982, Six and Bracewell 2015). Particular attention has been paid to some of these bark beetles because of the severe damage they cause in their native range as well as in recently colonized areas. The mountain pine beetle *D. ponderosae* produces severe outbreaks in the northern part of its range, devastating million hectares of forest in British Columbia and Alberta (Canada) and constitutes a serious threat to the boreal forests (Cullingham et al. 2011). The red turpentine beetle *D. valens* was recently introduced in China, causing high mortality to a major reforestation species, *Pinus tabulaeformis* (Yan et al. 2005, Sun et al. 2013). Given their capacity to kill trees, *Dendroctonus* species are frequently listed as quarantine species in numerous countries (i.e. Australia, China, European Union, New Zealand, etc.). For these species, intraspecific genetic divergence, shaped by a combination of past geologic events and glacial–interglacial cycles during the Pleistocene (Hewitt 1996), exhibits a marked geographical structure at the continental scale (Kelley et al. 1999, Maroja et al. 2007, Mock et al. 2007, Anducho-reyes et al. 2008, Cai et al. 2008, Ruiz et al. 2010, Sánchez-Sánchez et al. 2012). Consequently, the genus *Dendroctonus* is an ideal model to assess how the incorporation of the phylogeographic structure of pests affects risk assessment. In addition, the origin of the invasion of *D. valens* has been elucidated (Cognato et al. 2005, Cai et al. 2008) and consequently provides an interesting case to investigate the similarity of climates in invaded and native regions.

## Species and occurrence data

We investigated the realized climatic niche of intraspecific lineages within five species of *Dendroctonus* that exhibited strong phylogeographic structures and for which a large number of occurrence records were available (Table 1, Supplementary material Appendix 1, Fig. A1). These species included the red turpentine beetle *Dendroctonus valens*, the mountain pine beetle *D. ponderosae*, the spruce beetle *D. rufipennis*, the Douglas fir beetle *D. pseudotsugae* and the western pine beetle *D. brevicomis*. Conspecific lineages of *D. valens* and *D. brevicomis* exhibit the strongest levels of genetic differentiation, similar to that observed between recognized *Dendroctonus* species, and thus should probably be considered a species complexes (Kelley et al. 1999, Cai et al. 2008). Low levels of genetic differentiation occur among conspecific lineages of *D. rufipennis* and *D. pseudotsugae*, suggesting a more recent divergence within species (i.e. estimated divergence times ranging from 1 to 2 million yr ago; Maroja et al. 2007, Ruiz et al. 2010). Finally, the intraspecific genetic divergence within *D. ponderosae* appears relatively low, suggesting that these lineages have recently diverged (Mock et al. 2007, Cullingham et al. 2012). We collected occurrence data from the literature (Wood 1982) and online databases (e.g. GBIF <<http://data.gbif.org>> or the T. H. Atkinson personal website on bark and ambrosia beetles <<http://www.barkbeetles.info/>>). We georeferenced using Google Earth most of the occurrence records obtained in literature (records with too 'imprecise' locality name were removed from the dataset to avoid using erroneously georeferenced records in the study). We also checked

Table 1. Bark beetles belonging to the *Dendroctonus* genus selected in this study to address intraspecific niche divergence at a continent-scale. We name the lineages by using their taxonomic names (in case of recognized subspecies), their geographic ranges or their main host name. We indicate the number of occurrences used for species distribution modeling as well as the references of the published phylogeographic studies.

with Google Earth the geographic coordinates of already georeferenced records (obviously erroneous records were also removed from our dataset). Each occurrence was assigned to a particular lineage, depending on the published phylogeography (Table 1, Supplementary material Appendix 1, Fig. A1). Globally, phylogeographic structures of most species were well resolved and most lineages occurred in relatively well-delimited geographic areas. This allowed us to confidently assign occurrences to lineages. *Dendroctonus ponderosae* exhibited a clear isolation by distance around the Great Basin desert (Mock et al. 2007) and an on-going process of reproductive isolation between western (California, Oregon) and eastern (Utah, Idaho) populations, on both sides of this desert (Bracewell et al. 2011). We used this intraspecific split to assign occurrences to lineages (Supplementary material Appendix 1, Fig. A1b). Differentiation between these two entities is confirmed by the fact that *D. ponderosae* was originally described as two entities by Hopkins (1909) based on morphology: *D. monticolae* corresponding to eastern populations and *D. ponderosae* including western and northern populations (Canada). These two entities were later synonymized to *D. ponderosae* by Wood (1963).

The distributions of two phylogeographic lineages of *D. valens* overlap in Mexico (Cai et al. 2008). Consequently, several occurrences were assigned to multiple lineages. We assigned all occurrences of *D. valens* from Mexico and Central America to the southern lineage, whereas we assigned occurrences from the Sierra Madre Occidental (SMOC, Mexico) and from all western America to the western lineage (Supplementary material Appendix 1, Fig A1a). We excluded two records of *D. valens* (Fort Chipewyan, Alberta, Canada and Fort Smith, Northwest Territories, Canada) found in Wood (1982) because they were sampled far away from the sampling area investigated by Cai et al. (2008). Similarly,

we did not include *D. rufipennis* specimens feeding on *Picea sitchensis* along the western coast of America, since this area was not sampled by Maroja et al. (2007).

## Bioclimatic data

Intraspecific climatic envelope divergence was investigated using a set of 19 bioclimatic variables available from the Worldclim database (Hijmans et al. 2005) at a resolution of 2.5 minutes (Table 2). We define here the climatic envelope of a lineage as the multidimensional object defined

Table 2. Bioclimatic variables used to investigate the climatic niche of *Dendroctonus* species and lineages.

Bioclimatic variables	Symbol
Annual mean temperature	BIO1
Mean diurnal range	BIO2
Isothermality	BIO3
Temperature seasonality	BIO4
Maximum temperature of warmest month	BIO5
Minimum temperature of coldest month	BIO6
Temperature annual range	BIO7
Mean temperature of wettest quarter	BIO8
Mean temperature of driest quarter	BIO9
Mean temperature of warmest quarter	BIO10
Mean temperature of coldest quarter	BIO11
Annual precipitation	BIO12
Precipitation of wettest month	BIO13
Precipitation of driest month	BIO14
Precipitation seasonality	BIO15
Precipitation of wettest quarter	BIO16
Precipitation of driest quarter	BIO17
Precipitation of warmest quarter	BIO18
Precipitation of coldest quarter	BIO19

by the presence of this lineage in the climatic space. These data were derived from monthly temperatures and annual rainfall trends between 1950–2000. All variables were considered when performing multivariate analysis (see below), whereas a reduced climatic dataset was used to fit SDMs. The choice of environmental descriptors is known to strongly affect SDMs performance when extrapolating in space or time (Peterson and Nakazawa 2008, Rödder and Lötters 2009). The best environmental dataset to assess invasion risk includes proximal, ecologically relevant and non-highly correlated variables (Elith and Leathwick 2009, Jiménez-Valverde et al. 2011, Dormann et al. 2013). Consequently, we fitted our models using temperature and rainfall extremes that are likely to convey conditions of physiological stress for bark beetles (Wood 1982, Ungerer et al. 1999). We avoided using highly correlated climatic descriptors (Pearson's correlation index  $< 0.7$ ; Dormann et al. 2013). Despite evidence suggesting that temperature seasonality is critical for some mass-attacking *Dendroctonus* species (Logan and Bentz 1999), we did not include these descriptors (e.g. bio2, bio3, bio4, and bio7 in Table 2) in models because they are highly correlated with temperature extremes in native and projected areas. Following Jiménez-Valverde et al. (2011), we adopted a conservative approach consisting of avoiding the overparameterization of models that could reduce their transferability to other spaces and increase omission error. Finally, a set of four climatic descriptors was used to fit SDMs, including the maximum temperature of the warmest quarter ('heat stress' – bio10), the minimum temperature of the coldest month ('cold stress' – bio6), the precipitation of the wettest quarter ('moisture stress' – bio16), and the precipitation of the driest quarter ('dry stress' – bio17).

### Multivariate analysis

We investigated climatic envelope divergence between conspecific lineages using multivariate analysis (Rivera et al. 2011). Such approaches depict the full variation of climatic variables and have none of the a priori assumptions inherent to modeling techniques (Legendre and Legendre 1998). For all species, we performed a principal component analysis followed by between-classes analysis (Dolédec and Chessel 1987) to compare climatic envelopes among lineages. Principal component analysis (PCA) is an ordination technique that maximizes the variance between individuals, whereas the between-classes analysis is a type of constrained PCA that maximizes both inter-individual and between-classes (here, the lineages) variance (Rossi and Blanchart 2005). We conducted multivariate analysis on 19 bioclimatic descriptors extracted from the WorldClim database for each occurrence. The climatic envelope associated to the invading population of *D. valens* (31 occurrences in China) was included in the multivariate analysis. We tested the significance of the between-classes structure using Monte Carlo permutation tests with 999 replications (Manly 2006). These multivariate analyses were computed using the *ade4* package (Dray and Dufour 2007) in R (R Development Core Team).

### Species distribution modeling

We modeled the distributions of species and lineages using an approach based on the maximum entropy method (MaxEnt with default settings; Phillips et al. 2006) and a machine-learning approach based on the boosted regressions trees (BRT; Elith et al. 2008). These modeling techniques were selected because they are ranked among the best-performing SDMs methods (Elith et al. 2006, Wisz et al. 2008). Both methods compare the climatic envelope experienced by a species with the climatic conditions found in locations where the species was undetected (i.e. pseudo-absences or background data). The positioning of background data is an important issue as it may significantly alter the predictions of models and must be set in accordance with the scale and the purpose of the study (VanDerWal et al. 2009, Anderson and Raza 2010). Since our study aims to assess invasion risk at the continent scale, we used wide background areas to enhance the transferability of models in other spaces (Elith et al. 2010). Both western part of North America and Central America were considered as background areas when modeling the distributions of *D. brevicornis*, *D. pseudotsugae*, *D. ponderosae* and the southern and western lineages of *D. valens*. The eastern part of North America was considered as a background area when modeling the distribution of the eastern lineage of *D. valens*. Finally, both North America and Central America were considered as background areas when modeling the distribution of *D. rufipennis* lineages. For MaxEnt, we randomly generated 10 000 background points, excluding the sites where the species was detected (Phillips et al. 2006). For each BRT model, we generated a number of pseudo-absences similar to the number of occurrences used for model calibration in the same background areas, as previously described (Barbet-Massin et al. 2012).

For each lineage, we independently fitted 10 models using both algorithms (called lineage-based models), using 10 different training datasets constituted by random subsets of 80% of the relevant occurrences and pseudo-absences. The remaining 20% of data were used for model evaluation (see below). We performed ten replicates to reduce uncertainty of SDMs projections resulting from the random partitioning of occurrences into calibration and evaluation datasets (Phillips et al. 2006). Subsequently, we pooled all occurrences from conspecific lineages to calibrate classical species models ('species-based models'). Similarly, each algorithm was run 10 times, using the same ratio of training/evaluation data. In each case, we constructed an additional prediction map by calculating the mean climatic suitability index displayed by the 10 models, which corresponded to the same species lineage. All climatic suitability maps were converted into binary maps of presence/absence on the basis of a single threshold. We used the lowest presence threshold (LPT; Pearson et al. 2007), a particular case of the minimum required sensitivity method (Pearson et al. 2004), that is well-adapted for SDMs designed to assess the risk of biological invasion for which omission errors have to be avoided (Freeman and Moisen 2008, Webber et al. 2011). A pixel was considered as climatically suitable for one lineage if more than 50% of the lineage-based models predicted this pixel as suitable (i.e. at least six out of 10 models). Finally, for

each species, an aggregated binary prediction was obtained by assigning a presence to each pixel that was predicted as climatically suitable for at least one lineage.

The predictive performance of the models was evaluated using the remaining 20% of available occurrences and pseudo-absences/background points. We calculated the area under the receiver-operator curve (AUC), which is a widely used threshold-independent evaluation measure (Fielding and Bell 1997). Since the use of AUC in species distribution modeling is debated (Lobo et al. 2010, Jiménez-Valverde 2012), we additionally calculated the continuous Boyce index, which is a reliable presence-only evaluation measure that is relatively insensitive to species prevalence (Hirzel et al. 2006). We computed multivariate environmental similarity surface (MESS) maps that describe the similarity in climatic space between the projected and the fitted areas (Elith et al. 2011). Models and computations were performed using the 'dismo' (Hijmans et al. 2013) and 'gbm' (Ridgeway and Ridgeway 2004) packages in R.

### Niche similarity and equivalency tests

In addition to multivariate analysis, we quantified the degree of niche similarity between conspecific lineages by implementing the niche comparison framework developed by Broennimann et al. (2012). We applied a smoother kernel to the densities of species occurrences in bioclimatic raster maps and subsequently calculated the metrics of niche overlap and tested niche conservatism hypotheses. We calculated Schoener's D index to measure the overlap of the SDMs projections, which varies from 0 for non-overlapping model predictions to 1 for complete overlap (Schoener 1968). Niche equivalency and similarity hypotheses were then tested using the algorithm MaxEnt.

The equivalency test aims to investigate whether the niches occupied by two lineages are equivalent. In this randomization test, we pooled and randomly split lineages occurrences in two datasets (maintaining the number of occurrences as in the original datasets) and measured niche overlap D value with these datasets (this procedure was repeated 100 times). The observed D value was then compared against the distribution of the 100 simulated D values. If the observed D value fell outside the distribution of the simulated D values, niche equivalency hypothesis was rejected (Broennimann et al. 2012). The niche similarity test investigates whether the niches occupied by two lineages are more similar than expected by chance. For this randomization test, the observed density of occurrences relative to one lineage was shifted within the geographic range available for this lineage. Then, we calculated the overlap D value between this simulated niche and the niche occupied by the other lineage (this procedure was repeated 100 times). If the observed D value is greater than 95% of the simulated D values, niches of lineages are considered as more similar than expected by chance (Broennimann et al. 2012). In these tests, we did not use the previously described background areas to generate pseudo-absences because investigating niche divergence among taxonomic entities require avoiding as much as possible sampling absences in a region where the taxa are not present because of dispersal limitations or biogeographic

events rather than for climatic unsuitability (Barve et al. 2011, Broennimann et al. 2012). In previous lineage-based SDMs, we mainly aimed to highlight the relative contributions of conspecific lineages in the potential distribution of pests and thus generated pseudo-absences in regions occupied by other conspecific lineages when modeling the distribution of a lineage. Here, selecting the background regions previously used in lineage-based models could lead to an artefactual inflation of niche divergence signal. For these analyses, we generated pseudo-absences in smallest background areas considering potential geographic barriers and past biogeographic events (Supplementary material Appendix 2).

## Results

### Realized niches differ among conspecific lineages

Graphical displays of PCAs (correlation circles and score plots) and the percentages of total inertia explained by the factorial axes are given in Fig. 1, 2 and Supplementary material Appendix 2, Fig. A3a–c. According to the Monte Carlo permutation tests, there was a significant difference between conspecific lineages ( $p < 0.001$ ). The PCAs discriminated lineages of *D. valens*, *D. pseudotsugae*, *D. rufipennis* according to temperature-related variables such as minimum temperatures (bio6, bio11) and temperature seasonality (bio2, bio3, bio4, see Fig. 1, and Supplementary material Appendix 2, Fig. A3a, b). The envelope of the invading populations of *D. valens* in China was closer to the envelopes of the north-eastern and western lineages of *D. valens* than that of the southern lineage (Fig. 1). Between-class PCA applied to *D. brevicomis* dataset was significant and revealed that the mean temperatures of the wettest and the driest quarters (bio8, bio9), the precipitation of the wettest and the warmest quarters (bio16, bio18) and the precipitation of the coldest quarter (bio19) contributed to segregate the lineages. The mean temperature of the wettest and driest quarters (bio8, bio9), the annual temperature range (bio7) and the precipitation of the coldest quarter (bio19) separated conspecific lineages of *D. ponderosae*.

The formal tests of niche equivalency indicated significant realized niche differences among conspecific lineages in all *Dendroctonus* species (Supplementary material Appendix 2, Fig. A4). Interestingly, albeit different, the realized niches of lineages were estimated to be more similar than expected by chance in all species (niche similarity tests, Supplementary material Appendix 2, Fig. A4).

### Potential geographical distributions

All models yielded an AUC above 0.68. Most of models displayed a continuous Boyce index greater than 0, indicating that these models better predict the presences of the evaluation dataset than a random model (Supplementary material Appendix 2, Table A5). Only several BRT models calibrated for *D. pseudotsugae barragani* displayed a Boyce index less than 0, warranting caution when interpreting these models. This probably resulted from the limited number of occurrences available for this subspecies. The ten SDMs replicates

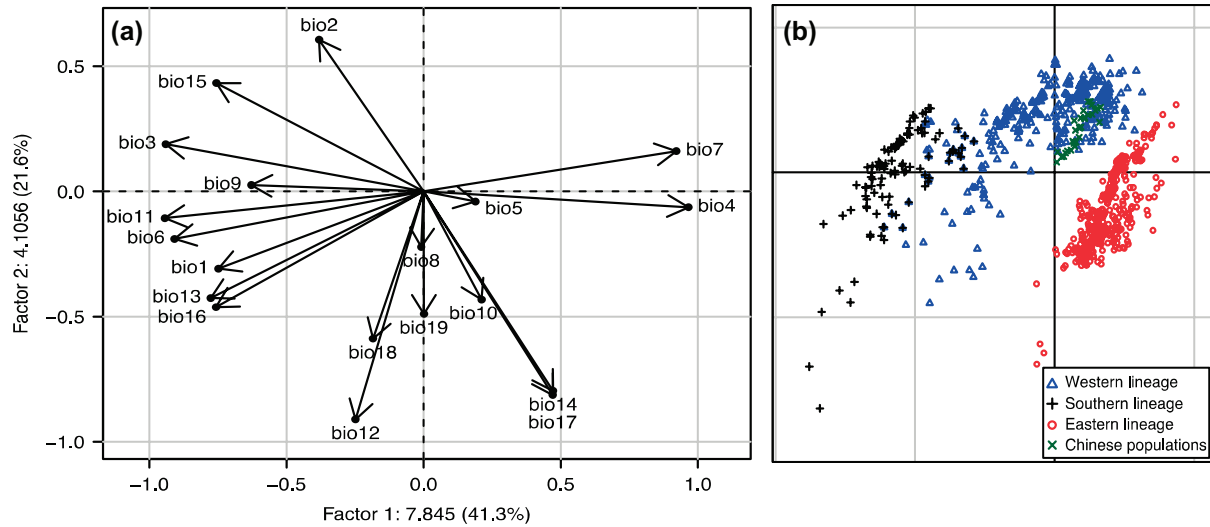

Figure 1. Principal components analysis of climatic data extracted from *Dendroctonus valens* occurrences from the Worldclim database (Hijmans et al. 2005; see Table 2 for symbol meanings). Circles of correlation (a) and factorial scores of records (b) are represented. Red circles, blue triangles and black crosses represent individuals assigned to the eastern, western and southern lineages, respectively. Green crosses represent invading populations.

displayed similar but non-equivalent binary predictions (Supplementary material Appendix 2, Fig. A6 and A7), highlighting the need to account for uncertainty associated with occurrence partitioning when transforming climatic suitability maps into binary presence/absence maps. Most of the projected area displayed positive MESS values, indicating a low level of climatic dissimilarity between the training climatic space and the projected area in Europe. Both modeling approaches showed similar trends and congruent projections (Fig. 4 and Supplementary material Appendix 2, Fig. A6 and A7) except for the subspecies *D. p. barragani* (Supplementary material Appendix 2, Fig. A6c and A7c).

Similar areas were predicted to be climatically suitable in Europe for *D. ponderosae*, *D. valens*, *D. pseudotsugae* and *D. brevicomis* (Fig. 3, 4, and Supplementary material Appendix 2, Fig. A6 and A7). As expected, the distributions of suitable

climatic conditions for *D. rufipennis* were predicted in colder areas of Eurasia at northern latitudes and in mountainous ranges (Fig. 3, and Supplementary material Appendix 2, Fig. A6c and A7c). Model predictions indicated that conspecific lineages differed in the potential area that was predicted to be climatically suitable in Europe for all species (Fig. 3, 4, and Supplementary material Appendix 2, Fig. A3, A4 and A5). In some cases, differences among lineages were very slight (e.g. *D. brevicomis*). *Dendroctonus valens* and *D. pseudotsugae* showed the lowest level of overlap of predicted climatic suitability among conspecific lineages (Fig. 3 and 4). The entire invaded range of *D. valens* was not predicted as climatically suitable for the three lineages (Fig. 4). Most of the invaded range of *D. valens* (100% and 93.5% of the occurrences in China for MaxEnt and BRT models, respectively) was predicted to be climatically suitable by the models,

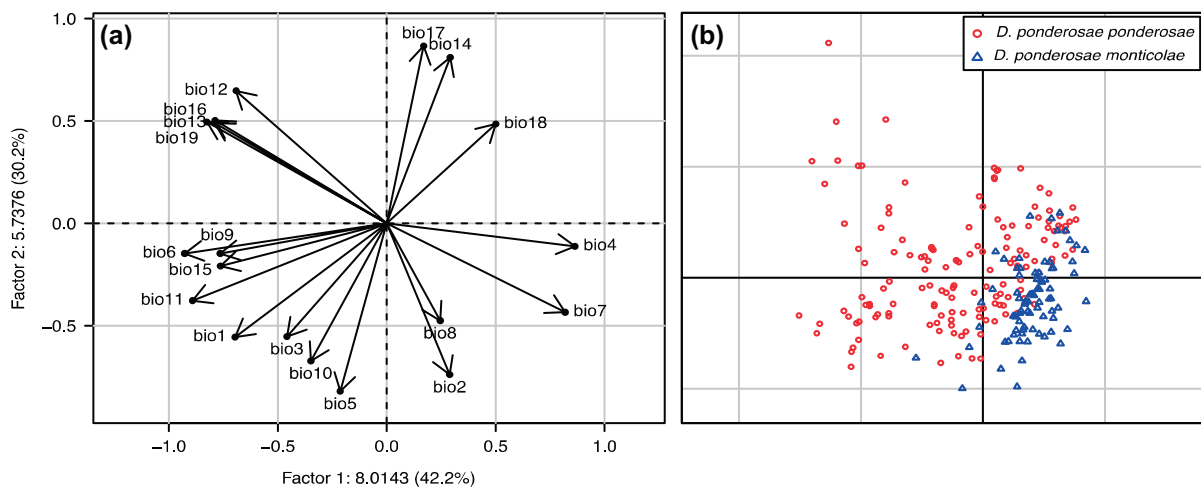

Figure 2. Principal components analysis of climatic data extracted from *Dendroctonus ponderosae* occurrences from the Worldclim database (Hijmans et al. 2005; see Table 2 for symbol meanings). Circles of correlation (a) and factorial scores of records (b) are represented. Red circles and blue triangles represent individuals assigned to the lineages *ponderosae* and *monticolae*, respectively.

Figure 3. Potential distribution of four *Dendroctonus* species (*D. brevicomis*, *D. pseudotsugae*, *D. rufipennis*, *D. ponderosae*) in Europe predicted by MaxEnt models. For each lineage, we calibrated 10 models. Map projections display the arithmetic mean of climatic suitability values predicted by the 10 replicates.

Figure 4. Potential distribution of *Dendroctonus valens* in Europe and in China predicted by the MaxEnt and BRT models. For each lineage, we calibrated 10 models with both algorithms. Binary maps of presence/absence were constructed using the lowest presence threshold (Pearson et al. 2007). The first four rows show map projections displaying the arithmetic mean of climatic suitability values predicted by the 10 replicates. The last two rows show maps indicating the number of models predicting a presence when implementing the threshold. Black dots represent occurrences in the invaded range.

corresponding to the eastern and western lineages (Fig. 4). On the contrary, most of the invaded range was predicted to be climatically unsuitable for the southern lineage (Fig. 4).

The distributions of suitable climate predicted by species-based models and aggregated binary projections did not perfectly overlap (Fig. 5, Table 3 and Supplementary material Appendix 2, Fig. A8). Differences varied in both magnitude (number of pixels that change status when comparing classical species-based predictions and aggregated binary projections) and direction (the number of pixels with predicted

presences in aggregated binary projections may be higher or lower than in classical species-based predictions), according to the species and the SDM approach (Table 3). Mismatches usually concerned a small percentage of the total area that was predicted as climatically suitable (Table 3). For example, for *D. pseudotsugae*, differences between aggregated binary projections and species-based models predictions did not exceed 16% of the geographic extent that was considered suitable by one approach (Table 3, and Supplementary material Appendix 2, Fig. A8). However, in a few cases, aggregated

Figure 5. Maps showing the change in worldwide suitable climatic conditions when aggregating the binary predictions of lineage-based models of *Dendroctonus rufipennis*. These predictions were compared with the classical species-based models. These projections were obtained by assigning a presence to each pixel that was predicted as being climatically suitable for at least one lineage. A pixel was considered as climatically suitable for one lineage if more than 50% of the lineage-based models (i.e. at least six out of 10 models) predicted this pixel as suitable when implementing the lowest presence threshold (Pearson et al. 2007).

binary models and species-based models showed differences in prediction up to 44% of the geographic extent that was considered suitable by one model (e.g. *D. rufipennis*; Table 3, Fig. 5).

## Discussion

### Realized niche of conspecific lineages: similar but not equivalent

This study shows that the realized niches of conspecific lineages of all *Dendroctonus* species were more similar than

expected by chance, without thereby being equivalent. Similarity means that species include lineages sharing similar realized niches at continent-scale (Warren et al. 2008, 2014). On the opposite, the absence of equivalency implies that although close, the realized niches are not identical and that lineages display significant differences with respect to the bioclimatic variables involved in species distribution modeling.

The phylogeographic structure of *Dendroctonus* species has been probably shaped by glaciations that fragmented their host-plant ranges and reduced gene flow between populations from different glacial refugia (Maroja et al. 2007). During their full-glacial isolation in refugia and subsequent

Table 3. Percentage of change (number of pixels) in worldwide suitable climatic conditions when aggregating binary predictions of lineage-based models. These predictions were compared with the classical species-based models. These projections were obtained by assigning a presence to each pixel that was predicted as climatically suitable for at least one lineage. A pixel was considered as climatically suitable for one lineage if more than 50% of the IS-models (i.e. at least six out of 10 models) predicted this pixel as suitable when implementing the lowest presence threshold (Pearson et al. 2007).

Species	Modeling approach			
	MaxEnt		BRT	
	% pixels gained	% pixels lost	% pixels gained	% pixels lost
<i>Dendroctonus brevicornis</i>	16.96	12.205	13.289	15.687
<i>Dendroctonus ponderosae</i>	4.526	23.233	3.963	27.863
<i>Dendroctonus rufipennis</i>	44.12	1.313	11.932	7.246
<i>Dendroctonus pseudotsugae</i>	6.818	1.225	5.727	2.526
<i>Dendroctonus valens</i>	24.373	9.49	18.375	6.885

post-glacial recolonization, phylogeographic lineages have mostly conserved the climatic tolerances of their ancestors. Nowadays, lineages occur in geographical areas differing with regards to bioclimatic descriptors leading to significant departure from niche equivalency sensu Broennimann et al. (2012). The observed differences in the realized climatic niches do not necessarily mean that the fundamental niches have diverged (Araújo and Peterson 2012). Various factors such as biotic interactions and spatial constraints, affect the occupancy of the fundamental niche that may lead to dissimilarities in realized niche. Biotic factors include interspecific relationships with host trees, competitors, parasitoids or fungal symbionts that are obligate for numerous bark beetles (Six 2012). Some recent results on vertebrates indicate that the thermal component of the fundamental niche is more conserved than usually deduced from SDMs (Araújo et al. 2013). If this is also true for bark beetles, it would imply that the observed differences of realized niches mostly convey patterns of niche occupation.

If niche differences correspond to discrepancies in fundamental niche between conspecific lineages, physiological adaptations to local conditions could be expected and this would be meaningful in terms of invasion risk. Since the intraspecific genetic structure is usually inferred from the use of neutral molecular markers, it is not directly informative concerning effective physiological adaptations to environment. There is increasing evidence that recently evolved populations within widespread species, including those from *Dendroctonus* and *Pinus*, show significant genetic-based adaptations to local conditions (Rehfeldt et al. 1999, Savolainen et al. 2007, Rey et al. 2012, Bentz et al. 2014, Janes et al. 2014). However, the potential contributions of these adaptations to invasion success remain to be explored using physiological and genomic approaches (Fitzpatrick and Keller 2014, Janes et al. 2014). Finally, because the invasiveness of phytophagous insects in one area results from numerous interdependent factors, e.g. life-history traits, propagule pressure and host specificity (Leung et al. 2012, Bacon et al. 2014), additional data concerning the ecological and biological specificities of lineages should also be integrated into invasion risk assessments.

### ***Dendroctonus* species as potential invasive organisms: the threat is real**

*Dendroctonus* species require particular attention from biosecurity agencies, since they are highly damaging pests responsible for huge economic losses in their native and invaded ranges (Yan et al. 2005). To our knowledge, this study is the first to predict the potential distribution in Europe of harmful *Dendroctonus* using SDMs. Our predictions strongly suggest that most of Europe offers climatic conditions suitable for the *Dendroctonus* species considered in this study. In addition, the large diversity of conifers occurring in Europe increases the probability that some *Dendroctonus* species may become invasive. However, climatic tolerances are not the only factors determining the invasive potential of these bark beetles. Most species also depend upon obligate fungal symbionts whose climatic tolerances might also influence their distributions (Addison et al. 2013). Propagule pres-

sure is another factor that determines the invasive potential of insects (Lockwood et al. 2005, Bacon et al. 2014). This is certainly true for some *Dendroctonus* (e.g. *D. ponderosae*) that mass-attack trees. The success of such species highly depends on the number of introduced propagules. However, propagule pressure required to invade a new region likely differ among species (e.g. *D. valens*, the only North American *Dendroctonus* that invaded a new area, is a solitary attacker that does not mass-attack trees).

Our results indicate that the threat is real when we consider the potential invasiveness of *Dendroctonus* species. The species-based bioclimatic models fitted to *D. valens* dataset accurately predicted the invaded range thus suggesting that the climatic niche of this species has been conserved during its invasion of China. This highlights the reliability of our projections to predict the invaded range by this species. Moreover, these results are in accordance with the general expectation of niche conservatism during invasions (Peterson 2011, Petitpierre et al. 2012, Strubbe et al. 2013).

### **Integrating intraspecific genetic structure in species distribution modeling**

Our results showed that integrating phylogeographical information into SDMs potentially alters the classical species-based invasion risk assessment. We observed that binary predictions constructed by aggregating the lineage-based model predictions could differ from binary species-based predictions. The directions and the magnitude of these changes appeared to be dependent both on the species and the modeling approaches. Similar trends have been observed when integrating the phylogeographic structure of species into SDMs to design conservation plans (Pearman et al. 2010, D'Amen et al. 2013). These surveys suggested that species-based models tend to smooth out the climatic response curves specific to the different lineages. Although differences between predictions were relatively slight in most cases, such features could have practical importance for plant biosecurity agencies when designing costly quarantine measures and prevention plans against invasive species.

Here we report that several species show strong intraspecific divergence in the climatic envelope. Indeed, latitudinally-separated lineages (e.g. *D. valens*, *D. pseudotsugae*, *D. rufipennis*) occurred in areas that strongly differed in winter temperatures and seasonal structure of climate, e.g. the mean temperature of the coldest month experienced by *D. pseudotsugae* ranged from 5.9 to  $-4.9^{\circ}\text{C}$  in Mexico and from 5.5 to  $-18.8^{\circ}\text{C}$  in northwestern America. Consequently, SDMs predicted different geographic areas across Europe as being climatically suitable for lineages. This illustrates how lineage-based SDMs could highlight the different contributions of lineages in the predicted potential distribution of species. We recognize that these observations do not indicate that lineages display different potential distributions since SDMs do not depict the fundamental niches of species. However, it warrants investigating the climatic preferences and potential adaptations of phylogeographic lineages to environment in order to improve the PRAs' reliability.

## Towards improved PRA?

Recent studies highlighted the poor performance of lineage-based modeling approaches in describing an invasion process (e.g. the inability of lineage-based SDMs to predict the entire invaded range of a species; Thompson et al. 2011, Schulte et al. 2012, Beaumont et al. 2014). Interestingly, the relevance of such tools is still debated and requires validation through analyses of past or ongoing invasions. Since the intraspecific identity of *D. valens* populations that have invaded China has been elucidated (Cognato et al. 2005, Cai et al. 2008), this species provided the opportunity to test the lineage-based approach using a successful invasion. Genetic analyses suggested western America as the most likely origin of the invading population (Cai et al. 2008) and our SDM analyses came to a similar conclusion. We observed, indeed, a high climatic similarity between the areas occupied by *D. valens* in western America and China suggesting that lineages' preadaptations to climate might have played a crucial role during this invasion. There is increasing evidence that preadaptations to environment increase the probability of initial establishment of introduced populations in a new region (Duncan et al. 2001, Lachmuth et al. 2010, Rey et al. 2012). Since invasion of *D. valens* is relatively recent, it is difficult to determine whether spread of the invasive lineage would be prevented or at least slowed in regions predicted as more climatically suitable for the other lineages by our SDMs. A close monitoring of the spread of *D. valens* in China would be of help to clarify this question.

Pest risk analysis would benefit from improved SDM projections based on the aggregated predictions obtained for each lineage. Another idea would be to dedicate more resources to inspect goods originating from regions associated to lineages showing higher risk. This invasion management option might reduce the number of new invaders since there is increasing evidence that intraspecific units may display preadaptations to different climatic conditions and thus contrasted risk of establishment in new geographic regions especially when populations densities are low as it is usually the case during the first phases of invasions (Rey et al. 2012). However, the success of this management option is uncertain since pests might be transported from one region to another within a country (in reason for intranational exchange) before being introduced into other countries. Finally, molecular tools allowing rapid and precise identification of intercepted organisms are increasingly available to plant biosecurity agencies (e.g. DNA barcoding; Armstrong and Ball 2005, Coeur d'acier et al. 2014). These tools allow the identification of the organisms and the identification of the lineage they belong to. If lineages differ in the risk they are associated to, then the design of management plans could be adapted to the organism soon after interception. If intraspecific climatic niche divergence is undoubtedly demonstrated, we suggest that quarantine status or management plans might differ among conspecific lineages. For these reasons, lineage-based approaches should be considered whenever possible i.e. when consistent phylogeographic analyses are available together with a sufficient amount of occurrence data enabling SDM analysis.
