Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

Ultrafast Barrierless Photoisomerization and Strong UV Absorption of Photoproducts in Plant Sunscreens

ABSTRACT: Sunscreens are aimed at protecting skins from solar UV irradiation. By utilizing femtosecond transient absorption spectroscopy and time-dependent density functional theory, we explain nature's selection of sinapoyl malate rather than sinapic acid as the plant sunscreen molecule. In physiological pH condition, the two molecules are deprotonated and their excited $\pi\pi^*$ states are found to relax to the ground states in a few tens of picoseconds via a barrierless trans-cis photoisomerization. After forming the cis-photoproduct, the efficacy of sinapic acid is reduced much. In contrast, the efficacy of sinapoyl malate is affected slightly because the cis-product still absorbs UV light strongly. In addition, protonated sinapic acid is found to be a good potential sunscreen molecule.

An over exposure to ultraviolet (UV) radiation has deleterious effects on animals and higher plants, and with the depletion of the ozone layer due to the increasing pollution, this exposure of UV is increasing day by day.¹⁻³ Various sunscreens are designed to protect skins from damages by UV light, such as oxybenzone⁴ and cinnamate-based molecules.⁵⁻⁷ A good sunscreen agent should have a large absorption section on UVB (285-320 nm) and UVA (320-400 nm) light and dissipate the energy into surroundings efficiently.⁸ Plants sustain much longer exposure to UV radiation than animals. As a result, nature has selected efficient screening agents to protect plants. In adult *Arabidopsis* plants, sinapoyl malate is deposited in the leaf epidermis to prevent penetration of UV radiation.⁹⁻¹¹ Sinapoyl malate is an ester derivative of sinapic acid. Both of them can efficiently dissipate the energy into their surroundings.¹² As a result, an interesting question is why nature selects sinapoyl malate rather than sinapic acid as the plant sunscreen?

Figure 1. Chemical structures of sinapic acid in acidic environment (SA) and neutral environment (SA⁻), as well as the chemical structures of sinapoyl malate in acidic environment (SM) and neutral environment (SM²⁻).

Sinapoyl malate in the gas phase exhibits a more broadening absorption spectrum in the UVB region than sinapic acid, which is suggested to be the reason for nature's selection of sinapoyl

malate as the sunscreen molecule.¹³ However, in dioxane, acetonitrile and methanol, the two molecules both exhibit high extinction coefficients in the UVB region and thus the reason for the selection is still under discussion.¹² In addition, the excited-state relaxation mechanisms of sinapic acid and sinapoyl malate in the gas phase differ from that in organic solvents. In the gas phase, the initially populated $\pi\pi^*$ states are suggested to relax to long-lived $n\pi^*$ states through internal conversion.¹³ However, a femtosecond study suggests that in organic solvents the $\pi\pi^*$ states relax to the ground state (S_0) via an ultrafast trans-cis photoisomerization.¹² The trans-cis photoisomerization is also found in the relaxations of the closely related para-methoxy methylcinnamate (p-MMC) in aqueous solution,^{5,6} as well as sinapic acid in aqueous solution.¹⁴ However, the relaxation mechanism of sinapoyl malate in aqueous solution is unknown.

Herein, we explore the excited-state dynamics of sinapic acid and sinapoyl malate in aqueous solution. In pH = 6~8 aqueous solution, the carboxyl group is deprotonated and the phenolic hydroxyl group is protonated.¹⁵ Thus, sinapic acid and sinapoyl malate exist as SA^- and SM^{2-} species, respectively, as shown in Figure 1. The protonated SA species is also studied under acidic environment in order to provide a guideline for the chemical modification of sinapic acid, such as methyl sinapate.^{12,13} The potentials of SA, SA^- and SM^{2-} as sunscreen molecules are investigated using static absorption and femtosecond transient absorption (FTA) spectroscopy, as well as time-dependent density functional theory (TD-DFT). Note that the abbreviation SA only represents the protonated form of sinapic acid in acidic environment. The ultrafast barrierless photoisomerization of the three species are identified. The electronic absorption properties of their cis-photoproducts are also discussed.

Sinapic acid ($\geq 98\%$, Sigma-Aldrich) was dissolved in water and hydrochloric acid ($\sim 1\text{mM}$) to obtain the SA^- and SA aqueous solution, respectively. Sinapoyl malate was synthesized as

1
2
3 described in previous studies.¹⁶ The high-purity powder was dissolved in water and thus the SM²⁻
4
5 aqueous solution was obtained. The three species were confirmed by UV-Vis absorption
6
7 spectroscopy measurements (Perkin-Elmer). The FTA setup was used as described in previous
8
9 studies.^{17,18} Briefly, the pump pulse was 320 nm for SA, 305 nm for SA⁻, and 325 nm for SM²⁻.
10
11 The powers of these excitation pulses were about 0.5 mW. Probe pulse was drawn from a broad-
12
13 band white-light continuum (400-700 nm), generated by focusing a weak 800 nm pulse into a
14
15 sapphire. The polarization of the pump pulse was set to the magic angle (54.7°) relative to the
16
17 probe pulse. To avoid the concentration of cis-products induced by UV excitation, transient
18
19 absorption spectra were taken using a flow cell. The UV-Visible spectra before and after FTA
20
21 measurements were shown in Figure S1 (see the supporting information, SI). Continuous UV
22
23 irradiation studies were performed on the three solutions using a nanosecond 355 nm pulse with
24
25 the power of 3 mW in a 10mm * 10mm quartz cuvette. The 355 nm pulse was chosen because it
26
27 was near the center of UVA light. The UV-Vis absorption spectra were taken to probe the
28
29 changes upon photoexcitation.

37 All the ab initio calculations were performed using the Gaussian09 program.¹⁹ Default
38
39 parameters were used unless otherwise indicated. TD-DFT with the M062X functional²⁰ was
40
41 employed, combined with the linear-response polarized continuum model (LR-PCM)^{21,22} and 6-
42
43 31+g(d, p) basis set. All the optimized ground-state and excited-state geometries were confirmed
44
45 by frequency calculations. Trans-cis photoisomerization paths were constructed by linearly
46
47 interpolated internal coordinate (LIIC) method at the LR-PCM/TD-M062X/6-31+g(d, p)
48
49 calculation level. Further details could be found in the SI.

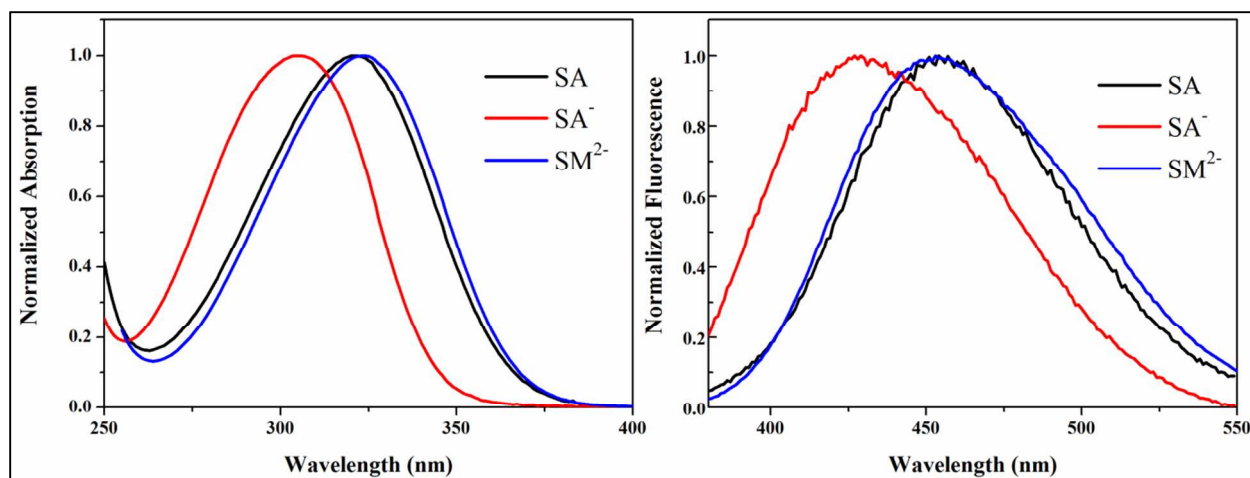

Figure 2. Normalized steady-state absorption (left) and fluorescence (right) spectra of SA, SA⁻ and SM²⁻ in aqueous solution.

The steady-state UV-Vis absorption and fluorescence spectra of SA, SA⁻ and SM²⁻ are shown in Figure 2. All the three species have large absorption section at UVB and high-energy UVA regions. The absorption spectrum of SA⁻ is peaked at 304 nm and its intensity decreases to zero at approximately 360 nm. Comparatively, the absorption spectra of SA and SM²⁻ are slightly red shifted. Their absorption maxima are both at 320 nm and they absorb UVA light till approximately 380 nm. The more broadening absorption of SA and SM²⁻ relative to SA⁻ makes them behave as better sunscreen molecules. The fluorescence spectra of SA and SM²⁻ are both peaked at approximately 450 nm, also slightly red shifted compared to the fluorescence spectrum of SA⁻, which is peaked at approximately 425 nm. The deprotonation state of sinapic acid affects its electronic absorption characteristics.¹⁴ For example, deprotonating the carboxylic group of sinapic acid results in the absorption maximum blue shifted slightly from 320 to 304 nm. In contrast, further deprotonating the phenolic hydroxyl group (SA²⁻) makes the absorption maximum red shifted largely to 350 nm, as shown in Figure S2. This implies that deprotonating the carboxylic group and phenolic hydroxyl group have exactly the opposite effects on the

electronic excitation energy of sinapic acid. This phenomenon is also observed in sinapoyl malate. Deprotonating the carboxyl group of sinapoyl malate only leads to the absorption maximum blue shifted slightly from 328 to 320 nm, while further deprotonating the phenolic hydroxyl group (SM^{3-}) leads to the absorption maximum largely red shifted to 380 nm (Figure S2). The small absorption cross section in UVB region makes SA^{2-} and SM^{3-} not suitable to serve as sunscreen molecules.

Figure 3. Femtosecond wavelength evolution curves of (a) SA, (b) SA^- , and (c) SM^{2-} . Fitting results of the decay of (d) SA at 430 nm, (e) SA^- at 430 nm, and (f) SM^{2-} at 453 nm. Black circles represent the experimental data and red lines represent the fitting curves.

Figure 3 shows the FTA spectra of SA, SA^- and SM^{2-} for photoexcitation at 320, 305 and 325 nm, respectively. For SA, the FTA spectra are dominated by a broad feature spanning the spectral region of ~ 400 -500 nm centered at 450 nm. This is attributed to the stimulated emission, which is in line with the steady-state fluorescence (Figure 2).¹²⁻¹⁴ In this region, the absorption of

1
2
3 solvated electron and phenoxy-type radical species can be ignored due to the strong absorption
4 intensity of solutes (Figure S1) and much shorter lifetime relative to the radicals.¹⁴ At 0.2 ps, the
5
6 stimulated emission is peaked at ~ 430 nm and then it red shifts to ~ 450 nm at 1 ps, induced by
7
8 the intramolecular vibrational energy redistribution (IVR) and solvation relaxation. The negative
9
10 absorption finally decays to the baseline by ~ 20 ps. The FTA spectra for SA⁻ and SM²⁻ are also
11
12 dominated by their negative stimulated emissions. Obviously, SA⁻ decays slower than the other
13
14 two molecules. To give a quantitative insight into their dynamical relaxations, the decays of their
15
16 stimulated emissions are fitted by mono- or bi-exponential functions. The lifetimes of the three
17
18 species are summarized in Table 1. A bi-exponential function fits well the decays of SA and SA⁻.
19
20 In SA, the τ_1 (0.28 ps) with a positive pre-exponential factor is assigned to the coupled IVR and
21
22 solvation relaxation processes, while the τ_2 (6.1 ps) with a negative pre-exponential factor is
23
24 assigned to the decay of $\pi\pi^*$ state. The $\pi\pi^*$ state might relax to a dark $n\pi^*$ state like in the gas
25
26 phase and/or decay back to the S₀ state via trans-cis photoisomerization like cinnamate
27
28 derivatives,^{6,13} which will be discussed further by ab initio calculations. In addition, the
29
30 assignment strategy is also reasonable for the fitted lifetimes of SA⁻. The 23.5 ps lifetime of SA⁻
31
32 is in good agreement with the 26 ps lifetime measured by Vengris et al.¹⁴ The τ_1 of SA⁻ (1.1 ps)
33
34 is much longer than that of SA (0.28 ps), indicating that the IVR and solvation relaxation
35
36 processes are much slower for SA⁻. This can be also seen from their wavelength evolutions
37
38 (Figures 3a, 3b). The decay of SM²⁻ is fitted by a mono-exponential function and $\tau_1 = 16.9$ ps is
39
40 obtained, which corresponds to the decay of $\pi\pi^*$ state. The IVR and solvation relaxation
41
42 processes are absent in the fitting results. Based on the similar wavelength evolutions of SA and
43
44 SM²⁻ (Figures 3a, 3c), it can be inferred that the lifetime of IVR and solvation relaxation process
45
46 is at sub-ps timescale. Although the $\pi\pi^*$ state relaxation of SA⁻ is the slowest, it cannot conclude
47
48
49
50
51
52
53
54
55
56
57
58
59

that SA⁻ is not a suitable sunscreen molecule, because the lifetimes of the other two molecules are also at the same timescale. There should be other reasons for nature's selection of SM²⁻ as the sunscreen molecule.

Table 1. Summary of the excited-state lifetimes of SA, SA⁻ and SM²⁻ based on their decays of stimulated emissions

	SA	SA ⁻	SM ²⁻
a ₁	0.46±0.08	0.27±0.05	-46.3±1.0
τ ₁ /ps	0.28±0.09	1.1±0.4	16.9±1.1
a ₂	-1.14±0.03	-0.49±0.04	
τ ₂ /ps	6.1±0.4	23.5±3.0	

Table 2. Vertical excitation energies (in eV) including the first and second excited states (S₁, S₂) of trans- SA, SA⁻ and SM²⁻ at the LR-PCM/TD-M062X/6-31+g(d, p) level, as well as the S₁ state of their respective cis- forms. Oscillator strengths are shown in the parentheses.

	E (SA)/eV	E (SA ⁻)/eV	E (SM ²⁻)/eV
trans-S ₁	4.05 (0.69)	4.46 (0.64)	4.12 (0.73)
trans-S ₂	4.51 (0.03)	4.73 (0.00)	4.62 (0.02)
cis-S ₁	4.03 (0.57)	4.78 (0.46)	4.25 (0.39)

In order to determine whether the initially populated ππ* state decays to dark nπ* state or the S₀ state via trans-cis photoisomerization, TD-DFT calculations are carried out. The S₀ geometries of trans-SA, SA⁻ and SM²⁻ are optimized, as shown in Figure S3. The dihedral angle η (C₁-C₂-C₃-C₄), defined to describe the double bond rotation, is 180° for all the three species. Based on

1
2
3 these equilibrium geometries, the vertical excitation energies and oscillator strengths of the S_1
4 and S_2 were calculated at the LR-PCM/TD-M062X/6-31+g(d, p) level, as collected in Table 2.
5
6 For all the trans-species, the S_1 state is bright $\pi\pi^*$ state and the S_2 state is dark $n\pi^*$ state. After
7
8 considering the intermolecular hydrogen bonding interactions with water, the results do not have
9
10 significant changes, as shown in Figure S4 and Table S1. This energy level sequence is contrast
11
12 with the case in the gas phase due to the strong polar aqueous environment stabilizing the $\pi\pi^*$
13
14 state and destabilizing the $n\pi^*$ state.^{5,13} The calculated excitation energies are overestimated
15
16 compared to the experimental absorption maxima. However, the calculated results are in
17
18 qualitative agreement with experiment. The electronic absorption energy of trans- SA^- is the
19
20 highest while that of trans-SA and trans- SM^{2-} are similar.
21
22
23
24
25
26
27

28 In order to evaluate the possibility of the $\pi\pi^*-n\pi^*$ internal conversion, the $n\pi^*$ geometries of
29
30 trans-SA, SA^- and SM^{2-} are optimized and their vertical electronic transitions are calculated, as
31
32 shown in Table S2. For trans-SA and SM^{2-} , the $n\pi^*$ state is still described as the S_2 state while
33
34 the S_1 state is the $\pi\pi^*$ state, indicating that the $n\pi^*$ state always lies in a higher energy level than
35
36 the $\pi\pi^*$ state. Thus, the $\pi\pi^*-n\pi^*$ internal conversion cannot occur. In contrast, the $\pi\pi^*-n\pi^*$
37
38 internal conversion of trans- SA^- is possible because the $n\pi^*$ state is more stable than the $\pi\pi^*$
39
40 state in the equilibrium $n\pi^*$ geometry of trans- SA^- . However, FTA spectra suggest that the
41
42 excited-state evolutions of SA^- and SA are very similar. In addition, in less polar organic
43
44 solvents where the $n\pi^*$ state is more stable than in aqueous solution,²³ there is no significant
45
46 evidence to support the $\pi\pi^*-n\pi^*$ internal conversion.¹² As a result, the role of the $n\pi^*$ state in the
47
48 $\pi\pi^*$ state relaxations can be ignored. This is in a good agreement with the results that the
49
50 hydration of p-MMC impedes the $\pi\pi^*-n\pi^*$ internal conversion.²⁴

Now that the $\pi\pi^*$ - $n\pi^*$ internal conversion is unlikely to occur, in order to confirm the $\pi\pi^*$ relaxation through the trans-cis photoisomerization, the potential energy surfaces (PESs) of the photoisomerization of SA, SA⁻ and SM²⁻ are constructed by LIIC method at the LR-PCM/TD-M062X/6-31+g(d, p) calculation level, as shown in Figure 4. The isomerization paths of the three species are all barrierless, indicating that the photoisomerization occurs dynamically on PES, in agreement with the photoisomerization of the closely related p-MMC.⁶ Note that for every point in the three PESs, the S₁ state is always the $\pi\pi^*$ state. The barrierless relaxation path is in good agreement with the ultrafast decays of $\pi\pi^*$ states, which are completed less than tens of picoseconds. Although TD-DFT is unable to locate the conical intersection (CI), it can give a qualitative description if the energy gap between the S₀ and S₁ states is small enough.²⁵ Thus, the PESs shown in Figure 4 are believable. After initial photoexcitation, the $\pi\pi^*$ state evolves along the barrierless photoisomerization path characterized by the decreasing η . When the $\pi\pi^*$ state reaches the low-lying $\pi\pi^*$ -S₀CI, η is 80° for SA⁻ and 90° for both SA and SM²⁻. At this point, ultrafast nonradiative decay to the S₀ state is extremely efficient. The system can either evolve to the cis-product or reverse back to the original trans-reactant. In addition, the reverse cis-trans isomerization is also barrierless, indicating that there is a dynamical equilibrium between the trans-cis and cis-trans reactions, similar to the case of p-MMC.⁶

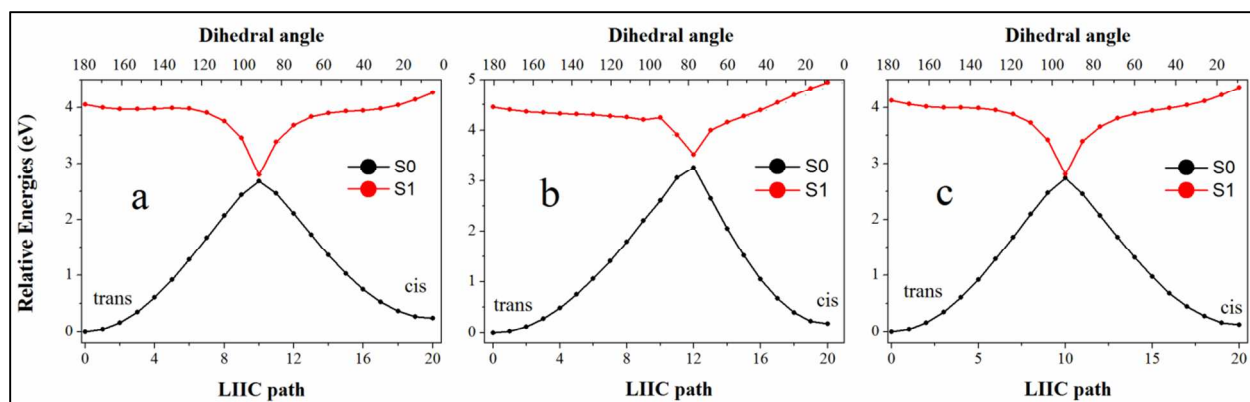

Figure 4. LR-PCM/TD-M062X/6-31+g(d, p) calculated linearly interpolated internal coordinate (LIIC) paths of the trans-cis photoisomerization of (a) SA, (b) SA⁻, and (c) SM²⁻. Dihedral angle η (C₁-C₂-C₃-C₄) is also represented. In the original trans-reactant, the dihedral angle is 180°. And in the final cis-product, the dihedral angle is near to 0°.

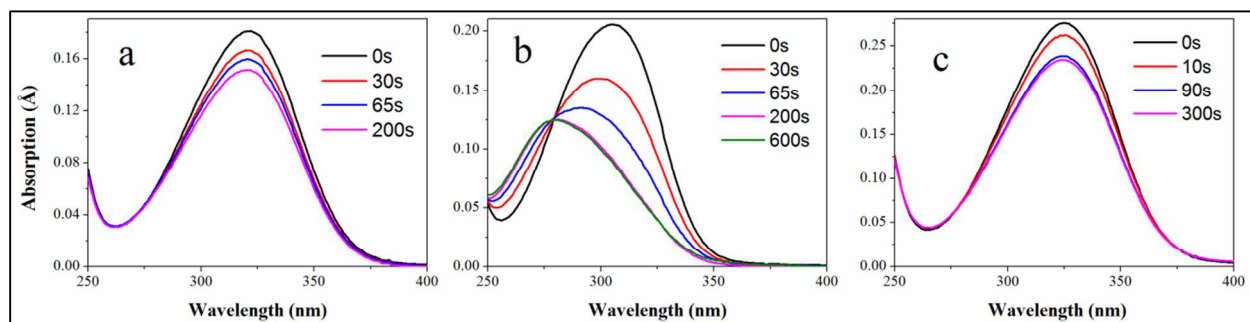

Figure 5. The absorption spectra of (a) SA, (b) SA⁻, and (c) SM²⁻ after a period of 355 nm pulse irradiation.

As has been discussed, cis-photoproducts can be formed by nonradiative trans-cis photoisomerization.¹² To evaluate the effect of the formation of cis-products on the efficacy of sunscreen molecules, a continuous UV irradiation study is performed using the 355 nm pulse with a power of 3 mW. Steady-state UV-Vis spectroscopy is used to probe the absorption changes induced by the formation of cis-photoproducts. As shown in Figure 5b, after 355 nm

1
2
3 light irradiation, the absorption spectra of SA⁻ are blue shifted significantly accompanied with
4 largely decreasing intensities. This will largely reduce the efficacy of SA⁻ as a sunscreen
5 molecule. The spectral changes of SA⁻ are in good agreement with the TD-DFT results shown in
6 Table 2. TD-DFT results suggest that electronic excitation energy of cis-SA⁻ is higher than that
7 of trans-SA⁻ and the oscillator strength of the former is smaller. As to SA and SM²⁻, the
8 absorption spectra after the 355 nm light irradiation show no spectral shift and their intensities
9 only decrease slightly, in agreement with the TD-DFT results that trans-SA and cis-SA have the
10 same electronic excitation energies (Table 2). Although cis-SM²⁻ has 0.13 eV higher excitation
11 energy than trans-SM²⁻, the TD-DFT results is generally in good agreement with the irradiation
12 results. As a result, SA and SM²⁻ are better sunscreen molecules than SA⁻.

28 In conclusion, we have studied the photoprotection mechanism of SA, SA⁻ and SM²⁻ in
29 aqueous solution. The initially populated $\pi\pi^*$ states of the three species all decay to the S₀ state
30 nonradiatively via a barrierless trans-cis photoisomerization, which are completed in a few tens
31 of picoseconds. The photoisomerization leads to the formation of cis-photoproducts. Cis-SA has
32 much higher excitation energy and a decreased absorption cross section in the UV light than
33 trans-SA⁻. Thus, the efficacy of SA⁻ as sunscreen is reduced largely after photoexcitation. In
34 contrast, the absorption spectra of SA and SM²⁻ after photoisomerization just show slightly
35 decreased intensities. These results suggest that SM²⁻ is a better sunscreen molecule than SA⁻,
36 explaining nature's selection of sinapoyl malate rather than sinapic acid as the plant sunscreen.
37 In addition, the protonated SA exhibits an ultrafast excited-state lifetime and its cis product still
38 has a large absorption cross section on the UV region. An appropriate chemical modification on
39 SA can make it a good sunscreen molecule used in neutral pH condition. These results highlight
