15 Abstract

16 Many fungi can develop on building material in indoor environments if moisture is high
17 enough. Among species that are frequently observed, some are known to be potent mycotoxin
18 producers. This presence of toxinogenic fungi in indoor environments raises the question of
19 the possible exposure of occupants to these toxic compounds by inhalation after
20 aerosolization.

21 This study investigated the mycotoxin production by *Penicillium brevicompactum*,
22 *Aspergillus versicolor* and *Stachybotrys chartarum* during their growth on wallpaper and the
23 possible subsequent aerosolization of produced mycotoxins from contaminated substrates.

24 We demonstrated that mycophenolic acid, sterigmatocystin and macrocyclic
25 trichothecenes (sum of 4 major compounds) could be produced at levels of 1.8, 112.1 and
26 27.8 mg/m², respectively on wallpaper. Moreover, part of the produced toxins could be
27 aerosolized from substrate. The propensity to aerosolization differed according to the fungal

28 species. Thus, particles were aerosolized from wallpaper contaminated with *P.*
29 *brevicompactum* when air velocity of just 0.3 m/s was applied, where *S. chartarum* required
30 air velocity of 5.9 m/s. *A. versicolor* was intermediate since aerosolization occurred under air
31 velocity of 2 m/s.

32 Quantification of the toxic content revealed that toxic load was mostly associated with
33 particles of size equal or higher of 3 μm , which may correspond to spores. However, some
34 macrocyclic trichothecenes (especially satratoxin H and verrucarins J) can also be found on
35 smaller particles that can penetrate deeply in the respiratory tract upon inhalation. These
36 elements are important for risk assessment related to mouldy environments.

41

42 **IMPORTANCE**

43 The possible colonisation of building material by toxinogenic fungi in case of moistening
44 raises the question of the subsequent exposure of occupants to aerosolized mycotoxins. In this
45 study, we demonstrated that three different toxinogenic species produce mycotoxins during
46 their development on wallpaper. These toxins can subsequently be aerosolized, at least partly,
47 from mouldy material. This transfer to air requires air velocities that can be encountered in
48 « real life conditions » in buildings. The most part of the aerosolized toxic load is found in
49 particles whose size corresponds to spores or mycelium fragments. However, some toxins
50 were also found on particles smaller than spores that are easily respirable and can deeply
51 penetrate into human respiratory tract. All these data are important for risk assessment related
52 to fungal contamination of indoor environments.

53

54

55 INTRODUCTION

56

57 In industrialized countries, people spend most of their time inside buildings (1). Many
58 physical, chemical or microbiological pollutants can have detrimental effects for occupants,
59 such as allergies or infections (2, 3). Among the microorganisms that are present in indoor
60 environments, micromycetes are ubiquitous and capable of growing on most construction and
61 decoration materials if appropriate environmental conditions are present (4–6). Thus, it is
62 estimated that, in Northern Europe and North America, 20 to 40 % of buildings display
63 macroscopically visible fungal growth (7, 8).

64 Among the fungal species commonly observed in habitats, some are known to produce
65 toxic secondary metabolites called mycotoxins (4, 9, 10). For instance, *Aspergillus versicolor*,
66 a potent producer of sterigmatocystin (STG), is one of the most frequent fungal contaminant
67 of indoor environments that can be found together on building materials, in dust or in the air
68 samples (4, 11). On the other hand, *Stachybotrys chartarum* is often isolated from building
69 materials in homes that have suffered from water damages (12–14). This species is known to
70 be able to produce different toxic compounds belonging to the family of macrocyclic
71 trichothecenes (MCT) (satratoxins G (SG) and H (SH), roridin L2 (RL2), verrucarins J (VerJ))
72 (15, 16). On the same way, *Penicillium brevicompactum*, a species able to produce
73 mycophenolic acid (MPA), was also frequently identified in indoor environments (17).

74 Such observations raise the question of the possible occupants' exposure to these toxic
75 compounds by contact or inhalation following their aerosolization. Indeed, it has been shown
76 that mycotoxins can be found in fungal spores (9) and could therefore subsequently be inhaled
77 (18, 19).

78 To evaluate presence of these contaminants in indoor environments, some studies have
79 measured mycotoxins on contaminated materials (20–23) or settled dust (24, 25). Thus, STG

80 could be found in more than 20 % of analyzed samples. Similarly, MCT were also found on
81 material samples taken from water-damaged homes (13).

82 However the toxin quantification from material or settled dust does not predict the
83 airborne toxic load nor toxin quantities potentially inhaled by the occupants. Indeed, the
84 relationship between contaminated surfaces, mycotoxin production and transfer to the air of
85 these toxic substances is poorly documented. Most studies have focus primarily on
86 aerosolization of conidia or fungal fragments (26–28) without associating them with
87 mycotoxins. Only one previous work demonstrated the presence of MCT in highly respirable
88 particles ($< 1 \mu\text{m}$) (29). In this study, the authors demonstrated that, while passing over
89 cellulose ceiling tiles contaminated with a toxinogenic strain of *S. chartarum*, house air could
90 be contaminated with MCT, in relation with aerosolization of fungal particles but also due to
91 the presence of toxins on particles smaller than spores.

92 Within this context, the aim of this study was to quantify mycotoxins production by three
93 fungal species often present in indoor environments that are *P. brevicompactum*, *A.*
94 *versicolor*, and *S. chartarum*, during their growth on wallpaper. We also aimed to evaluate
95 possible aerosolization of produced toxins as a function of both air velocity and size of
96 released particles. Wallpaper was chosen since it has been shown that this substrate is
97 favorable for mycotoxin production (13, 14, 21). Moreover, this material is often used in
98 indoor furnishing and is therefore in direct contact with indoor air.

99 We demonstrate here that part of mycotoxins, produced on wallpaper during fungal
100 growth, can be aerosolized following air velocities that can be encountered in buildings.
101 Toxic load is mostly observed on particles whose size corresponds to spores but some toxins
102 could also be found in easily respirable particles of less than $2 \mu\text{m}$.

103

104

105

106 **MATERIALS AND METHODS**

107

108 **Mycotoxin standards.** Mycophenolic acid (MPA), sterigmatocystin (STG), verrucarins A
109 (VerA), o-methylsterigmatocystin (o-mSTG) and mycophenolic acid-d₃ (MPA-d₃) were
110 purchased from Sigma (Saint-Quentin Fallavier, France). Standards of satratoxin G (SG),
111 satratoxin H (SH), roridin L2 (RL2) and verrucarins J (VerJ) were gracious gift from Professor
112 J.J. Pestka (Department of Microbiology and Molecular Genetics, Michigan State University,
113 USA).

114 All standards were dissolved in methanol (MeOH) to obtain stock solutions that were
115 stored at -20 °C as recommended by manufacturer.

116

117 **Solvents and reagents.** All reagents and solvents were purchased from ICS (Lapeyrouse-
118 Fossat, France) and were analytical grade. Acetonitrile (AcN) used for mobile phase was
119 LC/MS grade and purchased from Thermo Fischer Scientific (Illkirch, France) and water was
120 obtained from an ultrapure water (18.2 MΩ) system (Elga Labwater Veolia, Anthony,
121 France).

122 Wallpaper (WP) (Papier Peint BLAN BLA 0 INSP, Leroy Merlin) was purchased in a
123 specialized store. The material, visually clean and dry, was cut into 2×5 cm pieces and then
124 sterilized by autoclaving at 121 °C for 20 min before use(27, 30).

125

126 **Fungal strains.** *P. brevicompactum* IBT 23078 strain was a gracious gift from Dr J.B.
127 Nielsen (Assistant Professor, Technical University of Denmark, Lyngby, Denmark), *A.*
128 *versicolor* NCPT 54 was a gift from Dr O. Puel (INRA, Toulouse, France), and *S. chartarum*
129 82 (ST82) strain was previously isolated in our laboratory (31). These three strains were
130 selected for their ability to produce mycophenolic acid, sterigmatocystin and macrocyclic

131 trichothecenes, respectively. All strains were maintained in the laboratory on malt extract agar
132 (MEA, Biokar, France) at 4°C and were regularly checked for viability by culturing on MEA.

133

134 **Growth and toxinogenesis of fungi on wallpaper.** The fungal strains were grown on potato
135 dextrose agar (PDA, Biokar, France) for 14 days at 25 °C to obtain highly sporulating
136 cultures. Spores were harvested by flooding the plate with 10 mL of Tween 80 (0.05 %).
137 Spores were suspended by smoothly scraping the medium with sterile inoculating loop and
138 liquid was then collected. Spore concentration was measured by direct counting on a counting
139 cell (Malassez cell, CML, Nemours, France). Spore suspensions were then diluted to reach a
140 concentration of 2×10^6 spores/mL and contamination was achieved by applying dropwise 500
141 μ L of those suspensions (10^6 spores/sample) on the decorative side of sterile wallpaper. This
142 contamination level was previously identified as sufficient to observe a fungal development
143 within few days (31).

144 Contaminated wallpaper pieces (2 x 5 cm) were placed in flasks, on a layer of 2 cm of
145 glass beads and 8 mL of sterile water, in order to maintain moisture level at saturation
146 throughout the test, and incubated for 10 days at 25 °C in darkness. After incubation, fungal
147 growth was assessed by visual examination of samples (importance of colonized surface).
148 Both hyphae development and density of sporulated conidial heads on the whole sample
149 surface (10 cm²) were observed by examination under stereomicroscope (magnification from
150 12 to 120) (Olympus SZX9) and under Scanning Electron Microscopy (SEM) (Jeol JSM
151 5600LV) (magnification from 40 to 30 000).

152 Some samples were used for mycotoxin determination whereas others, incubated in the
153 same conditions, were used for aerosolization as described below.

154 Initial mycotoxin baseline due to inoculum deposit on materials (= T0 value) was
155 measured using samples that were frozen immediately after spores deposit, without incubation
156 to avoid fungal growth.

157 All analysis were done in triplicate and three independent experiments were carried out.

158

159 **Aerosolization of mycotoxins from wallpaper.** To evaluate aerosolization of particles and
160 toxins from wallpaper, a specific experimental device capable of producing controlled air
161 velocities over contaminated substrates was developed. The principle of this device is shown
162 on Figure 1. To ensure the safety of the operator, the entire assembly was placed in a
163 microbiological safety cabinet.

164 The developed assembly presents cylindrical volume of 10.5 L equipped with a blowing
165 device provided with filtered humidified air (50 % RH at 22 °C) to ensure the aerodynamic
166 stresses on contaminated material. The blowing device placed in the closed space consists of
167 16 semicircular holes of 1 mm diameter (PNR industrie, Collègien, France). It was placed so
168 that the air stream forms an angle of 45 ° with respect to the contaminated material.
169 Moreover, the assembly is leveled so the distance between the bottom of the blowing nozzles
170 and the fungal cultures was 1 cm (Figure 1). Characterization of the air speed over the
171 substrate as a function of the flow from the blowing device was characterized (supplementary
172 data 1).

173 Different increasing air velocities were firstly tested to define air speeds allowing
174 significant particles' aerosolization from substrates for the three fungal species
175 (supplementary data 2). Once air velocity was defined for each fungal species, the
176 characterization of aerosol was done following air jets of 5 seconds each that were repeated
177 until the measured concentration of aerosolized particles decreased to 1 particle/L.

178 The physical characterization of the produced aerosols was carried out using an optical
179 counter (Model 3340, TSI) set at 0.1 L/min. An Andersen multi-stage impactor (Tish
180 Environmental, OH, USA)), was used for capturing particles according to 6 ranges of size and
181 aerodynamic characteristics. Each stage of the impactor was equipped with fiberglass disk to
182 collect particles and allow mycotoxin determination as described below. Filters were placed

183 on support whose thickness preserved the right distance between the orifice inlet of the
184 impactor and the filter.

185

186 **Mycotoxin determination.** Four MCT (SG, SH, VerJ and RL2), MPA and STG were
187 extracted from samples (wallpaper and fiberglass disks) by gentle mechanical agitation on an
188 agitation table (Reciprocating Shaker, IKA HS501 Digital, Grosseron, France) in
189 chloroform:methanol (2:1). Mycophenolic acid- d_3 and o-methyl sterigmatocystin were added
190 at known concentration before starting extraction in order to serve as internal standards for
191 MPA and STG respectively. For MCT, verrucaric acid was chosen as internal standard as
192 already described (31).

193 After 4 hours, extracts were centrifuged for 5 min at 3500 rpm and filtered through a
194 phase separator filter (Whatman 1 PS). Filtered extracts were evaporated to dryness and
195 suspended in 1mL of methanol.

196 Quantification of mycotoxins was performed using an Acquity ultra performance liquid
197 chromatography (UPLC) system coupled to a Xevo triple quadrupole mass spectrometer
198 (Waters, Milford, MA, USA). The desolvation temperature and nitrogen flow rate were set at
199 650 °C and 800 L/h, respectively. Argon was used as the collision gas at a flow rate of 0.12
200 mL/min.

201 Mycotoxins (5 μ L of samples) were eluted on an Acquity BEH C18 column (2.1 x 100
202 mm; 1.7 μ m; Waters) with an AcN/H₂O gradient ($t(0-0.5$ min): 10 % AcN; $t(0.5-4$ min): 90 %
203 AcN) at a flow rate of 0.35 mL/min. Quantification was carried out by Multiple Reaction
204 Monitoring (MRM) mode in positive electrospray ionization (ESI+). MRM transitions, cone
205 voltage and collision energies used for the different toxins are listed in Table 1.
206 Chromatographic data were monitored by Masslynx 4.1 software (Waters, Milford, MA,
207 USA).

208 Limits of detection (LOD) were determined from 3 injections of the mycotoxins
209 standards at the lowest concentration that could be detected with a signal to noise ≥ 3 . They
210 were 1 ng/ml for MPA and STG, 0.2 ng/mL for RL2, 5 ng/mL for VerJ, 10 ng/mL for SH and
211 SG. The limit of quantification (LOQ) was determined and validated for the lowest
212 concentration of the calibration curve chosen for its relevance to mycotoxin investigation on
213 wallpaper. The LOQs were set at 10 ng/mL for MPA, STG, RL2 and VerJ, and 100 ng/mL for
214 SG and SH. .

215 For all analyzed toxins, percentage of aerosolized toxin from contaminated substrates
216 was calculated as follow:

$$\% \text{ of airborne toxin} = \frac{\text{quantity of airborne toxin}}{\text{quantity of produced toxin on WP sample}} * 100$$

217
218 **Statistical analysis.** Data were analysed with GraphPad Prism statistical software version
219 v4.0. Student's t-test was used to analyse the differences between initial concentration of
220 toxins on materials (T_0) and toxins' concentrations after incubation period. The differences
221 were considered to be statistically significant when p-value was lower than 0.05.

222

223

224

225 **RESULTS**

226

227 **Growth and toxinogenesis of fungal strains on wallpaper.** After 10 days of incubation at
228 25 °C, the three tested fungal species grew and sporulated on wallpaper. Nevertheless, some
229 differences could be observed between species (Figure 2).

230 *P. brevicompactum* colonized almost the entire surface of wallpaper, with a loosened
231 mycelium. Numerous large and compact *penicilli* were observed under stereomicroscope and,
232 at microscopic level, long terverticillate conidiophores with adjoined branches sometimes
233 bent away from the axis. Inflated *metulae* bore divergent phialides' clusters and very long, dry
234 and disordered chains of spores.

235 As for *P.brevicompactum*, *A. versicolor* growth covered almost all the sample but with a
236 heterogeneous density. Stereomicroscope examination revealed a dense field of aerial and
237 closely interwoven hyphae bearing conidiophores. Classical microscopic features were
238 observed: radiate and biserial conidial heads, closely packed *metulae* and phialides bearing
239 short chains of spores.

240 *S. chartarum* displayed an intense and regular growth with abundant hyphae colonizing
241 the whole sample's surface with many sporulated heads. Conidiophores were simple or
242 branched. Phialides, organized in clusters, bore black ellipsoidal conidia agglomerated by a
243 slimy coating.

244 Mycotoxins measurements revealed that all three species produced mycotoxin(s) during
245 their growth on wallpaper (Table 2). STG was produced in larger quantities with more than
246 110 mg/m². The four analysed MCT were also found. SH was the most abundant one,
247 followed by SG and RL2. Only mild amounts of VerJ were measured after growth of *S.*
248 *chartarum* ST82 strain on wallpaper.

249

250 **Aerosolization of particles from wallpaper.** To define the conditions leading to particle
251 aerosolization from substrate as a function of the fungal species, contaminated wallpaper
252 samples were submitted to increasing aeraulic stresses. It appeared that for *P.*
253 *brevicompactum*, air velocity of 0.3 m/s was sufficient to aerosolize some particles from
254 substrate. An increment in air velocity increased the number of aerosolized particles from
255 wallpaper without any modification of the bioaerosol profile (Supplementary data 2). For *A.*
256 *versicolor*, an air velocity of 2 m/s was required to aerosolize a significant number of particles
257 from substrate. In order to compare aerosolization of these two species, airflow of 2 m/s was
258 applied on contaminated wallpaper to further characterize bioaerosols and airborne
259 mycotoxins.

260 By contrast, for *S. chartarum*, air speed of almost 6 m/s was needed to observe an
261 aerosolization of particles. This air velocity was therefore applied for toxin measurement.

262

263 **Characterization of bioaerosols.** For *P. brevicompactum*, the application of an air velocity
264 of 2 m/s led to the release of a total number of particles of 5.6×10^4 from mouldy wallpaper.
265 They were distributed mainly in:

- 266 ○ Fine aerosols with optical diameter about 100 nm (maximal concentration of 10^3
267 particles/L)
- 268 ○ Particles with optical diameter between 2 and 8 μm (maximal concentration of 2.3×10^3
269 particles/L).

270 For *A. versicolor*, an air velocity of 2 m/s allowed the aerosolization of a total number of
271 1.5×10^4 counted particles that were mostly made of fine aerosols with optical diameter about
272 100 nm (maximal concentration of 1.2×10^3 particles/L) and few particles with optical
273 diameter between 2 and 8 μm (maximal concentration of 700 particles/L).

274 For *S. chartarum*, application of an air speed of almost 6 m/s led to the overall
275 production of 7×10^3 counted particles from substrate with a poly-dispersed distribution of

276 particle sizes. The production of sub-micronic particles represented 77.5 % of the total
277 airborne particles.

278 The distribution of particle size in bioaerosols obtained from the three species is
279 represented in Figure 3.

280

281 **Airborne mycotoxins.** The aerosolization of mycotoxins from wallpaper was measured
282 following air velocities of 2, 2 and 6 m/s for *P. brevicompactum*, *A. versicolor* and *S.*
283 *chartarum*, respectively. The global mycotoxins loads of aerosols from the three fungal
284 species are reported in Table 3.

285 All analysed toxins were found in the aerosols but it appeared that the percentage of
286 airborne toxins strongly differed between them. Fifteen per cent of the MPA present on
287 wallpaper was transferred to air. It represented a total quantity of 271 ng of MPA. By
288 contrast, the percentage of aerosolized STG was only 0.2 %. However, since it was the most
289 produced toxin on wallpaper, total quantity of airborne STG reached almost 180 ng. The
290 proportion of total aerosolized MCT was 4.5 %. It has to be noted that, even if *S. chartarum*
291 required a higher air speed to be aerosolized than the two-other species, the total quantity of
292 airborne toxins was the most important for that species. Among the 4 analysed trichothecenes,
293 VerJ was the most aerosolized with 13.3 % of the initial toxic load, followed by SH, SG and
294 RL2. However, when considering the quantities that were transferred from substrate to air, SH
295 appeared predominant, representing almost 80 % of the overall toxic load.

296 In order to analyse the distribution of mycotoxins as a function of particle sizes and
297 subsequent risk of inhalation, the mycotoxin loads of each domain size of released aerosols
298 were quantified and results are presented in Table 4.

299 MPA was quantifiable on 5 of the 6 considered granulometric ranges, the maximum
300 (about 140 ng) being associated with the particles collected on the third stage of the impactor,
301 with a granulometric domain between 3.3 and 4.7 μm . For STG, no toxin was found on stages

302 corresponding to the particles with size below 2.1 μm and total mycotoxin load was
303 associated with bigger particles. Almost 95% of the toxic load was associated with particles
304 bigger than 3.3 μm . Macrocytic trichothecenes produced by *S. chartarum* and aerosolized
305 from wallpaper were detected in all stages of Andersen collector, even on stages 5 and 6 that
306 correspond to sub-micron particles. Nevertheless, 90 % of the total toxic load (1129 ng) was
307 found on stages 1, 3 and 5.

308 The four-analysed macrocytic trichothecenes were differently distributed within
309 Andersen collector's stages. RL2 was found on all stages. SG was exclusively found on stages
310 1 to 3, SH on stages 1, 3, 5 and 6. VerJ was found on stages 3, 5 and 6 with 86 % of the total
311 toxic load being associated with these two later stages whereas no toxin was measured on
312 stages 1, 2 and 4. Stage 3 that corresponds to particles ranging from 3.3 to 4.7 μm was the
313 most contaminated with 41 % of the total MCT load. It was also the only one containing all
314 four-tested macrocytic trichothecenes.

315

316

317

318 DISCUSSION

319

320 The possible implication of mycotoxins in some disorders observed in occupants of mouldy
321 homes is a growing public health question, worldwide (32–34). Indeed, the risk of exposure to
322 those fungal toxic metabolites by inhalation emerged in the late 90's, when macrocytic
323 trichothecenes produced by *S. chartarum* were implicated in the appearance of pulmonary
324 haemorrhages in infants in the USA (35). More recently, these mycotoxins were also
325 suspected to play a role in the sick building syndrome (36, 37). However, data on the direct
326 relationship between mycotoxin production on materials and their transfer to air are missing
327 and therefore do not allow precise risk assessment. That is why the present study aimed to

328 evaluate the ability of mycotoxins produced by *A. versicolor*, *P. brevicompactum* and *S.*
329 *chartarum* to be aerosolized from mouldy wallpaper.

330 Firstly, we investigated the ability of these three toxinogenic species to grow and
331 produce toxic compounds on wallpaper. This material, frequently used for indoor decoration,
332 allowed both mycelial growth and sporulation in conditions that can be considered as “worst
333 case” but that can be encountered in homes (25°C, humidity and darkness), especially behind
334 furnitures, during warm seasons. This is in agreement with surveys reporting a frequent
335 contamination of such materials by moulds, particularly in case of water damage (14, 21, 38,
336 39). Of note, for *P. brevicompactum* some morphological features were peculiar when this
337 species was grown on wallpaper compared to agar culture media. Indeed, usual aspect of *P.*
338 *brevicompactum* colony on agar medium is dominated by a dense felt of large and compact
339 conidiophores and a velutinous aspect of the thallus with only few trailing (40). On wallpaper,
340 the colony displayed more abundant aerial mycelium with conidiophores borne by aerial
341 hyphae. Such structure may have an important role in facilitating aerosolization of fungal
342 structures.

343 Wallpaper also allowed mycotoxin production by the tested species. Concentrations as
344 high as 112 mg/m², 14 mg/m² and 7 mg/m² were found for STG, SH and SG, respectively.
345 These findings are in agreement with previous studies about production on wallpaper of SG
346 and SH by Gottschalk et al. (14) and STG by Polizzi et al. (21).

347 The investigation of the aerosolization of mycotoxins produced on wallpaper firstly
348 showed that aerosolization of particles from substrate strongly differed from one species to
349 another, possibly related to mycelium organization and conidial structures. As an illustration,
350 both *A. versicolor* and *P. brevicompactum* are fungal species characterized by the presence of
351 small and light spores organized in chains at the extremity of phialides (41). For these two
352 species, air velocity of 2 m/s, which matches air speed observed due to mechanical and
353 natural ventilation in tertiary buildings (28), allowed the aerosolization of numerous particles

354 from wallpaper. These particles were distributed in two main categories: one including very
355 small particles, smaller than 0.15 μm , and the second including particles ranging from 2 to 6
356 μm . This second group may correspond to spores, groups of spores or mycelium debris (40,
357 41), in agreement with previous data on aerosolization of these fungal species (42–44). One
358 can note that for *P. brevicompactum*, the total number of particles aerosolized from substrate
359 was higher than for *A. versicolor*. This is in relation with the disposition of spores on mycelial
360 structures. In *P. brevicompactum*, long chains of spores are borne by aerial conidiophores and
361 may easily be aerosolized. For *A. versicolor*, spores' chains are shorter and located on tight
362 and compact phialides, making them mildly more difficult to aerosolize from material.

363 For *S. chartarum*, a higher air velocity was required for aerosolization from substrate.
364 An air velocity of about 6 m/s is more frequent outdoor but could also be encountered in
365 buildings due to mechanical ventilation (28). The use of fans may also generate airflows able
366 to aerosolize *S. chartarum*. Of note, the total number of airborne particles was lower than that
367 observed for other species and this may explain why this fungal species is not commonly
368 observed in air samples and is more frequently found by direct examination of building
369 materials (12–14). In case of a sufficient airflow, a poly-dispersed particle cloud was
370 generated from *S. chartarum* contaminated substrate. There was an important cluster made of
371 particles ranging from 0.4 to 1 μm , which are therefore smaller than spores. It could
372 correspond to micro-fungal particles, debris of wallpaper released from substrate due to
373 cellulolytic activity of *S. chartarum*, or exudate droplets from culture (45). Such finding is
374 important since these small particles could easily penetrate deeply in human respiratory tract
375 in case of inhalation.

376 All tested mycotoxins were found in aerosols generated from mouldy wallpaper and the
377 proportion transferred to air varied with fungal species. MPA was the most aerosolized, with
378 15 % of the produced toxin. This is related to the higher facility of *P. brevicompactum* to be
379 aerosolized from substrate compared to other species. By contrast, the proportion of airborne

380 STG was low (0.2 %). Since numerous particles can be released from substrate contaminated
381 with *A. versicolor*, this suggests that STG could be located in fungal parts that are strongly
382 adherent to the substrate and probably mainly present/located in mycelium (5, 7). However,
383 considering that STG was the major produced toxin, the quantity of airborne STG was
384 comparable to MPA.

385 For MCT, even if the required air speed for aerosolization was higher, it has to be
386 highlighted that the four analyzed toxins were found in aerosols and total aerosolized toxic
387 load was 5 times higher than that of other toxins.

388 The analysis of the toxin distribution according to the aerosol profile and size of released
389 particles also brought some important information. For MPA and STG, maximal toxic load
390 was found on particles whose size corresponds to spores, groups of spores or mycelium
391 debris. However, low proportion of MPA was also found on particle smaller than spores. It
392 could be related to the excretion of part of the toxin in exudate droplets as previously
393 demonstrated for other *Penicillia* (46). The excreted toxin could be then adsorbed on small
394 particles of dust.

395 The distribution of MCT was different. Toxins were found in all stages of Andersen
396 collector, even those collecting particles smaller than spores. This result is in agreement with
397 a study by Brasel et al. (29). As for *P. brevicompactum*, it could be the result of the excretion
398 of MCT by fungus in droplets outside the mycelium (45) and their adsorption on dust
399 particles or wallpaper debris generated by cellulolytic activity of *S. chartarum*.

400 Of note, the analyzed MCT differed regarding their distribution in the various particles
401 sizes. This result suggests that the different MCT analyzed in this study could be differently
402 distributed/excreted within fungal structures. Further studies are required to characterize the
403 distribution of macrocyclic trichothecenes in *S. chartarum* mycelium. It would help better
404 understanding the biosynthetic pathway and processing of these compounds in fungal cells.

405 All these results on aerosolization of mycotoxin according to particle size bring
406 important insight for risk assessment and possible subsequent toxicity after inhalation.
407 Although no clear dose-effect relationship has been established for these mycotoxins in case
408 of inhalation, it has been demonstrated that intranasal exposure could be highly toxic. For
409 instance, Carey et al. (47) showed that exposure to 5 µg SG for 4 days led to widespread
410 apoptosis of olfactory sensory neurons and to epithelial and olfactory nerve atrophy as well as
411 acute neutrophilic rhinitis in Rhesus monkey.

412

413

414 **CONCLUSION.** This study demonstrated that during their growth on wallpaper, *P.*
415 *brevicompactum*, *A. versicolor* and *S. chartarum*, that are frequently found indoor, produce
416 mycotoxins. These toxins can subsequently be aerosolized, at least partly, from mouldy
417 material. This transfer to air requires air velocities that can be encountered in building since
418 they correspond to movement of people in a room (0.2 m/s), air speed in ceiling diffusers (2
419 m/s), slamming door, air drafts from opening the window or mechanical ventilation (6 m/s).

420 Most of the aerosolized toxic load is found in particles whose size corresponds to spores
421 or mycelium fragments. However, for MPA and mainly MCT, toxins were found also on
422 particles smaller than spores, that could be easily inhaled by occupants and deeply penetrate
423 into respiratory tract. It seems important to take these data in consideration for risk
424 assessment related to fungal contamination of indoor environment and the possible toxicity
425 associated to inhalation of these toxins.

426

427

428 **Acknowledgements**

429 The authors would like to thank Professors JJ Pestka (Department of Microbiology and
430 Molecular Genetics, Michigan State University, USA) for toxins' standards; Dr J.B. Nielsen

431 (Technical University of Denmark, Lyngby, Denmark) for strain of *P. brevicompactum* and
432 Dr O. Puel (INRA, UMR Toxalim) for strain of *A. versicolor*.

436 **Funding sources**

437 This work was financed by the French Ministry of Ecology, Sustainable Development
438 and Energy (PRIMEQUAL project DSC-BIO/2013-121) and by the French Environment and
439 Energy Management agency (ADEME) and the Scientific and Technical Centre for Building
440 (CSTB) (Ph.D. grant for B. Aleksic).

441

442 **Author contribution statements**

443 Brankica Aleksic performed experiments and participated to the article redaction;
444 Marjorie Draghi and Sebastien Ritoux designed the device to study aerosolization of particles
445 and mycotoxins from mouldy wallpaper; Sylviane Bailly did the morphological analysis of
446 wallpaper after fungal development and participated to the development of the analytical
447 method for mycotoxin measurement; Marlène Lacroix did the toxin measurement on both
448 wallpaper and aerosols; Isabelle P. Oswald participated to the overall supervision of the
449 project and to the redaction of the article; Jean-Denis Bailly and Enric Robine supervised the
450 work and participated to the redaction of the article, Enric Robine took the SEM photos.
