## Abstract

The use of high strength Al-Zn-Mg-Cu alloys in automotive components is restricted by their low formability. Warm forming in the under-aged state improves formability, but induces a strain-dependent microstructure evolution due to dynamic precipitation. We present a new methodology to quantitatively evaluate the dynamic precipitation strain dependence which is applicable to strain rates relevant to forming. The plastic strain is varied using a tapered tensile sample and the precipitation state is measured in terms of size and volume fraction using spatially resolved small-angle X-ray scattering, showing its evolution during straining is dependent on the imposed strain level and rate.

Keywords: aluminum alloys, precipitation, dynamic phenomena, small angle X-ray scattering (SAXS)

Aluminium alloys from the 7xxx series (Al-Zn-Mg-Cu) are traditionally used in aerospace components due to their high level of yield strength [1,2]. This strength is related to a precipitation sequence which involves clustering and the formation of GP zones at room temperature, followed by transformation to the metastable  $\eta'$  phase at the peak strength and finally the transformation to the  $\eta$  phase during over-ageing [3–6]. The use of these alloys is also of interest for automotive applications where high strength alloys could lead to significant weight savings which is a viable strategy to reduce the environmental impact of automobiles while maintaining crash worthiness [7,8]. However, the use of 7xxx alloys in automotive components is restricted by their low formability in the T6 temper at ambient temperature [9–11]. In order to overcome that limitation, warm forming of alloys such as 7020, 7150, 7921 and 7075 alloys has been investigated and proven to enhance their formability [9–16]. In particular, some of these studies reported that the formability of 7075 alloy in the T6 condition is significantly improved around 200°C [9,11,12]. Only recently has there been some attention on the consequences of warm forming on the materials hardening phases and therefore on the final properties of the formed parts [10,11,14–16]. In order to benefit from improved ductility during forming without a loss of the material strength in the final part, recent research has proposed warm forming in the underaged state of these alloys [10]. This opens the possibility for dynamic precipitation which has previously been shown to occur in the 7XXX aluminum alloy series [17–19]. Dynamic precipitation during warm forming could be used to transform

1  
2  
3  
4 an underaged material to its peak strength concurrent with the forming. However, one of critical issues  
5 would be the effect of strain on dynamic precipitation [20–22], i.e. during forming of actual part, there  
6 would be wide range of local strains and strain rates. This is important since this inhomogeneity of strain  
7 and resulting effect on dynamic precipitation would translate to inhomogeneous properties in the final  
8 product.  
9

10  
11 Previous studies have shown that small angle X-ray scattering (SAXS) has the capability to accurately  
12 quantify the state of precipitation in 7xxx alloys. Thus, it is proposed that SAXS is a promising technique  
13 to evaluate the influence of initial microstructure, strain and strain rate, and deformation temperature  
14 [19–21] on the characteristics of dynamic precipitation. For example, SAXS studies have shown that  
15 deformation accelerates the precipitation of GP zones at room temperature [17,19] and the growth and  
16 coarsening of precipitates during artificial ageing [21]. The role of strain-induced excess vacancies has  
17 been proposed to explain the strain rate dependence of dynamic precipitation during monotonic  
18 straining at artificial ageing temperatures [21] as well as during room temperature cyclic straining [19].  
19 The introduction of *in-situ* tensile SAXS experiments during the 2000's [17,20] introduced a technique to  
20 follow the evolution of precipitate characteristics during deformation and therefore to evaluate  
21 precisely the strain-dependence of this process. However, such *in-situ* experiments are restricted to  
22 relatively low strain rates ( $\approx 10^{-3} \text{ s}^{-1}$ ), which are unrealistic for the application to warm forming of  
23 automotive components where strain rates are several orders of magnitude higher ( $\approx 0.1\text{-}10 \text{ s}^{-1}$ ). In this  
24 paper, we present a new methodology to analyze the strain dependence of dynamic precipitation to  
25 high strain rates. The strain level was continuously varied on a single tapered tensile sample, and the  
26 post-straining precipitation state was quantitatively evaluated using spatially-resolved small-angle X-ray  
27 scattering. These SAXS experiments permit a better understanding of the interplay between forming  
28 parameters, microstructure and properties of the warm formed products.  
29

31  
32  
33  
34

35 In the current work, the aluminum alloy 7068 was studied, (composition is given in **Table 1**).  
36 Axisymmetric tapered tensile samples (**Figure 1**) were machined from a 10 mm thick hot rolled plate.  
37 The samples had a symmetric gauge section whose diameter varied from 4.674 mm to 3.8 mm with a  
38 radius of curvature equal to 280 mm. The heat treatment of the samples involved a solution treatment  
39 at 753 K for 3.6 ks, followed by water quenching and then an artificial ageing step of 5.4 ks at 378 K to  
40 produce an underaged precipitation state. These tensile samples were loaded in the servo-hydraulic test  
41 frame (MTS 810 load frame), were heated to the test temperature of 448 K at constant heating rate of  
42 0.4 K/s, while the whole test set-up (tensile grips and specimen) was surrounded by insulation to ensure  
43 the test temperature homogeneity and stability during the experiment. Deformation at two different  
44 stroke rates (0.02 and 20 mm/s) was commenced as soon as the test temperature was reached with the  
45 maximum plastic strain reaching 0.145 and 0.181, respectively. After the test, the sample was  
46 immediately air quenched to room temperature (around 60 s to go from 448 K, at the end of  
47 deformation, to below 353 K). Since the specimen is not observable during deformation because of the  
48 set-up insulation, Digital Image Correlation (DIC) could not be used. Instead, a measurement of the total  
49 strain distribution along the sample axis was obtained by measuring, before and after deformation, the  
50 distances between adjacent grid points (4 lines parallel to the tensile axis all around the specimen  
51 crossed by perpendicular lines) which had been placed on the sample. Then, a 100  $\mu\text{m}$  thin slice parallel  
52 to the loading axis was produced from each tensile sample for the SAXS measurements by mechanical  
53 grinding and polishing. SAXS experiments were conducted on a laboratory instrument using a rotating  
54 anode with a Cu target and a Pilatus 2D detector. The beam width on the sample, which defines the  
55 spatial resolution of the precipitate characterization along the sample, was 0.5 and 1.0 mm for the  
56 samples deformed at 0.02 and 20 mm/s, respectively. The SAXS 2D-data was radially averaged and

**Table 1: Chemical composition of the studied 7068 aluminum alloy.**

**Figure 1: Samples geometry (all dimensions in mm).**

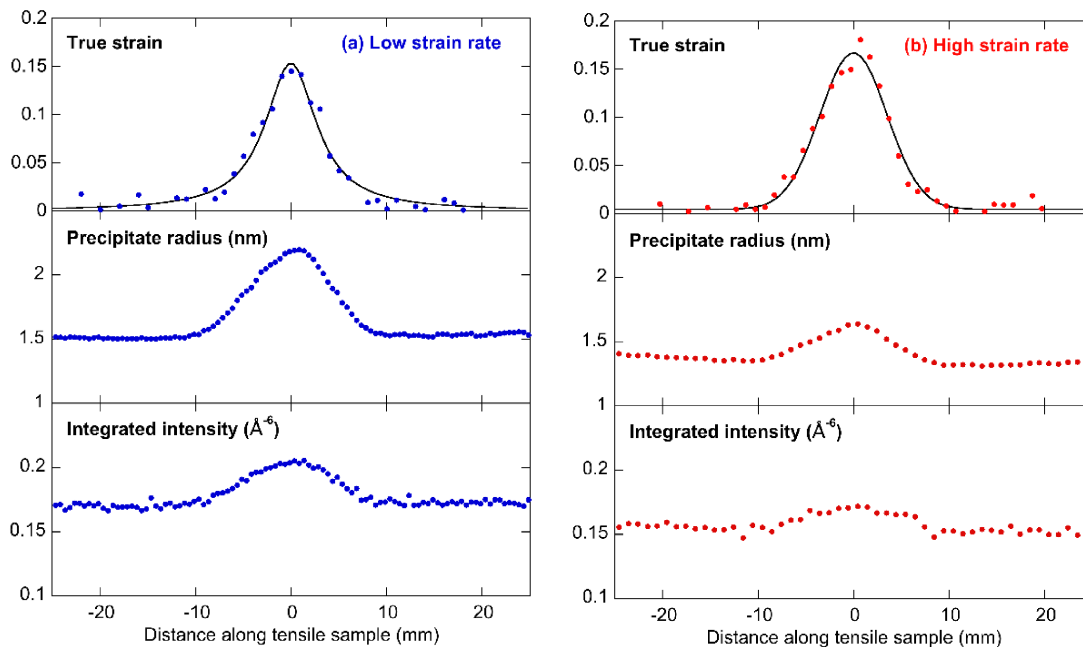

**Figure 2: Evolution of the Kratky representation ( $Iq^2$  vs.  $q$ ) along the tensile axis ( $x$ ) for the underaged 7068 samples deformed at 448 K at  $0.02 \text{ mm.s}^{-1}$  (a) and  $20 \text{ mm.s}^{-1}$  (b).**

**Note:  $x = 0$ , is the centre of the sample shown in Figure 1.**

**Figure 2** displays the results obtained during the SAXS experiments from the samples deformed at low and high stroke rate. These two graphs are Kratky representations of the azimuthally averaged scattered intensities measured along the samples. In this type of representation, the position of the maximum of  $Iq^2$  for different positions along the sample gauge length ( $x$ ) is inversely proportional to the average radius of the precipitates and the integrated intensity  $Q_0$  is proportional to the precipitate volume fraction [23]. This data illustrates that plastic deformation has a strong effect on the state of precipitation since these curves are markedly different in the central region (i.e. near  $x=0$ ) where the maximum level of deformation occurred, i.e. the maximum value of  $Iq^2$  is much larger for the sample

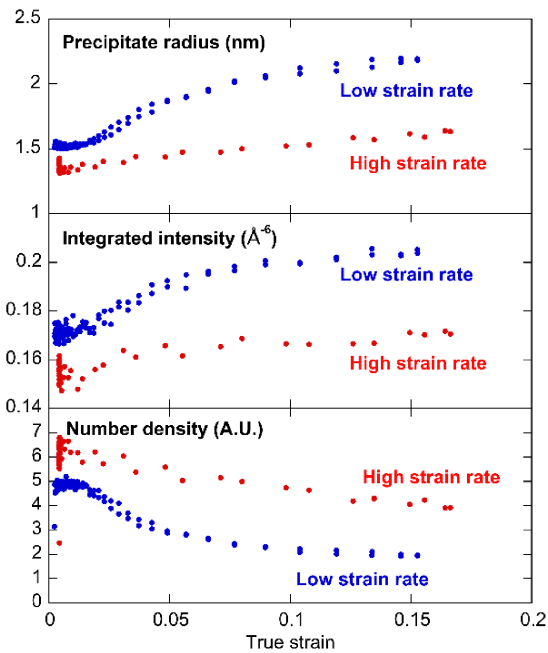

deformed at 0.02 mm/s compared to 20 mm/s, with maximum of  $Iq^2$  equal to  $1.78 \times 10^5 \text{ nm}^{-5}$  and to  $1.17 \times 10^5 \text{ nm}^{-5}$  respectively. Qualitatively, the general results can be deduced from the Kratky plots in Figure 2. At the ends of the samples, greater than  $\pm 20 \text{ mm}$  from the centre, where the diameter is the largest (4.67 mm), no plastic deformation occurs and precipitation is homogeneous as indicated by similar Kratky plots. As one moves towards the centre of the sample, the average size of the precipitates increases gradually with increasing strain level, i.e. the plastic strain increases as the diameter of the tensile sample decreases. Further, it is noted this effect is larger for the stroke rate of 0.02 mm/s compared to 20 mm/s. In the following, the Guinier radius,  $R_g$ , calculated in a self-consistent manner as described in [23] and the integrated intensity  $Q_0$  will be used to quantify the state of precipitation. For further details regarding the analysis of precipitation state using SAXS data, the reader is referred to the corresponding literature [23–25].

**Figure 3: Evolution of the local plastic strain, precipitates' Guinier radius and integrated intensity scattered by precipitates along the tensile axis for the underaged 7068 samples deformed at 448 K at  $0.02 \text{ mm.s}^{-1}$  (a) and  $20 \text{ mm.s}^{-1}$  (b). The local plastic strain measurements (dots) are represented together with the fit of their evolution with distance (pseudo-Voigt function) in black.**

**Figure 4: Evolution of the precipitates Guinier radius, the associated integrated intensity and the resulting number density of precipitates with the plastic strain for the underaged 7068 samples deformed at 448 K at  $20 \text{ mm.s}^{-1}$  (in red) and  $0.02 \text{ mm.s}^{-1}$  (in blue).**

**Figure 3** shows the precipitate characteristics,  $R_g$  and  $Q_0$ , and the plastic strain measurements along the length of the tensile samples for deformation conditions of 0.02 and 20 mm/s. It can be observed in the upper figure that going from left to right on the sample, the plastic strain increases from zero to a maximum of 15-20% and then decreases to zero again. This could be fit by pseudo-Voigt function [26,27]. Note, the maximum strain in the sample deformed at 20 mm/s was slightly larger than that of 0.02 mm/s, i.e. 0.181 vs 0.145, respectively. Turning to the state of precipitates, the first thing to notice is that SAXS measurements show that in the undeformed portion of the sample (i.e. greater than  $\pm 10$  mm) precipitates have a slightly larger radius (1.52 vs 1.36 nm) and a slightly higher volume fraction (higher  $Q_0$  of  $1.71$  vs  $1.55 \times 10^5 \text{ nm}^{-6}$ ) for the sample deformed at 0.02 mm/s. This can be attributed to the fact that the time required to conduct the deformation (and hence the time at temperature) at this low crosshead speed was longer, i.e. the material was aged at 448 K for 73 s for the deformation at 0.02 mm/s vs  $< 1$  s for the deformation at 20 mm/s and precipitate growth during this time would explain the difference.

1  
2  
3  
4 Next, it can be observed that even though the maximum strain reached in the case of the deformation  
5 at 20 mm/s is slightly higher than for the case of 0.02 mm/s, the increase in the precipitate radius at the  
6 centre of the sample compared to the shoulder of the sample is only 1.32 to 1.64 nm, compared to 1.50  
7 to 2.20 nm for the sample deformed at 0.02 mm/s. Further, the evolution of  $Q_0$  follows the same trend.  
8 The observation that the evolution of precipitate state depends on strain rate is consistent with what  
9 was measured previously by Deschamps et al. during the deformation of a 7010 alloy, albeit at much  
10 slower strain rates,  $4.10^{-3} \text{ s}^{-1}$  and  $2.10^{-4} \text{ s}^{-1}$ , and at room temperature [17]. To see the relationship  
11 between plastic strain and the state of precipitation derived from SAXS, the data can be cross-plotted by  
12 taking the precipitate state and the plastic strain measurement at the same spatial location in the  
13 sample (**Error! Reference source not found.**) using the pseudo-Voigt fit of the plastic strain (black line on  
14 the top graphs from **Figure 3**).

15  
16  
17  
18 **Error! Reference source not found.** displays the dependence of both  $R_g$  and  $Q_0$  with plastic strain  
19 recalling that  $Q_0$  is proportional to the precipitate volume fraction. The robustness of the measurements  
20 can be demonstrated by noting that the measurements from either side of the sample centre give very  
21 similar results (this is most clearly seen in the pairs of data points in the high strain rate sample). These  
22 results also illustrate the strong effect of plastic strain on precipitation, with a monotonic evolution of  
23 both size and precipitate volume fraction as a function of strain. Further, it can be clearly observed that  
24 the increase in precipitate radius or volume fraction during deformation is much greater for sample  
25 deformed at a slower speed. It is worth emphasizing that this is not just an effect of extra time which, as  
26 was previously mentioned, caused a change in radius of only  $\approx 0.1 \text{ nm}$  compared to difference of  $0.7 \text{ nm}$   
27 which was found in the sample deformed at  $0.02 \text{ mm/s}$ . It is also useful to consider the evolution of  
28 precipitate number density as function of plastic strain. This is shown in Figure 4 in arbitrary units and  
29 was calculated from  $Q_0$  and  $R_g$ , i.e.  $Q_0/R_g^3$ . The continuous decrease in precipitate number density during  
30 straining suggests that nucleation does not occur during these experiments, and, thus, that the main  
31 role of plastic strain is to accelerate precipitate growth and coarsening.

32  
33  
34  
35  
36  
37  
38 This observation would be consistent with the role of excess vacancies created by plastic straining on  
39 the diffusion rate of solutes [21]. A comparison of the two stroke rates shows that the rate of dynamic  
40 precipitation is strain rate dependent. Such a dependence was not observed by Fribourg et al. [20],  
41 although for lower strain rates as compared to the present study. They attributed their results to the  
42 competition between a shorter time available for dynamic precipitation and a higher rate of vacancy  
43 generation at high strain rates. On the other hand, Hutchinson et al. [19] showed a strain rate  
44 dependence in the case of low cycle fatigue, which they ascribed to the competition between vacancy  
45 generation and annihilation. Clearly the effect of strain rate on dynamic precipitation is a complex issue,  
46 which needs to be investigated in a wide range of experimental conditions.

47  
48  
49  
50 One limitation of the methodology is the variation of strain rate along the gauge length of the sample.  
51 One cannot assess experimentally the evolution of strain rate along the sample due to the inability to  
52 view the sample during the test because of the insulation surrounding the sample. However one can  
53 compute the average strain rate at the sample centre by taking the maximum strain divided by the time  
54 of test, which yields  $\approx 1.6 \times 10^{-3} \text{ s}^{-1}$  and  $\approx 1.8 \text{ s}^{-1}$  for tests done at  $0.02 \text{ mm/s}$  and  $20 \text{ mm/s}$  respectively. As  
55 one moves from the centre towards the end of the sample, the plastic strain decreases and thus, the  
56 corresponding strain rate decreases, for example, at a plastic strain of 0.05, the average strain rate for  
57 the deformation would be  $0.5 \text{ s}^{-1}$  and  $5.6 \times 10^{-4} \text{ s}^{-1}$ . It is proposed that this factor of  $\approx 3$  decrease in strain  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 rate is a second order effect compared to the overall difference in strain rate of  $\approx 1000$  between the two  
5 test conditions.  
6

7  
8 Further, our results show a negative dependence of the dynamic precipitation kinetics to strain rate,  
9 therefore the effect of strain on dynamic precipitation demonstrated along our samples of variable  
10 section is a lower bound of the same effect that would be obtained at constant strain rate. Moreover,  
11 the situation of an imposed strain (vs. an imposed strain rate) is close to that found during metal  
12 forming.  
13

14  
15 In summary, the methodology presented in this work opens the way for an efficient characterization of  
16 the strain dependence of dynamic precipitation in aluminum 7XXX alloys over a wide range of  
17 deformation rates and deformation levels. In particular, this allows for the investigation of precipitate  
18 evolution during warm forming i.e. involving very high strain rates that cannot be achieved during in-situ  
19 experiments. The results show that even at very high strain rates, dynamic precipitation occurs in under-  
20 aged 7XXX aluminum alloys, although the observed effect is smaller than that observed at lower strain  
21 rates. This methodology opens the way for a systematic investigation of the effect of the salient  
22 parameters such as strain rate, initial temper, temperature and alloy composition on the strain  
23 dependence of dynamic precipitation and its consequences on mechanical properties.
