ABSTRACT

Early-time observations of the Type II supernovae (SNe) 2013cu and 2013fs have revealed an interaction of ejecta with material near the star surface. Unlike the Type IIn SN 2010jl, which interacts with a dense wind for ~ 1 yr, the interaction ebbs after 2–3 d, suggesting a dense and compact circumstellar envelope. Here, we use multi-group radiation-hydrodynamics and non-local-thermodynamic-equilibrium radiative transfer to explore the properties of red supergiant (RSG) star explosions embedded in a variety of dense envelopes. We consider the cases of an extended static atmosphere or a steady-state wind, adopting a range of mass loss rates. The shock-breakout signal, the SN radiation up to 10 d, and the ejecta dynamics are strongly influenced by the properties of this nearby environment. This compromises the use of early-time observations to constrain R_* . The presence of narrow lines for 2–3 d in 2013fs and 2013cu require a cocoon of material of $\sim 0.01 M_\odot$ out to $5-10 R_*$. Spectral lines evolve from electron-scattering to Doppler broadened, with a growing blueshift of their emission peaks. Recent studies propose a super-wind phase with a mass loss rate from 0.001 up to $1 M_\odot \text{ yr}^{-1}$ in the last months/years of the RSG life, although there is no observational constraint that this external material is a steady-state outflow. Alternatively, observations may be explained by the explosion of a RSG star inside its complex atmosphere. Indeed, spatially resolved observations reveal that RSG stars have extended atmospheres, with the presence of downflows and upflows out to several R_* , even in a standard RSG like Betelgeuse. Mass loading in the region intermediate between star and wind can accommodate the $0.01 M_\odot$ needed to explain the observations of 2013fs. Signatures of interaction in early-time spectra of RSG star explosions may therefore be the norm, not the exception, and a puzzling super-wind phase prior to core-collapse may be superfluous.

Key words. radiative transfer – radiation hydrodynamics – supernovae: general – supernovae: individual: 2013fs.

1. Introduction

Radiation-hydrodynamic simulations of Type II supernovae (SNe) in the 1970s indicated that their progenitors were red-supergiant (RSG) stars (Grassberg et al. 1971; Falk & Arnett 1977). More recently, the analysis of pre-explosion images has confirmed this (Smartt 2009). The RSG progenitor properties are however uncertain because of the limitation in our understanding of the physics of RSG envelopes (e.g., in connection to convection; see, e.g., Meakin & Arnett 2007; Arnett et al. 2010), RSG atmospheres and environments (e.g., in connection to mass loss, dust/molecule formation, etc.; Josselin & Plez 2007), or their final core properties at collapse (Couch et al. 2015; Müller et al. 2016).

Single massive stars lose mass through a radiation-driven wind (Castor et al. 1975; de Jager et al. 1988). It is therefore unsurprising that a fraction of SNe exhibit signatures of ejecta interaction with circum-stellar material (CSM). The unambiguous signature of interaction with an optically-thick CSM moving at very slow speeds with respect to the SN ejecta is the observation of optical emission lines with narrow cores and broad electron-scattering wings. The frequency of such interactions is uncertain but is probably of the order of 5-10% of Type II SNe (e.g., Smith et al. 2011). Such events are classified as Type IIn SNe (Schlegel

1990). SNe IIn come, however, with a huge diversity of properties in light curves and spectra. Some show signatures of interaction for a few days (e.g., SN 2013cu, Gal-Yam et al. 2014), a few weeks (SN 1998S, Fassia et al. 2000; Leonard et al. 2000), or a few months (SN 2010jl, Zhang et al. 2012; Fransson et al. 2014), together with a wide range of luminosities. Numerical simulations of interacting SNe connect this diversity to variations in CSM location and structure (Moriya et al. 2011; Dessart et al. 2015). To avoid confusion, CSM refers here to circumstellar material detached from the star and typically located at large distances of $10-100 R_*$. For events in which the signatures of interaction are seen on the discovery spectrum but disappear after a few hours or a few days, like in SN 2013cu, we will refer to the atmosphere and/or wind – this material corresponds to the direct environment of the star, contiguous to the star surface (often referred to as the circumstellar envelope), rather than a standard CSM.

SN 2013fs is a recent example that illustrates the complexity and diversity of such interactions. This SN shows signatures of interaction for only ~ 2 d after explosion, while it resembles a very standard type II-P SN at $\gtrsim 10$ d (plateau light curve in visual bands; standard P-Cygni profiles for H I lines; Yaron et al. 2017). Signs of interaction have been observed at

early times in other Type II SNe (Khazov et al. 2016), although most of these do not show the 100-day long plateau light curve of SNe II-P. A prototypical, well observed, event showing narrow line profiles for 10–20 d after discovery and becoming a more standard Type II event with broad lines is SN 1998S (Leonard et al. 2000; Fassia et al. 2001). Simulations suggest the early line broadening mechanism is dominated by electron scattering (Chugai 2001; Shivvers et al. 2015; Dessart et al. 2016). By 20 d, the atmosphere/wind is optically thin and the spectrum forms in a fast expanding region with a steeply declining density profile (i.e., at the interface between progenitor and atmosphere/wind), leading to a featureless (and blue) continuum. At later times during the photospheric phase, the spectrum exhibits a ‘standard’ type II (non-interacting) SN spectrum with signs of line blanketing, P-Cygni profiles, and excess emission associated with the optically-thin cold-dense-shell. These three phases are well traced with radiation-hydrodynamic and non-local-thermodynamic-equilibrium (non-LTE) radiative-transfer modeling. In particular, the simultaneous presence of Doppler-broadened lines forming in the ejecta and narrow lines broadened by electron scattering in the atmosphere/wind is reproduced if the non-monotonicity of the velocity field is explicitly accounted for (Dessart et al. 2016).

The presence of an atmosphere/wind may also be inferred from the short-lived shock breakout signal. In a shock-driven explosion, the radiation-dominated shock will start to leak photons when the photon diffusion time at the shock $t_{\text{diff}} = 3\tau\Delta R/c$ becomes comparable to the shock crossing time $t_{\text{shock}} = \Delta R/v_{\text{shock}}$ through the outer layers of thickness ΔR of the progenitor star.¹ This shock breakout signal therefore starts at the optical depth $\tau \sim c/3v_{\text{shock}}$.² For the $\sim 10^{51}$ erg Type II SN explosions presented here, the shock speed is about 5000 km s^{-1} , so that the breakout signal will start from an optical depth of about 20. The actual duration of the shock breakout signal scales with ΔR , which is the length scale between the photosphere and $\tau = 20$. Depending on the RSG atmosphere/wind structure, this length scale may perhaps cover from 0.01 to $0.5R_*$. For a small scale height, the breakout signal is intrinsically short ($\lesssim 1000$ s). However, the timescale is stretched to at least R_*/c , hence about 30 min, for a distant observer. KSN 2011d is the first type II SN to exhibit this shock breakout signal (Garnavich et al. 2016), which indicates the absence of a dense wind or an extended atmosphere around its progenitor RSG. For a large scale height (as in the case of a dense wind), the duration can be hours, hence typically well in excess of R_*/c . The observations of a 1-day long UV burst in PS1-13arp by Gezari et al. (2015) suggests that the shock may have broken out into some dense and extended material. Observations as part of SHOOT by Tanaka et al. (2016) reveal a very short optical rise time that supports such a phenomenon. By lengthening the duration of the shock-breakout signal, the presence of a dense atmosphere/wind may facilitate its detection. Although very challenging, high-cadence surveys with a high limiting magnitude can capture the fleeting moment of shock breakout. The HITS survey (Förster et al. 2016) or SHOOT (Tanaka et al. 2016) have not yet been successful, but the KEPLER mission has made one unambiguous detection (Garnavich et al. 2016) – high cadence surveys that

fail to capture shock breakout do reveal critical information on the early phase evolution of the SN radiation.

Signatures of interaction with the atmosphere/wind may be short-lived and therefore generally missed by a delayed spectroscopic follow-up. Numerous events may therefore be classified as Type II-P (or II-L) while an earlier spectroscopic classification would have suggested a classification as Type II_n. One should however wonder whether a SN should be classified as a II_n because it shows narrow lines for a day or two, or as a II-P because it shows a 100-d long plateau with all the spectral characteristics of a standard SN II-P at all times past two days. Should the event be classified as a Type II_n if the narrow lines were seen for only one hour? This is not irrelevant. Once a SN has been classified as a Type II_n, it contributes to the number of events considered as interacting SNe, mixed in the sample with objects that show signs of interaction at all times, like SN 2010jl. Hence, it has strong implications for the interpretation of SN rates.

Based on the presence of early-time spectral signatures of interaction, Khazov et al. (2016) and Yaron et al. (2017) propose that numerous SNe II-P may undergo a super-wind phase before core collapse. Recently, Morozova et al. (2017) argue for such super-wind phases and propose that the resulting ejecta/wind interaction may explain the difference between Type II-L and Type II-P light curve morphologies. Very early observations were obtained with the Type IIb SN 2013cu, for which Gal-Yam et al. (2014) propose that the spectrum at 15.5 hr forms in the dense ($\dot{M} \gtrsim 0.03 M_{\odot} \text{ yr}^{-1}$) and fast (terminal velocity of 2500 km s^{-1}) wind of a Wolf-Rayet progenitor star. This interpretation rests partly on the idea that line broadening is caused by the Doppler effect. Instead, line broadening is likely caused by electron scattering. In this case, Groh (2014) propose a slow ($\lesssim 100 \text{ km s}^{-1}$) and dense ($3 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$) wind. This has been later refined by Gräfener & Vink (2016) who accounted for time delays. They propose a significant increase on the wind mass (to be at least $0.3 M_{\odot}$), and that the shock may be embedded within the optically-thick wind (whose outer edge is the photosphere) for two weeks. However, the narrow line profiles seen in SN 2013cu are strong at 15.5 hr after discovery, but weak at 3 d and absent at 6 d so the bulk of the dense (optically-thick) material is probably swept-up already after a few days. A total wind mass of $0.3 M_{\odot}$ is close to what is found for SN 1998S, and narrow lines profiles are seen for much longer ($\gtrsim 10$ d). In any case, despite slight differences in interpretation and modeling techniques, these studies argue for a super-wind phase immediately prior to the core collapse of SN 2013cu’s progenitor. These observations question whether there is something fundamentally missing in the 1-D quasi-steady-state treatment of stellar evolution and stellar winds. The eruptions observed in some very massive stars like η Car and the inference of ejecta interaction with a massive CSM in super-luminous SNe II_n give evidence in that direction.

Here, we use 1-D radiation-hydrodynamics and 1-D non-LTE radiative transfer modeling to characterize the bolometric, photometric, and spectroscopic signatures of RSG explosions embedded in an atmosphere/wind of modest extent (within $\sim 10 R_*$) and mass ($\lesssim 10^{-1} M_{\odot}$). Previous studies that have focused on ejecta/wind interactions used either grey/multi-group radiation-hydrodynamics without spectral calculations (Moriya et al. 2011; Morozova et al. 2017), or spectral calculations without dynamics (Yaron et al. 2017).

The structure of the paper is as follows. In the next section, we discuss the properties of the environment of RSG stars. We then present our numerical approach in Section 3. In Section 4, we discuss the results from the multi-group radiation-

¹ This diffusion time is representative for a random walk in a 3-D space of uniform density and constant photon-mean-free-path.

² Strictly speaking, the presence of a precursor is given by the local conditions at the shock. In the SN community, the term ‘precursor’ is usually meant as the precursor to shock emergence and explosion, and it stands more broadly for the shock-breakout signal.

Fig. 1. Initial density structure used in HERACLES for models r1w1, r1w2, r1w3, r1w4, r1w1h, r1w5h, r1w5r, r1w6, and r2w1. Model m15mlt3 (r1) is used for the ejecta of model r1w[1-6][h,p,r] and model m15mlt1 (r2) for the r2w1, taken at a few hours before shock breakout (Dessart et al. 2013). The atmosphere/wind density is built using a variety of wind mass loss rates and atmospheric scale heights. All models transition to a wind mass loss rate of $10^{-6} M_{\odot} \text{ yr}^{-1}$ beyond $2\text{--}5 \times 10^{14} \text{ cm}$ ($\equiv 5\text{--}10 R_{\star}$). [See Section 3 and Table 1 for details.]

hydrodynamics simulations with HERACLES, focusing on the properties of the bolometric light curves and the dynamic structure of the interaction between the SN ejecta and the progenitor atmosphere/wind (velocity, density, temperature, optical depth). These simulations are post-processed with CMFGEN using a non-LTE steady-state approach that works for an arbitrary velocity field. The resulting multi-band light curves and spectra are discussed in Section 5. We compare our results to observations in Section 6. We present our conclusions in Section 7.

2. The environment of red-supergiant stars

The complexity of RSG atmospheres prevents a physically consistent description of the density profile above the RSG surface radius (i.e., the location corresponding to R_{\star} in a stellar evolution model, as produced for example in MESA). RSG atmospheres are very complex, with density inhomogeneities, up-flows and down-flows seen out to several stellar radii (Kervella et al. 2009, 2011; Ohnaka et al. 2011; Kervella et al. 2016). These observations suggest that there is no well defined atmosphere and that the wind is not launched cleanly from R_{\star} but is instead slowly accelerated over an extended region.

A RSG model computed by a stellar evolution code (here MESA, but the point applies to all such codes) extends out to a minimum density of $10^{-9} \text{ g cm}^{-3}$, while the base density of a $10^{-5} M_{\odot} \text{ yr}^{-1}$ RSG wind is around $10^{-14} \text{ g cm}^{-3}$. There is therefore a density drop of 5 orders in magnitude between the R_{\star} from MESA and the actual wind. It is in this intermediate region, whose properties are poorly known both observationally and theoretically, that the SN spectrum will form during the first few days after explosion (between roughly 0.5 and $2 \times 10^{14} \text{ cm}$). In the present study, we assume that the distribution of this surrounding material is spherically symmetric around the star.

In the next section, we present two types of density structures for the near environment of the RSG star: an atmosphere with an extended scale height and/or a dense wind. Early-time observations of Type II SNe do not allow one to constrain the pre-SN velocity structure of this material, hence cannot firmly establish

the steady-state nature of a wind. They cannot either determine whether the atmospheric material is in hydrostatic equilibrium. This results in part from the limitations of observations, which may not have a high enough resolution. But it also stems physically from the acceleration produced by the intense radiation associated at shock breakout and after. Hence, these early-time SN observations only constrain the extent and density/mass of this material. Spatially-resolved observations of RSG clearly show that the environment of RSG is neither static nor steady-state (Kervella et al. 2009, 2011; Ohnaka et al. 2011; Kervella et al. 2016).

3. Initial conditions and methodology

3.1. Initial conditions

The initial ejecta structure, corresponding to the RSG star explosion, is taken from Dessart et al. (2013). We choose models m15mlt3 (here renamed r1; $R_{\star} = 501 R_{\odot}$) and m15mlt1 (here renamed r2; $R_{\star} = 1107 R_{\odot}$) in order to cover explosions from compact and extended RSG stars. In practice, the initial ejecta structure (radius, velocity, density, temperature) is taken from the radiation hydrodynamic simulation (carried out with V1D; see Dessart et al. 2013 for details) at $\lesssim 10^4 \text{ s}$ before shock breakout. In other words, the shock is within $\lesssim 100 R_{\odot}$ of the progenitor surface.

When embedding the RSG star initial interior structure (the shocked and un-shocked envelope layers) in an atmosphere/wind, we adopt a variety of density structures, varying the wind mass loss rate \dot{M} , the atmospheric scale height H_{ρ} , or both. In a first set of simulations, we add an atmosphere with a density scale height of $0.01 R_{\star}$ (this corresponds to the surface value in the MESA model) until the density reaches down to the wind density corresponding to wind mass loss rates between 10^{-6} and $10^{-2} M_{\odot} \text{ yr}^{-1}$. In our nomenclature, model suffixes w1, w2, w3, w4, w5, w6 correspond to wind mass loss rates of 10^{-6} , 10^{-5} , 10^{-4} , 10^{-3} , 5×10^{-3} , and $10^{-2} M_{\odot} \text{ yr}^{-1}$. To limit the extent of the dense wind, we smoothly switch to a low mass loss rate of $10^{-6} M_{\odot} \text{ yr}^{-1}$ beyond $5 \times 10^{14} \text{ cm}$, except for model r1w5r in which the transition to a low wind density is at $2 \times 10^{14} \text{ cm}$. For model r2, we only study the case of a low wind mass loss rate (model r2w1) because we believe SNe II-P do not stem from such extended RSG progenitors (Dessart et al. 2013) and also because the presence of a dense wind is the main ingredient controlling the resulting SN radiation (hence such simulations based on model r1 are sufficient).

In two additional models, we study the impact of increasing the atmospheric density scale height. We use $H_{\rho} = 0.3 R_{\star}$ down to $10^{-12} \text{ g cm}^{-3}$, followed by a power-law density profile with exponent 12 (model r1w1h) or $H_{\rho} = 0.1 R_{\star}$ followed by a wind mass loss rate of $5 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$ (model r1w5h). In both models, the wind density is forced to be at least that for a wind mass loss rate of $10^{-6} M_{\odot} \text{ yr}^{-1}$. Such variations in atmospheric scale height may appear large. However, they correspond to variations in density that are not greater than those imposed in models r1w1-r1w6. Secondly, they represent different ways of going from a density of $10^{-9} \text{ g cm}^{-3}$ at R_{\star} to a typical RSG wind density at a few R_{\star} . RSG atmospheres are observed to be extended, much more than given by the atmospheric scale height in MESA models at R_{\star} .

In all cases, the atmosphere/wind is given an initial temperature of 2000 K and the terminal velocity of the wind is v_{∞} of 50 km s^{-1} . We assume the atmosphere is in hydrostatic equilibrium (zero velocity) and that the wind accelerates promptly to

Fig. 2. Initial structure used in HERACLES for model r1w6. The time is a few hours before shock breakout (the prior evolution of the shock through the stellar interior was computed with V1D; Dessart et al. 2013).

Table 1. Summary of properties of the HERACLES simulations and their initial conditions. It takes t_{rise} for the recorded luminosity to rise from $5 \times 10^8 L_{\odot}$ to $L_{\text{bol,max}}$. Δt_{max} is the time during which L_{bol} remains above a tenth of $L_{\text{bol,max}}$. f_{drop} is the factor by which L_{bol} decreases in one day after the time of maximum. $\int L_{\text{bol}} dt$ gives the time integrated bolometric luminosity from first detection until 15 d later. R_{\star} is the progenitor radius, which corresponds to the RSG surface in the MESA model. M_{ejecta} and E_{kin} are the ejecta mass and kinetic energy (without the atmosphere/wind material). H_{ρ} is the atmospheric scale height in the intermediate region between R_{\star} and the base of the wind. n_{ρ} is the exponent of the power law joining this atmosphere and the base of the wind. The next column gives the wind mass loss rate within $2\text{--}5 \times 10^{14}$ cm – beyond this radius the wind mass loss rate is always set to $10^{-6} M_{\odot} \text{ yr}^{-1}$. The subscript ‘ext’ refers to the external material located beyond R_{\star} . Its optical depth is below unity before shock breakout (because of its low original temperature, typically below the RSG effective temperature of ~ 3000 K). Here, we give its optical depth for post shock breakout conditions, i.e., when H and He are fully ionized ($\kappa = 0.34 \text{ cm}^2 \text{ g}^{-1}$).

Model	t_{rise} [d]	Δt_{max} [d]	$L_{\text{bol,max}}$ [erg s $^{-1}$]	f_{drop}	$\int L_{\text{bol}} dt$ [erg]	R_{\star} [R_{\odot}]	M_{ejecta} [M_{\odot}]	E_{kin} [erg]	H_{ρ} [R_{\star}]	n_{ρ}	\dot{M} [$M_{\odot} \text{ yr}^{-1}$]	M_{ext} [M_{\odot}]	τ_{ext}

v_{∞} within a fraction of R_{\star} . The exact choice of velocity profile is irrelevant for various reasons. At shock breakout, the wind base will be strongly accelerated to velocities larger than v_{∞} . The shock and ejecta velocity are also 100 times larger. In this context, it is the density profile that matters for the dynamics.

Figure 1 shows the density profile versus radius for the whole set of HERACLES simulations. The profile for other quantities is shown for model r1w6 in Fig 2.

Table 1 summarizes the initial model properties. We define the external mass M_{ext} as the added mass beyond R_{\star} (as given in the stellar evolution model). This external material is not necessarily the wind itself, which is probably blown from a larger radius, but can be seen as some sort of cocoon of material stagnating at the base of the wind. In reality, the boundary between the star (interior to R_{\star}), this cocoon of mass, and the external wind is ill defined. Hence, the quoted external mass should be

interpreted with caution. One conclusion from this work is that this material may not stem from a super-wind phase but instead corresponds to the cocoon of material that is seen around all spatially resolved RSG atmospheres.

Table 1 also gives the optical depth of the atmosphere/wind assuming full ionization of H and He. The external material is cold and optically thin in the RSG progenitor (and its optical depth is $\lesssim 1$, although this greatly depends on whether dust or molecules are present) but it becomes fully ionized (at least for H and He) as soon as the shock breaks out. Hence, it is the optical depth of the ionized atmosphere/wind that matters for the evolution during and after shock breakout. Even in the case of a weak wind mass loss rate of $10^{-6} M_{\odot} \text{ yr}^{-1}$, the optical depth of the atmosphere above R_{*} is > 100 . This implies that shock breakout will take place outside of the region covered by the MESA model. In fact, the SN photosphere stays in this external region for about a week after shock breakout.

While we give a velocity profile to the material in the environment of the RSG star (which we call a wind or an atmosphere), the early-time SN radiation is primarily influenced by the extent and density/mass of this material — the influence of the initial velocity is negligible hence unconstrained. So, for all simulations, the results would be unchanged if the velocity of the CSE was set to zero.

3.2. Multi-group radiation-hydrodynamic simulations with HERACLES

The interaction configurations described above are used as initial conditions for the 1-D multi-group radiation-hydrodynamics simulations with the code HERACLES (González et al. 2007; Vaytet et al. 2011). The approach is identical to that used and described in Dessart et al. (2015, 2016). We use 8 groups that cover from the UV to the near-IR: one group for the entire Lyman continuum (including the X-ray range), two groups for the Balmer continuum, two for the Paschen continuum, and three groups for the Brackett continuum and beyond.³ A multi-group approach is superior to a grey approach because it better describes the opacity of the material to the radiation when they have widely different temperatures (e.g., high energy radiation crossing a cold gas; see Dessart et al. 2015 for discussion). Because the thermal energy of the gas is a negligible fraction of the total radiation energy in SNe, we adopt a simple equation of state that treats the gas as ideal with $\gamma = 5/3$. We have done tests using a mean-atomic-weight $\mu = 0.67$ (corresponding to full ionization) and 1.35 (neutral) and these yields the same results at early times.⁴

We concentrate on the early-time properties so we limit the simulations to times prior to ~ 15 d. For the shock speeds relevant to the present simulations, this requires placing the outer boundary at $R_{\text{max}} = 1.5 \times 10^{15}$ cm. We cover the ejecta down to a radius of a few $100 R_{\odot}$, which is deep enough to cover the reverse shock progressing into the He core.

³ Using more groups would make the simulation more costly and would not alter the fundamental results discussed here. At present, most simulations in the community are limited to grey transport. Our 8 groups are positioned to capture the relevant photoionization edges – the absorptive opacity varies very smoothly between these edges.

⁴ The major drawback here is not the neglect of the very small ionization/excitation energy. The main limitation in radiation hydrodynamics simulations is the treatment of the gas in LTE at $\tau \lesssim 20$ since the temperature/ionization is in reality influenced by both time dependence and non-LTE effects (Utrobin & Chugai 2005; Dessart & Hillier 2008), while the color temperature is influenced by electron scattering and line blanketing (Eastman et al. 1996; Dessart & Hillier 2005a).

Eulerian coordinates are not ideal for SN studies in 1D (although much better than Lagrangian coordinates when we extend such simulations to multiple dimensions, as in Vlasov et al. 2016) because the structure expands by orders of magnitude through the evolution. Resolving the ejecta at all times requires high resolution. We use 1-D spherical polar coordinates with a total of 10,000 radial points. To better resolve the ejecta at smaller radii (earlier times), we use a grid with a constant spacing from the minimum radius at $\sim 10^{13}$ cm up to $R_t = 5 \times 10^{14}$ cm, and then switch to a grid with a constant spacing in the log up to R_{max} . The grid is designed to have no sharp jump in spacing at R_t .

Because we focus on early times, we adopt a fixed composition corresponding to the outer ejecta of models m15mlt3 and m15mlt1 ($X_{\text{H}} = 0.65$, $X_{\text{He}} = 0.33$, and solar metallicity). This composition is only relevant for the computation of the opacities.

The bolometric light curves extracted from the HERACLES simulations are computed using the total radiative flux at the outer boundary. The bolometric luminosity should not be affected by the LTE assumption for the gas properties. However, multi-band light curves are sensitive to non-LTE effects, the wavelength dependent albedo, line blanketing, and are therefore computed with the 1-D non-LTE code CMFGEN. Post-processing an LTE calculation with a non-LTE code is not optimal, but it is a good start. For example, for the same hydrodynamical snapshot, assuming LTE in CMFGEN produces redder/cooler spectra than the corresponding non-LTE calculation.

3.3. non-LTE radiation-transfer simulations with CMFGEN

At selected epochs in the HERACLES simulations, the radius/velocity/density/temperature structure is remapped into CMFGEN (Hillier & Dessart 2012; Dessart et al. 2015) for the calculation of the emergent flux, from which the multi-band light curves and the spectral evolution are obtained. The code treats the non-monotonic velocity field produced by HERACLES. Hence, emission, absorption, and scattering from the fast ejecta regions and the slower atmosphere/wind regions is taken into account. We also allow for the non-coherent frequency redistribution by thermal electrons. We fix the temperature during the CMFGEN calculation because it results in a large part from the dynamics (shock deposited energy).

For a given snapshot, we only extract the region of the HERACLES simulation between the electron-scattering optical depths of 10^{-5} and 50 (the inner boundary is optically thick at all wavelengths). The grid in CMFGEN uses 100 points with the prescriptions that any two consecutive points should at most have a jump of 5% in radius, of 10% in temperature, of 10% in electron density, of 10% in density, and of 10% in the log of the optical depth. If two consecutive points in the HERACLES simulation violate any of these criteria, additional points are inserted in the CMFGEN grid. A finer grid is also used at the inner and outer boundaries.

For our CMFGEN calculations, we include H, He, C, N, O, and Fe, with the mass fractions 0.63972, 0.349, 0.00142, 0.0031, 0.00541, and 0.00135, respectively. No radioactive decay is accounted for here (all species/isotopes treated are stable) since the early-time evolution of SNe II is unaffected by decay heating. The minor abundance offset from the HERACLES simulation is irrelevant. Our study focuses primarily on dynamical issues and line profile morphology — slight variations in abundance that may occur through different levels of mixing, overshoot, etc. are not a concern at this stage. The study of their influence on early-time spectroscopic properties is deferred. For example,

the early-time observations of SNe 2013cu and 2013fs suggest that their respective progenitors may have different CNO surface abundances (although this may stem partly from different ionization conditions): SN 2013cu shows one strong line of nitrogen (Gal-Yam et al. 2014), while SN 2013fs shows primarily lines of oxygen (Yaron et al. 2017).

Depending on the post-shock-breakout phase, we adjust the model atoms in order to treat only the ions that contribute to the spectrum formation. At most, we include H I, He I–II, C II–V, N II–VI, O II–VI, Fe II–VIII.

4. Results from radiation-hydrodynamic simulations with HERACLES

4.1. Dynamical evolution for representative models of the sample

The dynamical evolution obtained in all HERACLES simulations is qualitatively similar, but variations in wind mass loss rate and atmospheric scale height introduce important quantitative differences. We describe in some detail below the cases of a weak wind (model r1w1; Fig. 3), a strong wind (model r1w6; Fig. 4), and an extended atmospheric scale height (model r1wh; Fig. 5). In this section, times are given with respect to the start of the HERACLES simulation (about 10^4 s before shock breakout), unless stated otherwise.

Figure 3 shows snapshots at 0.17, 1, and 2 d after the start of the HERACLES simulation (the shock crosses R_* at ~ 0.1 d). As the shock approaches R_* , a radiative precursor forms that ionizes the atmosphere and the base of wind. This shifts the photosphere outwards, beyond the R_* of the MESA model, at a density of about 10^{-12} g cm $^{-3}$. This implies that shock breakout actually occurs in regions of the star not covered by the MESA model. This arises because the MESA model has a cold optically-thin atmosphere. The radiative precursor heats, ionizes, and accelerates the material that it crosses on a light travel time. The strong radiative flux and energy accelerate both the ejecta and the wind. The ejecta reaches its asymptotic kinetic energy of 1.34×10^{51} erg at 10–15 d. The acceleration time scale depends on ejecta depth. The fastest material reaches 11500 km s $^{-1}$ at 0.5 d only (bottom row panels of Fig. A.1), while most of the H-rich ejecta regions are within a few per cent of their asymptotic velocity at 5 d. It is the deep ejecta layers that take much longer, because of the reverse shock and the slower expansion (the initial radius of the corresponding shells remains a sizable fraction of the current shell radius for longer). Because of the interaction with the low-density wind, the outer ejecta velocity (where it is maximum) is reduced by only $\sim 2\%$ between 0.5 d and 15 d later.

The dynamical evolution is much different if the wind mass loss rate is large. Figure 4 shows snapshots at 0.5, 2, and 8 d after the start of the HERACLES simulation. As the shock overtakes R_* , the atmosphere and the wind get progressively ionized. The opacity in the Lyman continuum is initially large (cold wind), so the heating occurs partially by absorption of lower energy photons because they have a longer mean free path. The photosphere progresses outwards in the dense wind until ~ 1 d and settles at $\sim 4 \times 10^{14}$ cm (four times further out at 1 d than in model r1w1). It takes nearly a week for the shock to reach this radius. During that time, energy from the shock is deposited in the wind (which is now optically-thick) and escapes on a diffusion time scale. As previously, the wind is accelerated by the radiation that crosses it, while the ejecta is both accelerated by radiation-pressure gradients and decelerated by the wind. The maximum ejecta velocity is in this case only 7200 km s $^{-1}$ at 15 d, hence 30% less than

in model r1w1 at the same time. The asymptotic kinetic energy is 1.32×10^{51} erg, hence 2×10^{49} erg lower than in the weak-wind model r1w1. This excess energy boosts the SN luminosity over the first week of evolution in the same proportion (see below). The drop in kinetic energy therefore arises because the wind is of sufficiently low-density that the shock energy can be sapped by radiative losses.

Varying the wind mass loss rate between 10^{-6} and $10^{-2} M_{\odot} \text{ yr}^{-1}$ or varying the extent of the high wind density region (model r1w5r) produce similar properties that are intermediate between those of models r1w1 and r1w6 (Fig. A.1).

Figure 5 shows snapshots at 1, 2, and 8 d after the start of the HERACLES simulation for model r1wh. Increasing the atmospheric scale height enhances the mass exterior to R_* but yields properties that are quantitatively different from enhancing the wind density. Indeed, a greater scale height extends the star but the bulk of the atmosphere mass resides in high density layers close to R_* , so the diffusion time through the atmosphere remains small. Consequently, there is no extended shock-breakout signal like in the high-mass loss rate model r1w6 and the photosphere after shock breakout remains closer to the fast-moving ejecta layers (rather than within the slowly moving wind like in model r1w6). The additional mass in the atmosphere leads to maximum velocities 1000 km s $^{-1}$ smaller than in model r1w1. The interaction of the ejecta with the atmosphere/wind (whose mass outside of R_* is $\sim 0.16 M_{\odot}$) leads to the extraction of 2×10^{49} erg compared to 7×10^{48} erg in model r1w1 (Table 1). As for model r1w6, this energy is primarily radiated, but with a very different power profile, as we discuss in the next section.

4.2. Bolometric, Far-UV, UV, and optical light curves

Figure 6 shows the bolometric light curves for the models computed with HERACLES (see previous section, Fig. 1, and Table 1 for a summary of initial properties and results). The bolometric luminosity is evaluated at the outer boundary from the sum of the fluxes in each group. Because of the time delay for the radiation to reach the outer boundary at $R_{\text{max}} = 1.5 \times 10^{15}$ cm, we shift all light curves in time so that the time origin corresponds to the first rise (at R_{max}) to a luminosity of $5 \times 10^8 L_{\odot}$. Because of optical depth effects, this time differs between models.

4.2.1. Sensivity to the wind mass loss rate

Models with increasing wind mass loss rates and the same atmospheric scale height (r1w[1-6] and r1w5r) have a longer rise time (from 0.03 to 1.72 d), a longer shock-breakout signal duration (from about an hour in model r1w1 up to a week in model r1w6, although in the latter the high-brightness phase after breakout includes both the precursor radiation and the leakage of shock-deposited energy in the wind), and a smaller bolometric maximum (from a maximum of 7.4×10^{44} erg s $^{-1}$ in model r1w1 down to 5.2×10^{43} erg s $^{-1}$ in model r1w6). Light-travel time effects, which spread the shock breakout signal over R_*/c , only matter for the weak-wind models. For dense winds, the intrinsic duration of the shock breakout signal exceeds R_*/c . This lengthening of the shock-breakout signal is related to the increasing photon diffusion time through the optically-thick atmosphere/wind region. If this was merely a spreading of the breakout signal, the bolometric maximum would decrease as the shock breakout signal duration increases (and it does), but we would obtain the same time-integrated bolometric luminosity. Instead, we find that the time-integrated bolometric luminosity over the

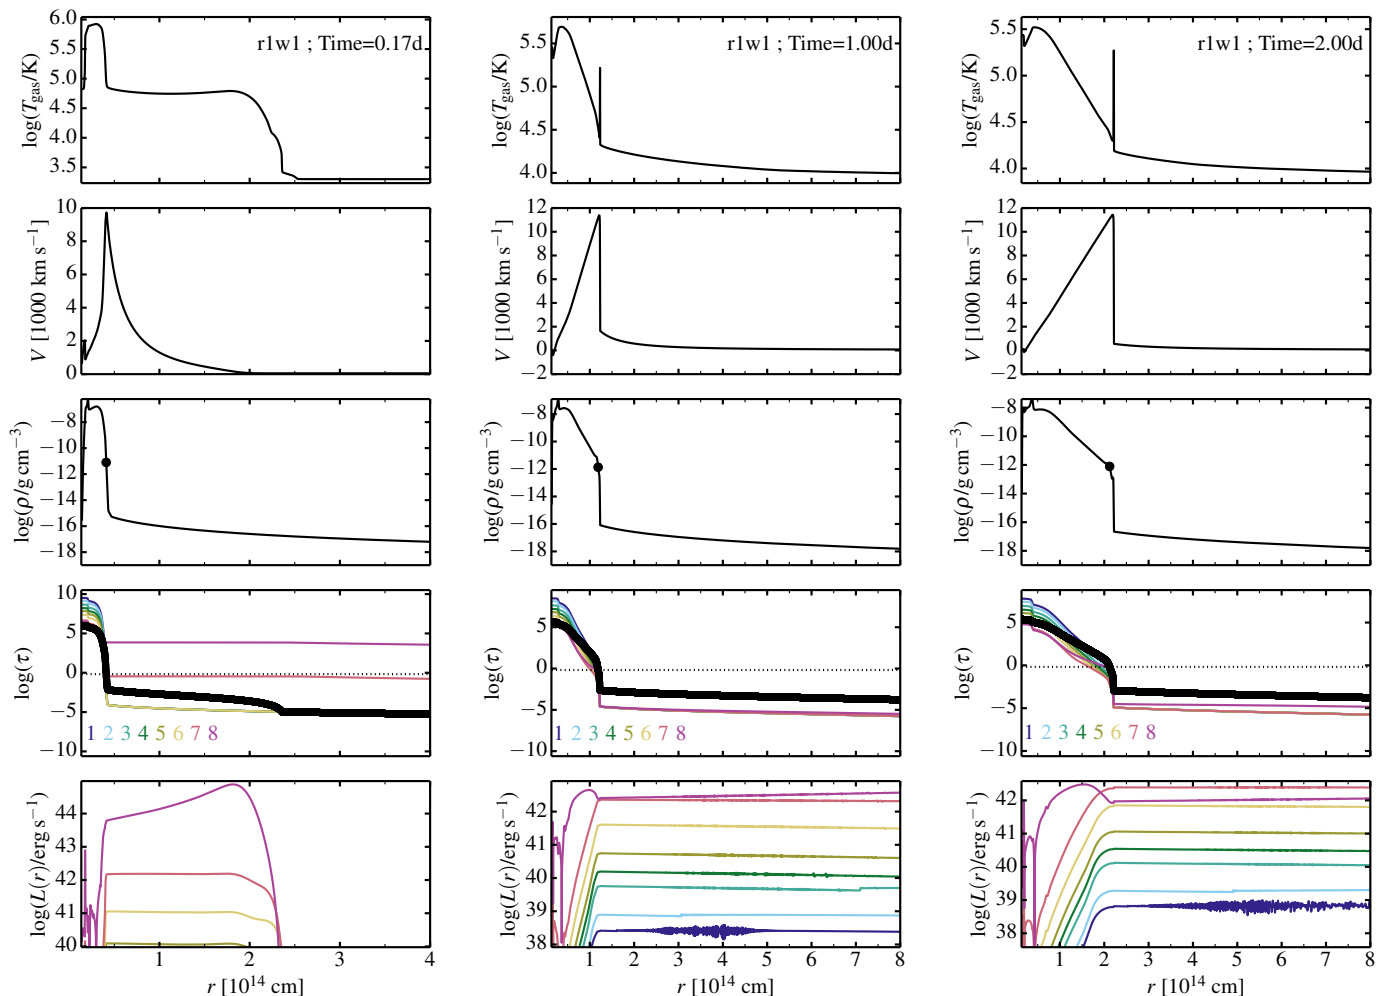

Fig. 3. Ejecta properties computed by HERACLES for model r1w1 (weak wind mass loss rate of $10^{-6} M_{\odot} \text{ yr}^{-1}$) at 0.17, 1, and 2 d after the start of the HERACLES simulation. The black dot in each of the middle panels corresponds to the electron-scattering photosphere. In the optical-depth panel, the colored numbers correspond to each energy group, ordered from low frequency (group 1 covers the far-IR) to high frequency (group 8 covers the Lyman continuum). The thick black line corresponds to the electron-scattering optical depth. Through this early evolution, we can see the ejecta accelerate, the wind acceleration by the SN radiation, the propagation of the radiation burst that coincided with shock breakout (at ~ 0.1 d), the heating and rapid ionization of the wind, the establishment of radiative equilibrium in the optically-thin regions at 2 d.

first 15 days of evolution increases from 7.26×10^{48} erg in the weak wind model r1w1 to 2.02×10^{49} erg in the strong wind model r1w6. The time integrated bolometric luminosity is in all cases equal within a few percent to the change in the total energy (the sum of the kinetic, radiative, and thermal contributions) on the grid. Variations in $\int L_{\text{bol}} dt$ thus reflect energy extraction from the ejecta as it interacts with the wind. Hence, if a dense wind is present, there is both a spread of the shock breakout signal by diffusion through the wind and a boost to the radiative flux from the interaction.

The presence of a dense wind leaves unambiguous signatures on the bolometric light curve. In model r1w6 there is a sudden drop in bolometric luminosity at one week, which coincides with the epoch when the interaction with the dense parts of the wind ceases. When the interaction with the dense wind is over in r1w3/r1w4/r1w5r/r1w6 at 5–10 d, the light curve agrees very closely with the weak-wind cases r1w1–r1w2. A short-lived super-wind phase with a mass loss rate greater than a few $10^{-4} M_{\odot} \text{ yr}^{-1}$ prior to core-collapse should therefore leave an

imprint on the bolometric light curve at early times (see also [Moriya et al. 2011](#)). If RSG stars have a super-wind phase before core collapse, one should expect a diversity of early-time light curve properties in a large sample of SNe II-P, with such breaks occurring at different epochs and with different magnitudes.

4.2.2. Sensivity to the progenitor radius

In model r2w1, the progenitor star at death is more than twice as large. The rise time to bolometric maximum and the shock breakout signal are three times longer than in model r1w1, while the bolometric maximum is about the same (Table 1). The differences are caused by the increased light travel time across the progenitor star.

Fig. 4. Ejecta properties computed by HERACLES for model r1w6 (strong wind mass loss rate of $10^{-2} M_{\odot} \text{ yr}^{-1}$) at 0.5, 2, and 8 d after the start of the HERACLES simulation. Compared to model r1w1, the ejecta is more decelerated by the dense wind (the maximum ejecta velocity levels off at $\sim 7000 \text{ km s}^{-1}$ compared to 11000 km s^{-1}), more radiation energy gets trapped within the optically-thick wind leading to a delayed but longer-lived shock break-out signal, a much more massive cold-dense-shell forms (containing the swept up wind material). All these properties produce unambiguous radiative signatures.

4.2.3. Sensivity to atmospheric scale height

Models with an extended atmospheric scale height (r1w1h and r1w5h) show a very different behavior from the weak-wind model r1w1. The rise time to maximum is short, the duration of the maximum phase is short, but the bolometric luminosity is significantly higher for 10–15 d. The higher density in the atmosphere (but close to R_{\star}) leads to a strong interaction. Energy is deposited in this outer region of moderate optical depth (i.e., ~ 5000 ; see Table 1), and released in the form of radiation for 15 d. The time-integrated bolometric luminosity is $2.06\text{--}2.15 \times 10^{49} \text{ erg}$ and comparable to that of model r1w6, but here the distribution of material in the atmosphere is much more confined. In this case, there is no break in the light curve. Compared to model r1w1h, the model r1w5h has a smaller density scale height but a greater density at large distances, producing a longer precursor and a smaller luminosity boost to later times.

4.2.4. Wavelength dependence of the shock breakout signal and observability

The complex morphology of bolometric light curves shown in Fig. 6 appears differently in selected spectral bands. Figure 7 shows the Far-UV, UV, and optical light curves from the HERACLES simulations of models r1w1, r1w5r, r1w1h, and r1w6. If the atmosphere/wind has a negligible mass/extent, a clear burst of radiation is seen simultaneously in the Lyman, Balmer, and Paschen continua (top row of Fig. 7). However, in the presence of a dense/extended atmosphere/wind, optical photons emerge earlier and more progressively than in the Balmer/Lyman continuum. While a clear burst may occur in the Far-UV, the optical signal will show a much slower rise with a smaller discontinuity (low-cadence observations may still capture a burst, but because of a lack of resolution). The multi-group approach in HERACLES captures this effect, which arises because the opacity for Lyman-continuum photons is orders of magnitude larger than for optical photons.

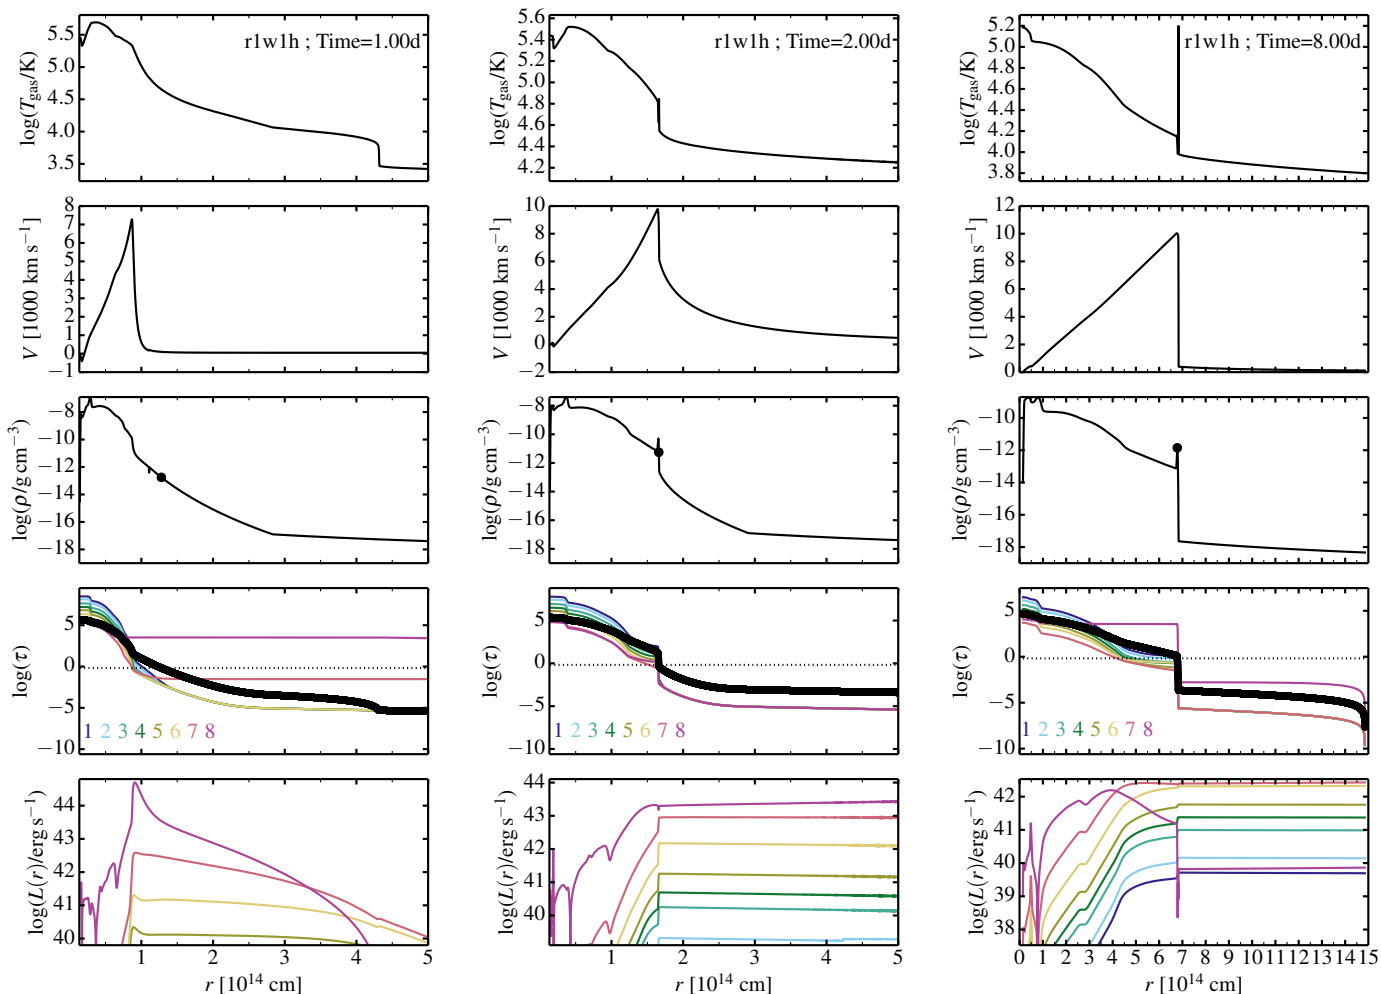

Fig. 5. Ejecta properties computed by HERACLES for model r1w1h (model with a weak wind but an extended atmospheric scale height) at 1, 2, and 8 d after the start of the HERACLES simulation. Compared to model r1w6, the shock is not as strongly decelerated by the atmosphere (which has a steep density profile), and the photosphere remains close to the fast-moving ejecta, inhibiting the formation of a long-lived shock-breakout signal.

For a blackbody at a temperature T the peak of the spectral energy distribution occurs at $\sim 2900/T_4 \text{ \AA}$, where $T_4 = T/10^4 \text{ K}$. Because of the high temperatures in the spectrum formation region (roughly between optical depth 0.1 and 10; see Fig. A.1), the bulk of the flux falls in the Lyman continuum for a few days, then in the Balmer continuum up to about 10 d, and in the optical at later times (this evolution is model dependent). The diversity of atmosphere/wind properties causes a large scatter in this evolution in our set of models. For example, in the strong wind case (model r1w6), the radiation energy from shock breakout E_{sbo} does not immediately escape but instead gets trapped within a large volume dV bounded by (roughly) R_* and the photospheric radius at about $5 \times 10^{14} \text{ cm}$. The larger this volume dV , the lower the representative radiation temperature T_{rad} because $E_{\text{sbo}} \sim a_{\text{R}} T_{\text{rad}}^4 dV$ (a_{R} is the radiation constant). In model r1w6, the Far-UV flux is much weaker and the UV flux is boosted relative to model r1w1.

It is clear from Fig. 7 that the detection of shock breakout is very difficult in the optical, although not impossible (Garnavich et al. 2016). The challenge is both the brightness of the burst in the corresponding spectral range, but also the way the

brightness changes with time. Garnavich et al. (2016) report the very weak and short lived bump ($< 1 \text{ hr}$) in the optical light curve of KSN 2011d, something that we do not actually obtain in our HERACLES simulations, perhaps because of numerical diffusion and accuracy (the optical flux is one part in 10^5 of the Far-UV/UV flux). Hunting for shock breakout in the UV or the far-UV, where the jump in flux in orders of magnitude, is obviously more suitable (Cenko et al. 2017).

5. Results from non-LTE steady-state radiative transfer simulations with CMFGEN

For a selection of HERACLES simulations (models r1w2 and r1w3 are omitted because they are intermediate cases of adjacent models r1w1 and r1w4), we compute CMFGEN models that solve for the non-LTE properties of the gas as well as the radiation field. We assume steady state in CMFGEN but time dependence is accounted for in HERACLES. The flux computed in CMFGEN at a given time corresponds to a later time in the HERACLES simulation, by at most 0.5 d. This inconsistency does not affect the relative spectral evolution computed by CMFGEN.

Fig. 6. Bolometric light curves computed with HERACLES for our full set of models. Times are given since first signal detection at the outer boundary. The time resolution in the HERACLES simulation is always less than a minute (and it is less than a second around the phase of shock breakout). The insets show the same quantity but zooming on the earliest times, concomitant with shock breakout. Progenitors with a larger radius or with a denser atmosphere/wind (here confined to within 5–10 R_*) have a longer shock-breakout signal and an enhanced luminosity at early times powered by the interaction with the atmosphere/wind.

The bolometric luminosity computed by CMFGEN (see Fig. B.1 in the appendix) agrees to within 10–20% with that computed by HERACLES (modulo the $\lesssim 0.5$ d shift mentioned above). For each snapshot treated, we also find that the CMFGEN results for the electron density and optical depth are within a few per cent of those computed by HERACLES.

5.1. Multi-band light curves

Figure 8 shows the light curves in $UVW2$ (Swift filter), B , and R (absolute magnitudes) for our CMFGEN simulations. A qualitatively similar evolution is obtained for other UV and optical bands. We find that the brightness increases initially to reach a peak within a maximum of 6 d in $UVW2$, from 4–8 d in U , 5–10 d in B , from 6 to >15 d in V , and from 5 to >15 d in R .

In the weak-wind models r1w1 and r2w1, there is a discontinuity at the earliest times in all three filters. This discontinuity corresponds to the shock breakout signal. The optical brightness jump in model r2w1 is greater than in the corresponding HERACLES model because in this study CMFGEN assumes steady state and therefore ignores light-travel time effects, while HERACLES is time dependent and accounts for time delays (spreading the breakout signal over R_*/c). In other models, the extended/dense

atmosphere/wind spreads that signal (computed by HERACLES or by CMFGEN) and no sharp discontinuity is seen.

In the case of a weak wind, the photometric evolution reflects the combined effects of expansion (which increases the surface area of the emitting surface) and cooling (which shifts the peak of the spectral energy distribution to longer wavelengths). For a given model, the peak brightness occurs earlier in bluer bands. In a given band, the peak brightness occurs earlier for a more compact progenitor star (compare models r1w1 and r2w1). Models with increasing wind mass loss rates exhibit a brightness boost in all bands from the stronger interaction, but with an obvious break in models r1w4, r1w5r, and r1w6 when that interaction ceases (or when the atmosphere/wind has been completely swept-up so that it no longer introduces an optical-depth effect).

Apart from model r2w1, all models have the same explosion energy and ejecta mass, so the presence of a dense atmosphere/wind alone can introduce significant UV-optical light curve variations at early times, up to 1–2 mag for this set of models and displace the times of maximum by more than a week. Once interaction is weak in all models ($\gtrsim 10$ d), the magnitude scatter in a given optical band is $\lesssim 0.2$ mag, but remains very large in the UV (if we exclude the strong wind model r1w6 and the model from a bigger star r2w1, the scatter is only 0.6 mag at 15 d).

Fig. 7. Far-UV, UV, and optical light curve computed with HERACLES for models r1w1, r1w1h, r1w5r, and r1w6. In practice, we show the evolution of the luminosity in the energy group number 8 (Far-UV), the luminosity from energy groups 6 and 7 between the Lyman and the Balmer edges (UV), and the luminosity from energy groups 4 and 5 between the Balmer and the Paschen edges (optical). Up to one day after the Far-UV burst, the bulk of the energy is emitted blueward of the Lyman edge but progressively shifts to the UV until it falls mostly in the optical after about 10 d. Models with a higher mass loss rate (right column) have a broader and redder shock-breakout signal.

Fig. 8. *UVW2*, *B*, and *R* band light curves obtained with CMFGEN for models r1w1, r1w1h, r1w4, r1w5h, r1w5r, r1w6, and r2w1. The time origin corresponds to shock breakout (taken to be when the luminosity at the photosphere rises to 10^{42} erg s $^{-1}$). The variations in atmosphere/wind density have considerable impact on the early-time light curves, generally reducing the rise times and potentially introducing breaks in the light curves (e.g., model r1w6).

Models with strong wind mass loss exhibit a break in all UV/optical bands (as we obtain in the HERACLES light curves; Fig. 6). This is not a generic property of SNe II light curves, but this jump could be turned into a more progressive decline by using a slowly declining mass loss rate (i.e., from $>10^{-4} M_\odot \text{ yr}^{-1}$ down to $10^{-6} M_\odot \text{ yr}^{-1}$; see Fig. 1). In contrast, no break is seen in the models with an extended atmospheric scale height, and the rise time to maximum in optical bands is brought to earlier times, in better agreement with observations (González-Gaitán et al. 2015).

5.2. Models of the spectral evolution

In this section, we discuss the spectral evolution up to 15 d after shock breakout for three representative models of atmosphere/wind configurations: 1) weak wind (model r1w1; top panel of Fig. 10); 2) strong wind (model r1w5r; middle panel of Fig. 10); 3) extended atmospheric scale height (model r1w1h; bottom panel of Fig. 10). The corresponding multi-band light curves are shown for completeness in Fig. 9. In the appendix,

Fig. 9. Multi-band UV and optical light curves for the weak-wind model r1w1 (left), the strong wind model r1w5r (center), and the model with an extended scale height r1w1h (right). The time origin corresponds to shock breakout (taken to be when the luminosity at the photosphere rises to 10^{42} erg s $^{-1}$). Models r1w5r and r1w1h both show much shorter rise times in most/all bands than the weak-wind model r1w1.

we show the complete set of spectral calculations for all models (Figs. C.1–C.7).

In all cases, the evolution of the spectrum over that timespan reflects the change in ejecta properties in the spectrum formation region. The gas temperature drops from $\sim 10^5$ down to $\sim 10^4$ K (which affects the ionization, and hence the sources of opacity/emissivity, themselves impacting the colors as well as the lines produced). The ejecta accelerates, as well as some of the wind material, while some ejecta deceleration takes place if the wind is very dense (this modulates the Doppler broadening of line profiles). The frequency redistribution by electron scattering ebbs as the atmosphere/wind optical depth drops. In nearly all cases, the spectra show at least once the lines associated with H I 4340 Å, 4862 Å, 6562 Å, He I 5875 Å, 6678 Å, He II 4686 Å, 4860 Å, 5411 Å, 6562 Å, C IV 5801–5812 Å, 7110 Å, N IV 4057 Å, 7122 Å, N V 4610 Å, O V 5597 Å, and O VI 3811–3834 Å. The spectral evolution is extremely rapid in our models (as observed, e.g., in SN 2013fs; Yaron et al. 2017), so that some lines/ions may only be present for a few hours. What differs between models is the duration over which these lines are seen and their morphologies. The critical element is whether line broadening is caused by non-coherent scattering with thermal electrons (which produces symmetric lines centered at the rest wavelength) or by large bulk motions (which produces asymmetric lines with a blueshifted peak emission; see Section 6.2 and Fig. 15 of Dessart et al. 2009).

For the weak wind case (top panel of Fig 10; the figure shows rectified spectra that have been scaled to better reveal the weak lines), the first spectrum, at the time of shock breakout, show narrow lines with electron-scattering wings (He II 4686 Å). At 1.6 hr, the spectrum then shows Doppler-broadened lines of O VI, N V, and He II, all with a marked blueshift in peak emission. At 5.6 hr, O VI has disappeared and we see lines of N V, He II, and O V. At 13.6 hr, O V has disappeared and we see lines of N IV, N V, He II, and C IV. As the temperature continues to drop, the ionization decreases, the spectrum is less and less blue, and we eventually see the typical Type II-P SN spectrum with lines of H I and He I. Because of optical depth and occultation effects, all lines have a blue-shifted peak emission (Dessart & Hillier 2005b; Anderson et al. 2014), except at the first epoch. A blue-shifted line emission peak is unambiguous evidence that the line is not primarily broadened by non-coherent electron scattering, which instead tends to cause a symmetric (narrow) profile.

In contrast, for a stronger wind case (model r1w5r; middle panel of Fig 10; the strong wind case model r1w6 is shown in Fig. C.6), the spectrum exhibits narrow and symmetric emission profiles typical of Type IIIn SNe for up to 1 d. At 4.0 hr, we see the

same lines as in the weak wind case but the lines, which show no absorption component, are now centered on the rest wavelength. Lines form in the slow moving (or weakly accelerating wind) and are affected by frequency redistribution by thermal electrons. At 12.0 hr, the ionization has dropped (O VI has disappeared and O V is present) but the narrow emission features are still present. After 1 d, there is only weak evidence for the reprocessing of photons by the atmosphere/wind. Its optical depth is too small to produce strong electron-scattering wings, although we do see a very narrow emission in He II for up to 2 d. The spectrum starts to show P-Cygni profiles with a broad blueshifted absorption and a very weak emission. At this time, the spectrum forms in the dense shell of swept-up atmosphere/wind material. The lack of an emission component in line profiles is caused by the steeply declining density profile within that dense shell. Such properties and evolution are reminiscent of SN 1998S (Dessart et al. 2016).

For the model r1w1h with an extended atmospheric scale height (bottom panel of Fig 10), despite the large amount of atmospheric material (more than ten times as much as in model r1w5r), the signatures of interaction (i.e., narrow symmetric lines) are present only in the first spectrum, which coincides with the time of shock breakout. Only He II 4686 Å shows this morphology. The spectral evolution proceeds as in model r1w1, although emission profiles are much stronger because the density does not fall as steeply as in model r1w1. The biggest difference between model r1w1h and model r1w1 is not spectroscopic but bolometric and photometric, with model r1w1h showing a much more extended phase of high luminosity and an earlier time of maximum in all UV/optical bands (Figs. 6–7–8).

All models are shown in the appendix, with properties that vary somewhat from the above. For example, in the strong wind cases r1w4 and r1w6, the ionization seen in the spectra at all epochs is much lower than in other models with a more confined and tenuous atmosphere/wind. One signature of this is the absence of O V and O VI lines in model r1w6. In model r1w4, O VI is also absent but O V is present. In model r1w5r, the progenitor environment is dense but less extended. Consequently, the atmosphere/wind temperature reaches much higher temperatures and the spectral lines identified are similar to those in the weak wind model r1w1. In other words, the extent/mass/density of the atmosphere/wind has a strong influence on the ionization in the spectrum formation region, which complements what can be inferred from the line profile morphology.

While we do not have a model that fits all multi-epoch spectra of SN 2013fs, our set of models show a good correspondence at selected epochs for a sample of features. For

Fig. 10. Same as Fig. 9, but now showing multi-epoch optical spectra. We show the quantity $[(F_\lambda/F_c - 1) \times \alpha + 1]$, where F_c is the continuum flux. To better show the weak lines, we take $\alpha = 3$. The time origin corresponds to shock breakout (taken to be when the luminosity at the photosphere rises to $10^{42} \text{ erg s}^{-1}$). All three models show narrow line profiles at the earliest times, but only the models with a dense atmosphere/wind retain this property, for a duration that depends on the density and extent of this external material, as well as the SN shock speed. When spectral lines are primarily electron-scattering broadened, the peak emission is centered on the line rest wavelength. When spectral lines are primarily Doppler broadened, the peak emission is blueshifted, which can compromise a robust identification or lead to an erroneous measure of the redshift if the blueshift is ignored, as in Gezari et al. (2009).

example, model r1w5h follows closely the ionization seen in SN2013fs (top panel of Fig. 11), while model r1w5r shows a line profile morphology that evolves closely to that seen in SN2013fs (bottom panel of Fig. 11). Building a full progenitor/explosion/interaction model for any observed SN is obviously a challenge. The model presented in Yaron et al. (2017) fits better the observation, but it does so at one epoch only, has not hydrodynamical consistency, and imposes radiative equilibrium. So, our approach lacks the flexibility needed to achieve a good fit (this would require hundreds of simulations), but it has physical consistency so that a grid of models, as presented here, can cover the broad parameter space in which a given SN resides and identify the basic trends.

6. Comparison to other observations

Figure 12 shows a comparison of optical light curves from our HERACLES simulations (we account for the flux between the Balmer and Paschen edges) with the observations of KSN2011a and KSN2011d (Garnavich et al. 2016), and SN2006bp (Quimby et al. 2007). Our explosion models from a big star (r2w1) and/or weak winds rise too slowly in the optical. Models accounting for an extended dense wind produce a flux excess in the optical light curve that is not observed. The best match to the KSN2011d and SN2006bp is for models with an extended scale height or with a dense wind confined to the surface of the star (model r1w5r).⁵ None of our models, even with interaction, match the fast rise of KSN2011a.

Our results are somewhat in tension with Garnavich et al. (2016), who find a good match for KSN2011d for a RSG with a weak or no wind and a radius of $490 R_{\odot}$. For KSN2011a, they argue for wind interaction and/or a compact RSG progenitor with a radius of $280 R_{\odot}$. Their inferences are based on the semi-analytical modeling of Rabinak & Waxman (2011), who assume that the progenitor density profile goes as $1/r^{1.5}$. This density profile corresponds to the deep convective envelope, not the outer layers in which the SN spectrum forms for a week, so this may be the origin of the difference in our results. It still remains very surprising that a RSG could radiate in the optical at 1 d as much as $\sim 50\%$ of the flux that it radiates at 10–15 d. This is the case for SN1987A, but KSN2011a does not have a Type II-pec light curve morphology. Optical spectra for this SN would probably have helped understanding this very fast optical rise.

The KSN2011d observation of Garnavich et al. (2016) also reveals an initial short and weak optical burst of < 1 hr. As discussed earlier, our HERACLES simulation do not show such a sharp feature in the optical light curve, probably because of an accuracy issue (numerical diffusion). The CMFGEN simulations for model r2w1 show a sharp and small optical burst but this is most likely because of the neglect of time delays. However, in the case of KSN2011d, the observation of this bump suggests that the RSG progenitor was not surrounded by an extended and dense wind.

In addition, the earliest time spectra of SN2006bp do not exhibit narrow line profiles with extended symmetric wings. Instead, SN2006bp shows a P-Cygni profiles with blue-shifted emission peak (e.g., He II 4686 Å, C IV 5808 Å, and H α), together with a narrow component at the corresponding rest wavelength (Quimby et al. 2007). The strong blueshifted emission is clear evidence that the atmosphere/wind material, if present at the corresponding epoch, is already optically thin (otherwise

⁵ These HERACLES optical light curves reflect closely the *R*-band light curve properties obtained with CMFGEN (see Fig. 8).

line emission would peak at the rest wavelength and electron-scattering wings would be seen).

7. Conclusion

We have used 1-D Eulerian multi-group radiation-hydrodynamics and 1-D non-LTE radiative transfer modeling to characterize the bolometric, photometric, and spectroscopic signatures of RSG explosions embedded in an atmosphere/wind of modest extent (within $\sim 10 R_{*}$) and mass ($\lesssim 10^{-1} M_{\odot}$). Our work is conceptually analogous to the studies of Moriya et al. (2011) and Morozova et al. (2017) but includes the computation of multi-epoch spectra as a post-treatment of multi-group radiation hydrodynamics. Our initial ejecta/atmosphere/wind structures also extend to low density (and large radii), which ensures the proper computation of the shock breakout and the associated burst of radiation. For the spectral calculations, we work from physical models of the explosion/interaction and make allowance for the non-monotonicity of the velocity field, both not treated in Yaron et al. (2017). The numerical approach is similar to a recent study for SN1998S (Dessart et al. 2016). Our simulations are 1D and therefore do not predict the disruption of the cold-dense-shell that forms from the swept-up atmosphere/wind material. We also adopt a spherically-symmetric density distribution for this external material initially, although there is ample evidence that RSG environments are structured and complex.

In the case of a weak progenitor wind (model r1w1), the model spectra show a blue nearly featureless spectrum for about a week, with lines of He II, C IV, N V, O V, O VI that may be present for no more than a few hours. As time passes, the temperature and ionization decrease and eventually H I and He I lines appear, producing a spectrum analogous to those of standard SNe II-P. In the absence of interaction, all lines form in the fast expanding ejecta and exhibit a strong peak blueshift at all times. Photometrically, this model shows a rise time in the *B* band of about 10 d.

In the case of a strong progenitor wind (up to a maximum of $10^{-2} M_{\odot} \text{ yr}^{-1}$ in model r1w6), the spectral and photometric evolution during the first 15 d are very different. As long as the spectrum forms in the slow (un-shocked) and optically thick wind, the lines exhibit a narrow emission peak with symmetric wings in place of a blueshifted Doppler-broadened emission peak. The dense wind material is eventually swept up into a dense shell. When the spectrum forms in that shell, the profiles start exhibiting a blueshifted and broad absorption with weak or no emission. Eventually, the photosphere recedes through this shell and the spectrum then resembles a more typical SN II spectrum with P-Cygni profile associated with H I and He I lines. Photometrically, the shock breakout in the progenitor environment is fainter and longer, except if the wind material is massive enough to allow the extraction of ejecta kinetic energy. In our simulations, we find that the time-integrated luminosity over the first 10–15 d can be boosted by a factor of a few.

The greater the luminosity boost from the ejecta/wind interaction, the greater the ejecta deceleration. In our strong-wind model r1w6, the maximum velocity is only $\sim 7000 \text{ km s}^{-1}$ at 10 d, compared to $\sim 11000 \text{ km s}^{-1}$ in our weak-wind model r1w1. This implies narrower (Doppler-broadened) line profiles for the SN. In model r1w6, no line shows absorption/emission at $\gtrsim 7000 \text{ km s}^{-1}$. The greater the wind mass loss rate, the greater the reduction. Because this deceleration does not affect the inner ejecta, the ejecta interaction with a dense wind should produce SNe that have narrower lines at early time, and nor-

mal line widths at later times. [Faran et al. \(2014\)](#) report that faster-declining Type II SNe indeed have narrower line profiles early on, but also broader ones at late times, which suggests ejecta/wind interaction alone may not explain fast-declining Type II. This needs to be considered when assessing the suitability of ejecta/wind interaction to explain SNe II-L ([Morozova et al. 2017](#)).

Early interaction with a dense wind reduces the rise time in optical bands and may help reduce the discrepancies with the observations ([González-Gaitán et al. 2015](#)). The early time light curve depends, however, on the properties of the atmosphere/wind (i.e., the atmospheric scale height and the wind density/extent). We find that when the interaction with a dense wind (with $\dot{M} < 10^{-2} M_{\odot} \text{ yr}^{-1}$) ebbs, the multi-band light curves show a break that is not obviously seen in Type II SN observations. A second issue with a strong wind is that they should come with a variety of strength in Nature, and therefore the observations should reveal a wide range of early time light curve properties, with breaks occurring at different epochs, function of the extent of the high density wind.

We have also investigated configurations in which the RSG atmosphere has a larger scale height. The corresponding change in density profile brings important differences. The bolometric and multi-band light curves no longer show a break, the rise times are very short, the bolometric luminosity may be boosted for 15 d, all of which seem to be in agreement with the observations ([González-Gaitán et al. 2015](#)). This stems from the strong interaction with the dense material at the base of the atmosphere. Its optical depth is large but not as large as the underlying ejecta so that the extra shock deposited energy can be released progressively over 15 d. The spectral signatures of atmosphere/wind interaction are short lived. The extra energy in this configuration produces blue colors for longer.

We find that all our simulations, irrespective of wind density, exhibit narrow line profiles at the earliest times. These narrow spectral signatures last as long the shock is embedded within some optically-thick slow-moving material. If the wind is tenuous, this region is the atmosphere of the RSG. If the wind is dense, this region is the wind itself. Ignoring material acceleration, these narrow line profiles last for the duration of the shock breakout (i.e., until the shock overtakes the photosphere).

Our results reproduce some of the characteristic properties observed in SN 2013fs ([Yaron et al. 2017](#)). For about a week, SN 2013fs shows a blue and nearly featureless spectrum. Up until < 2 d, the SN exhibits lines from He II, NV, OV, OVI, with a narrow and symmetric profile. Subsequently, the SN exhibits a blue nearly featureless spectrum, with narrow and weak emission line peaks that lack broad wings. This property implies a low electron scattering optical depth at 5 d (the dense external material is overtaken by ~ 2 d). Our model r1w5r is reminiscent of these properties, with a pre-SN mass loss rate of $5 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$ extending out to about 2×10^{14} cm. These values are consistent with those inferred by [Yaron et al. 2017](#), although observations strongly suggest that the dense wind does not extend to a radius of 10^{15} cm — it should be no more than about 2×10^{14} cm, hence a few stellar radii only. Our interpretation of the origin of this external material is, however, completely different.

The term flash-ionization used to explain the early-time properties ([Khazov et al. 2016](#)) is somewhat misleading. The shock breakout radiation is indeed characterized by very high temperatures and a huge ionizing flux, which promptly ionizes all the H and He in the RSG environment. However, in RSG explosions, the photospheric temperature and the ionizing flux remain large for at least a week. The recombination time scale

at the photospheric densities relevant here are of the order of minutes. Hence, the large ionization inferred from spectra stems from the sustained UV flux and large temperatures in the spectrum formation region, and not exclusively from a flash associated with shock breakout.

The mechanism at the origin of this external material, which is dense and contiguous to the stellar surface, is unclear. Drawing an analogy from the very massive star eruptions at the origin of super-luminous SNe of Type IIn (see, e.g., [Smith et al. 2007](#)), one may wonder whether RSG may undergo a super-wind phase in the final stages of their evolution. Various mechanisms involving fluid instabilities, nuclear burning, or pulsations have been proposed ([Heger et al. 1997](#); [Shiode & Quataert 2014](#); [Smith & Arnett 2014](#); [Yoon & Cantiello 2010](#); [Woolley & Heger 2015](#)).

[Morozova et al. \(2017\)](#) proposed a model with a strong pre-SN wind mass loss rate of $0.15\text{--}1.5 M_{\odot} \text{ yr}^{-1}$ out to a radius of $1900 R_{\odot}$ to explain the observations of SN 2013fs. Such a mass loss rate implies densities of the order of $10^{-10} \text{ g cm}^{-3}$. When the SN shock arrives in this wind, there is in fact no precursor because the photon mean free path is too small. In that case, the shock breaks out when it reaches $1900 R_{\odot}$ (i.e., their adopted wind merely extends the star) and there is no lengthening of the shock-breakout signal. Because of this, this model cannot produce the IIn signatures seen for 2 d in SN 2013fs. The IIn signatures can only form if there is radiation leakage from the shock into the slow-moving atmosphere/wind above, and this cannot occur if its density is too high⁶. We have done an HERACLES simulation using the initial conditions for SN 2013fs proposed by [Morozova et al.](#) and we illustrate the results together with those of model r1w6 in Fig. 13. In the MPV simulation, the photosphere (filled dot) always resides in the fast moving ejecta after shock breakout – there is no reprocessing by a slow moving dense wind. Hence, the model of MPV is unable to reproduce the early-time spectra of SN 2013fs. In contrast, in model r1w6, the photosphere is well above the embedded shock for a few days after breakout (from within the star) so that photons emitted at the shock are reprocessed by the slow-moving optically thick wind.

In reality, the observations of SN 2013fs only provide a constraint on the mass and extent of the external material ($\sim 0.01 M_{\odot}$ spread over $\sim 2 \times 10^{14}$ cm). There is no observational constraint on the velocity profile and in particular, whether this material is static or if it is part of an outflow. These are speculations. There may, however, be a simpler explanation for the observations of SN 2013fs, which has to do with the standard properties of RSG atmospheres, and may therefore apply with different magnitudes in all Type II SNe. Stellar evolution models of RSG stars set the photosphere at a density of about $10^{-9} \text{ g cm}^{-3}$. This photospheric density is very high for such a large radius because of the low surface temperature, making the contribution of electron scattering to the opacity very small. In contrast, the base of a typical RSG wind is at a density of $10^{-14} \text{ g cm}^{-3}$ (e.g., Betelgeuse has an inferred wind mass loss rate of about $3 \times 10^{-6} M_{\odot} \text{ yr}^{-1}$; [Harper et al. 2001](#)). This represents a drop in density by 5 orders of magnitude. At the surface of the MESA model, the density scale height is about $0.01 R_{*}$. Extrapolated down to $10^{-14} \text{ g cm}^{-3}$, the base of the wind would be $\sim 60 R_{\odot}$ above R_{*} , hence at about $1.1 R_{*}$. Observations of RSG atmospheres suggest that the wind is actually launched from further out. The direct environment of Betelgeuse has been spatially resolved with adaptive optics or interferometry. [Kervella](#)

⁶ If the densities are of the order of $10^{-10}\text{--}10^{-9} \text{ g cm}^{-3}$ at 10^{14} cm, the photon mean free path $1/\kappa\rho$ is of the order of $10^9\text{--}10^{10}$ cm and no extended radiative precursor takes place.

et al. (2011) report on the detection of emission in the NIR out to large distances (up to $10R_*$), with the presence of inhomogeneities (surface brightness variations) or clumps. Ohnaka et al. (2011) discussed the dynamics of this inhomogeneous atmosphere and reports on the presence of upflows and downflows at the 10 km s^{-1} level out to several R_* . Similar conclusions are made by Josselin & Plez (2007). These observations suggest that the wind is driven from larger radii, and implies that there is an extended intermediate region where material moves up and down on a year timescale, and fed somehow from R_* , perhaps by pulsations or convective motions. The observations of SN 2013fs may suggest that this buffer region of a few R_* may actually contain $0.01\text{--}0.1 M_\odot$ of material. This material is optically-thin to electron-scattering in the RSG, but becomes optically thick when the shock breaks out. Such a small mass is sufficiently optically thick to give rise to the narrow symmetric line profiles observed in SN 2013fs at $\lesssim 2 \text{ d}$.

Hence, rather than a super wind, the environment inferred from the observations of some Type II SNe at early times may simply correspond to the cocoon of material that is observed around RSG stars like Betelgeuse. The shock is simply breaking out into the RSG atmosphere.

Fig. 11. Comparison of the multi-epoch spectra of SN 2013fs at early times with the spectra for models r1w5h (top) and r1w5r (bottom). All spectra have been scaled and shifted. The observations have been corrected for redshift but not for reddening. These two models roughly encompass the properties of SN 2013fs, with small offsets in the persistence of some lines (e.g., OVI 3811–3834 \AA). [See Section 5.2 for discussion.]

Fig. 12. Comparison between the optical flux (relative to the flux at 13 d) from our HERACLES simulations (we account for the flux between the Balmer and Paschen edges) and the observations of KSN 2011a (left), KSN 2011d (middle; [Garnavich et al. 2016](#)) and SN 2006bp (right; [Quimby et al. 2007](#)). The time origin is conveniently adjusted to correspond to the rise of the optical flux. A better match to the light curves is obtained for models with a dense/confined atmosphere/wind. None of our models match the fast rise of KSN 2011a.

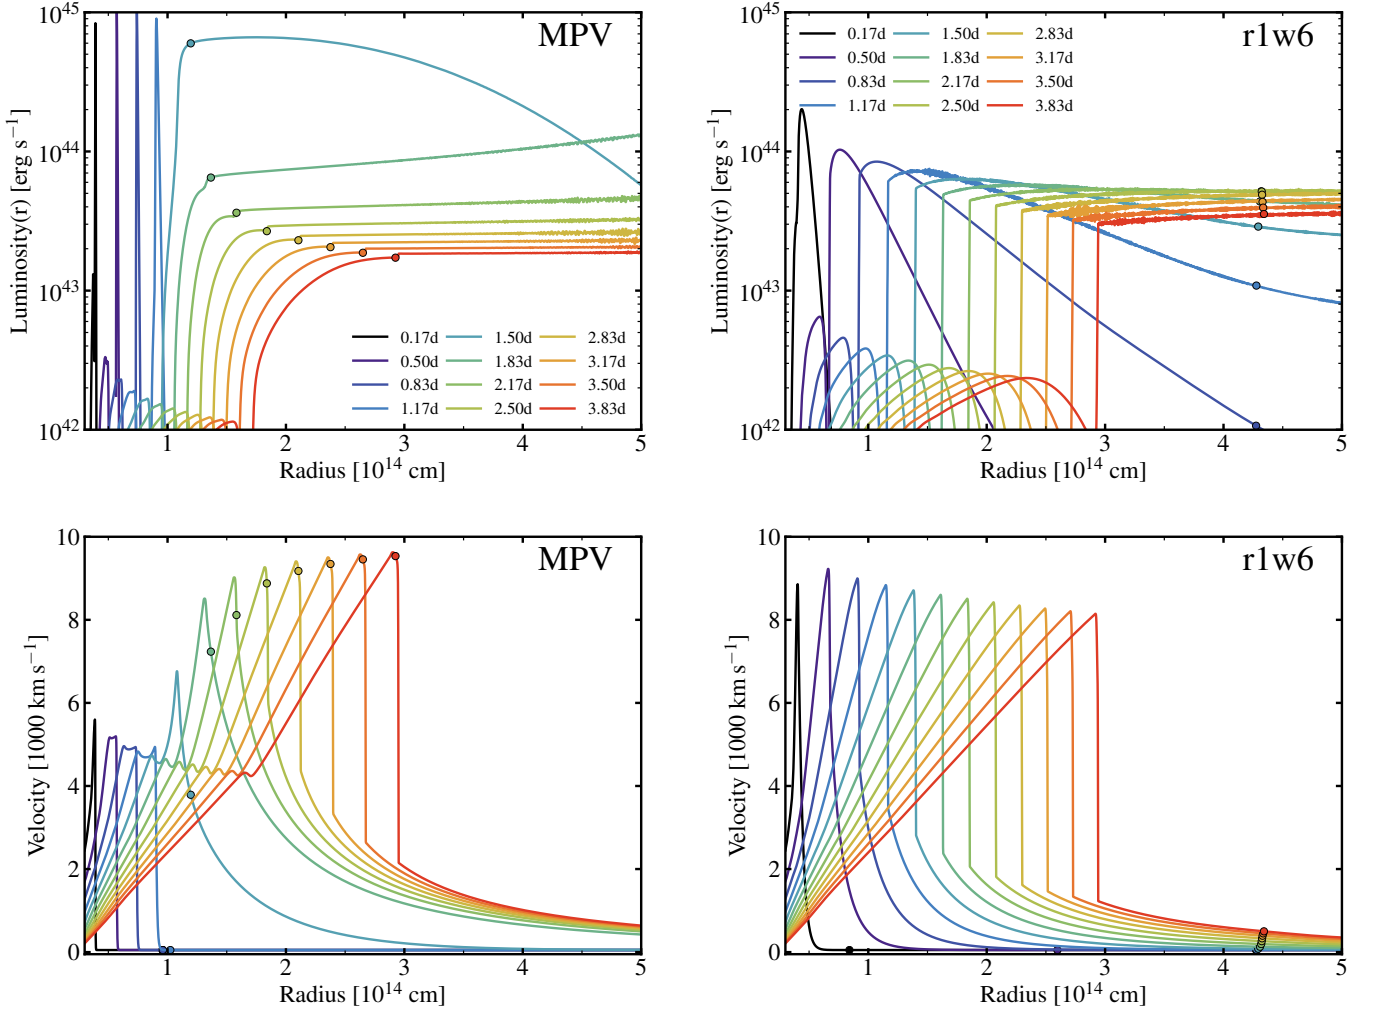

Fig. 13. Left: Evolution of the local radiative luminosity (top) and velocity (bottom) for the SN 2013fs model of [Morozova et al. \(2017, MPV\)](#). Right: Same as left, but now for model r1w6 characterized by a dense wind (but about 50 times less dense). The filled circle is the location of the photosphere at each epoch. In all panels, the same set of epochs is shown (from 0.17 until 3.83 d after the start of the simulation). In model r1w6, the luminosity maximum occurs well below the photosphere, and the slow material in between is at the origin of the narrow line profile cores with extended wings. In the configuration of MPV, this buffer of slow material is absent, there is no radiative precursor, and the event will show broad lines (with blueshifted emission peaks) immediately after shock breakout. The model of MPV, despite the interaction, will therefore not look like a SN IIn and will not match the earliest spectra of SN 2013fs.

CMFGEN**

**Appendix C: Montage of CMFGEN spectra for all
epochs and for all models**

Fig. A.1. Evolution of some ejecta properties computed by HERACLES for our set of models. In the top row, we show the velocity (left) and the radius (right) at an optical depth of 2/3 (solid line) and 10 (dashed line). In the middle row, we show the evolution of the gas temperature at an optical depth of 2/3 (left) and 10 (right). In the bottom row, we show the evolution of the maximum velocity on the grid (left) and of the total energy on the grid (kinetic: solid line; radiation: dashed line).

Fig. B.1. Bolometric light curves obtained with CMFGEN for models r1w1, r1w4, r1w1h, r1w5h, r1w5r, r1w6, and r2w1. The time origin corresponds to shock breakout. The CMFGEN models are computed adopting the radius, the velocity, the density, and the gas temperature from the HERACLES simulations at each epoch. The luminosity offset between the HERACLES and the CMFGEN simulations is about 10–20%, and the resulting light curves are very similar (compare with Fig. 6). There is a conceptual difference between the two codes since HERACLES takes explicit account of time dependence while CMFGEN computes the spectrum in steady state but adopting the time-dependent structure from HERACLES). HERACLES treats the gas in LTE while CMFGEN uses a non-LTE approach.

Fig. C.1. Montage of spectral for model r1w1 shown at all epochs computed. The time origin corresponds to shock breakout. The spectra are rectified and scaled (and finally stacked vertically). For the spectra, we actually show the quantity $[(F_\lambda/F_c - 1) \times \alpha + 1]$, where F_c is the continuum flux. To better show the weak lines, we take $\alpha = 3$.
