9

10 **Abstract** Chemical analysis of soils contaminated with coal tar indicated that most organic
11 compounds, and particularly PAHs, were contained in coarser particles (> 200 µm). Microscopic
12 observations of this fraction, carried out on polished sections, reported the presence of organic
13 particles in addition to mineral particles. Some organic particles had a very low porosity and their
14 microstructure did not evolve during biotreatment. Alternatively, other organic particles had a large
15 porosity composed of an interconnected pore network that was open to coal tar surface and thus in
16 contact with soil water. Interconnected porosity seemed to increase during biotreatment in relation
17 to a decrease in the amount of organic compounds. The amount of open porosity in contact with
18 soil water was expected to increase the desorption rate of PAHs. Consequently, the environmental
19 hazard could depend on the amount of open porosity in addition to chemical properties of organic
20 particles, such as their concentration in PAHs. Thus, microscopy can be complementary to
21 chemical analysis and ecotoxicological assays to assess the best strategy for remediation but also to
22 follow the advancement of a biotreatment.

27 **Introduction**

28 Industrial activities have led to the discharge of a wide range of hazardous chemical in soils, such
29 as coal tar that contains Non-Aqueous Phase Liquids (NAPLs). The composition of coal tar varies
30 widely depending on its origin (Brown et al. 2006). Nevertheless, coal tars are always composed of
31 hundreds of organic compounds but also of some inorganic constituents. Main organic compounds
32 are polynuclear aromatic hydrocarbons (PAHs), phenolic compounds, such as cresols, BTEX as
33 well as aliphatic and polar hydrocarbons (EPRI 1993). The microstructure of coal tars and their
34 cokes is complex and also varies markedly according to processing conditions. Some more or less
35 anisotropic textures are found along with variable amounts of porosity (Panaitescu and Predeanu
36 2007; Picon-Hernandez et al. 2008).

37 Most organic substances contained in coal tars are potentially toxic, mutagenic and
38 carcinogenic (White and Claxton 2004). Thus, once soils have been polluted by coal tar, it is
39 important to assess their environmental risk and try to suppress or at least to mitigate it. Some
40 remediation techniques are applied, such as bioremediation that is often used to cure PAH-
41 contaminated soils (Johnsen et al. 2005). Finally, the efficiency of a treatment also requires the
42 evaluation of post-treatment environmental risk.

43 Microbial degradation, one of the most important processes of PAH destruction in soils,
44 has been extensively studied. The transfer of PAHs from coal tar to soil water is the first critical
45 step before PAHs can be metabolized (Mahjoub et al. 2000; Nambi and Powers 2000; Semple et al.
46 2003; Benhabib et al. 2010). Thus, PAH availability to microorganisms depends primarily on PAH
47 transfer rate that is controlled by several mechanisms, such as (i) the diffusion of PAHs from coal
48 tar to soil water, (ii) the solubility of PAHs that decreases with increasing number of rings, (iii) the
49 contact surface of coal tar in soil water, and (iv) soil properties. The surface of coal tar particles in
50 contact with soil water depends on their shape, size and distribution in the different soil fractions
51 (Chung and Alexander 2002; Vulava et al. 2007; Al-Raoush 2014). However, despite of the
52 importance of coal tar microstructure in the bioremediation process, microscopic observations of
53 coal tar in polluted soils are scarce (Ghosh et al. 2000). A precise description of polluted soils is
54 also infrequent despite its usefulness to better understand the physicochemical processes involved.
55 For example, PAH availability to microorganisms can be reduced if PAHs are adsorbed to some
56 compounds of the soil, such as organic matter or clay particles, which protect them from
57 degradation (Vulava et al. 2012). Consequently, higher microbial degradation rates occur in soils
58 with lower amounts of soil organic matter and clay (Thiele-Bruhn and Brümmer 2004; Rhodes et
59 al. 2008).

60 Considering the complexity of the mechanisms involved, environmental risk is thus often

61 assessed by a global approach thanks to ecotoxicological bioassays. These bioassays indirectly
62 assess the bioavailability of PAHs in polluted soils (Peijnenburg et al. 2002; Eom et al. 2007;
63 Riding et al. 2013). However, bioassays are not compound-specific and the availability of
64 pollutants is also specifically linked to soil properties (Riding et al. 2013). PAH bioavailability is
65 thus related to the fraction actually available for the organisms used in the bioassay.

66 The present work aimed at further assessing the environmental hazard of three soils
67 polluted by coal tar that was previously estimated by an ecoscore calculated from a complete
68 battery of acute and chronic toxicity bioassays (Lors et al. 2010, 2011). In these previous studies,
69 ecotoxicity assessed by ecoscores was not connected with the total concentration of PAHs. A more
70 precise study of these three soils was thus performed to bring further explanations for the reported
71 differences. First, a chemical analysis was performed on several fractions of each soil to assess how
72 coal tar particles and PAHs were distributed. Second, a special attention was paid to the
73 observation of the microstructure of coal tar particles by several microscopic techniques. Finally,
74 the impact of both PAHs concentration in coal tar particles and their microstructure was discussed
75 with respect to the desorption rate of PAHs, and consequently to environmental hazard assessment.

76

77 **Material and methods**

78 **Soil samples**

79 Experiments were carried out on three coal tar-contaminated sandy soils sampled from two
80 historical industrial sites located in the North of France, in which the distillation of coal tar was the
81 main activity. Properties of these soils were detailed in previous papers (Lors et al. 2010, 2011).
82 Briefly, a soil was collected in one of the two sites, before (soil S3) after 6-month windrow
83 biotreatment (soil S3T), while soil S2 was collected in another site after 18-month windrow
84 biotreatment.

85

86 **Chemical and ecotoxicological analyses**

87 The three sandy soils were separated into six fractions: < 2, 2-20, 20-50, 50-200, 200-2000, and
88 > 2000 μm . The first three fractions were obtained by dry sieving using sieves between 50 and
89 200 μm . The smaller fractions (< 50 μm) were obtained by moist way, at first by sieving soil under
90 water through a sieve of 20 μm . The fraction retrieved on the sieve, corresponding to the fraction
91 20-50 μm , was dried to 30°C. The filtrate suspension, corresponding to the fraction < 20 μm , was

92 centrifuged to 1000 rpm during 3.5 min, enabling us to separate fractions 2-20 μm and $< 2 \mu\text{m}$. The
93 different fractions were dried at 30°C , then analysed to measure the concentration of the 16 PAHs
94 of the US-EPA list according to ISO 13877 (ISO 1998) and the total organic carbon (TOC)
95 concentration according to ISO 10694 (ISO 1995). Additionally, the mineral composition of the
96 soils was studied by X-ray diffraction.

97 Ecotoxicity was evaluated with the help of ecoscores, based on a restricted array of
98 biological endpoints. The calculation of ecoscores has been detailed in Lors et al. (2010, 2011,
99 2017). The set of bioassays was selected by Lors et al. (2011) from nine bioassays tested on the
100 basis of their best sensitivity to PAH pollution. This set of bioassays included both solid and liquid
101 phases and addressed acute and chronic toxicities and genotoxicity: two rapid bioassays (Microtox[®]
102 and springtail avoidance), a micronucleus test and three bioassays of a longer duration (algal
103 growth, lettuce germination and springtail reproduction).

104

105 **Microscopic observations of soil samples**

106 The soil fraction larger than $200 \mu\text{m}$ was prepared, in order to be observed by scanning electron
107 microscopy and by optical microscopy. The soil fraction was impregnated under vacuum with
108 epoxy resin in circular moulds (diameter: 2 cm). After hardening of the epoxy resin, the surface
109 was pre-polished under water using several diamond-covered polishing discs having a decreasing
110 particle size: 151, 75, 46 and $16 \mu\text{m}$. To obtain a flat surface prior to fine polishing steps, samples
111 were polished using a silicon carbide grinding wheel (particle size: $8 \mu\text{m}$). The fine polishing steps
112 were performed using diamond pastes of decreasing particle size (9, 6, 3, 1, $\frac{1}{2}$, and $\frac{1}{4} \mu\text{m}$).
113 Samples were gold coated before observation under a scanning electron microscope (Hitachi S-
114 4300SE/N) operating in backscattered electron (BSE) mode (20 KeV and 2 KA). Elemental
115 chemical analysis was performed with a Thermoscientific Ultradry EDX detector running at 15 kV.
116 Complementary experiments carried out with an optical microscope (Leica DMRXP) under
117 reflected light were performed directly on uncoated samples. Image analysis of BSE images was
118 performed using a specific procedure adapted from the statistical analysis of BSE images
119 performed on hydrated cement paste (Hu and Ma. 2016). First, one hundred coal tar particles were
120 cut manually using Adobe Photoshop[®] from several BSE images (3968×2232 pixels) taken at a
121 magnification of 100 x. Then, each digital coal tar particle was pasted in a separate rectangular
122 image having a white background colour. The total surface of coal tar particles was estimated by
123 counting the number of pixels having a level of grey different than white, using a MATLAB[®]
124 procedure. Then, coal tar images were segmented based on grey levels of pixels associated to the
125 organic compounds of coal tar. Indeed, the contrast organic phases, pore-intruding resin, empty

126 pores and mineral phases contained in the pores of coal tar particles was sufficient to easily depict
127 organic compounds. The content of organic compounds was determined by dividing the pixels of
128 segmented images by the total pixels of coal tar particles. Finally, the porosity of coal tar grains
129 was equal to the surface fraction that was not attributed to organic compounds. As 100 coal tar
130 particles were treated by image analysis for each soil, the surface fractions of coal tar particle
131 components were equal to their volume fraction (Igarashi et al., 2004).

132

133 **Results**

134 **Chemical analysis of soils as a function of soil fractions**

135 The biotreatment decreased PAH and total organic carbon (TOC), resulting in decreased
136 ecotoxicity, as expected (Fig. 1). However, soil S2 was much less ecotoxic than soil S3 despite its
137 higher amount of PAHs (Lors et al. 2017).

138 For all three soils, the fraction larger than 200 μm ($> 200 \mu\text{m}$) represents more than 70% of
139 the soil mass (Table 1). From a mineralogical point of view, all soils are mostly composed of
140 quartz with some feldspar as minor phase and traces of clay in accordance with the sandy nature of
141 the soils. The windrow treatment (S3T versus S3) did not alter the distribution of the different
142 mineral fractions. In all three soils the fraction 200-2000 μm contains the majority of total soil
143 organic carbon (TOC) and PAHs (Tables 2-4).

144 The advancement of the microbial degradation of PAHs contained in coal tar particles can
145 be estimated by considering the relative amount of most soluble (better bioavailable, with a lower
146 number of rings) over less soluble PAHs (Bamforth and Singleton 2005). This parameter, noted as
147 2-4/5-6 ratio, was calculated by dividing the concentrations of 2-4-ring PAHs by the concentrations
148 of 5-6-ring PAHs. This ratio is thus expected to decrease with the advancement of degradation. The
149 concentration of 5-6-ring PAHs is high relatively to 2-4-ring PAHs in all fractions of soil S2 (2-
150 4/5-6 ratio ranging from 0.83 to 1.55), in agreement with its previous windrow treatment (Table 2),
151 although a comparison with this soil previous to 18-month biotreatment is not possible. In soil S3;
152 the 2-4/5-6 ratio is much higher than in soil S2 and decreases from 9.8 to 4.4 from the coarsest to
153 the finest fraction, with an average value of 8.4 (Table 3).

154 Given that all three soils are strongly polluted with coal tar (Lors et al. 2010, 2011), tar
155 concentration can be approximated from the total organic content of the soil, other sources of
156 organic carbon being negligible compared to coal tar. The PAH concentration of coal tar particles
157 was thus estimated by the PAH concentration of the soil divided by its total organic content (noted

158 thereafter PAHs/TOC). This ratio is low for all fractions, with an average value of 0.83% indicating
159 a low PAH concentration in the remaining coal tar particles. Indeed, as the amounts of clay and
160 organic matter are very low in soil S2, most of the PAHs remaining after biotreatment are
161 entrapped in coal tar particles. The value of PAHs/TOC is higher in soil S3 than in soil S2, with an
162 average value of 3.2% (Tables 2 and 3). Thus, despite similar total PAH concentrations in these
163 soils, PAHs are more concentrated in the coal tar of soil S3. Additionally, soil S3 is also richer in 3-
164 and 4-ring PAHs and poorer in 2-, 5- and 6- ring PAHs.

165 As expected, soil S3T that was subjected to a windrow-treatment has a lower PAH
166 concentration than soil S3 whatever the fraction considered (Table 4). The windrow treatment did
167 not modify the distribution of PAHs between the different soil fractions, most PAHs being still
168 contained in the 200-2000 μm fraction (82%). The 2-4/5-6 ratios range from 1.4 to 4.0 according to
169 fraction, with an average value of 2.6 compared to 8.4 for the untreated soil. The reported values
170 indicate that 2- to 4-ring PAHs were more degraded than 5- to 6-ring PAHs during the
171 biotreatment. This can be explained by the higher bioavailability of 2- to 4-ring PAHs in
172 connection to their higher solubility (Bamforth and Singleton 2005). Nevertheless, despite of 6-
173 month windrow treatment, soil S3T has a higher 2-4/5-6 ratio than soil S2 even after 18-month
174 biotreatment, suggesting (in the absence of knowledge of initial values) that soil S2 is probably at a
175 more advanced stage of bioremediation than soil S3T. However, despite that bioremediation is
176 more advanced in soil S2, soil S3T has a value for PAHs/TOC lower than soil S2 (0.62% compared
177 to 0.83%) and its total amount of PAHs is also lower than soil S2 that contains a greater amount of
178 coal tar estimated by TOC. This suggests that soil S2 had been more heavily polluted than soil S3
179 before biotreatment. Additionally, the efficiency of the biotreatment applied to soil S3 can be
180 assessed by a strong drop in PAHs/TOC value, from 3.2% to 0.6%. Some of the organic
181 compounds contained in coal tar were thus degraded more slowly than PAHs or even not degraded
182 at all.

183

184 **Microscopic observations**

185 The observation of the soil fractions above 200 μm was performed on polished sections instead of
186 soil particles directly deposited on a sample holder. This method allows observing the internal
187 microstructure of the particles as cross sections are made during polishing. Moreover, chemical
188 analyses performed by EDS under SEM are more accurate on the flat surfaces of polished sections.

189 Microscopic observations by SEM of coarse grains of soil S2 indicate that most of them
190 are aggregates of small particles showing a large array of sizes, generally from 1 to 500 μm , with

191 different levels of grey (Fig. 2a). These levels of grey are linked to the mean atomic weight of the
192 compounds contained in the particles, darker levels corresponding to lower mean atomic weights.
193 Thus, organic compounds (with a skeleton made of carbon, $A_r = 12.01$) are dark grey while
194 mineral compounds (with a skeleton made of silicon in the present case, $A_r = 28.09$) are light grey.
195 The resin, used to impregnate the soil before sectioning it, appears dark grey like organic
196 compounds contained in soil particles.

197 Some organic compounds of soil S2 have angular shapes and are very homogeneous,
198 without visible internal porosity. These angular shapes can be linked to the break-up of larger
199 fragile particles, suggesting that these organic compounds are solid. Other organic particles have a
200 smooth rounded shape and are seemingly composed of high-viscosity organic compounds liquid.
201 Polished sections reveal the presence of a pore network that was not intruded by resin during
202 preparation. Pores have a flat shape and a size most often smaller than $10\ \mu\text{m}$ in diameter (Fig. 2b,
203 enlargement of Fig. 2a). These two major types of organic particles cannot be differentiated by
204 their chemical composition (EDS analysis): most carbon is found along with some oxygen and
205 traces of sulphur, as frequently observed in coal tar or coke particles (Picon-Hernandez et al. 2008).

206 Soil S3 also presents some large grains made of smaller organic and mineral particles (Fig.
207 2c). Contrary to soil S2, most coal tar particles are lens shaped, in agreement with viscous organic
208 compounds contained in quartziferous sandy soils (Vulava et al. 2007). Smaller soil grains are
209 often mostly comprised of a unique coal tar particle finely covered with very small mineral
210 particles glued to its surface (Fig. 2d). Almost all coal tar particles display a large porosity. Pore
211 networks are most often filled by the resin intruded during the preparation. EDS chemical analysis
212 was used to differentiate coal tar from resin, both showing almost identical grey levels: the resin
213 contains chloride whereas coal tar contains sulphur. The presence of resin in the pores indicates
214 that most pores are connected with the surface of coal tar particles. Some pores opening to the
215 surface have been reported previously from the observation of the surface of coal tar or coke
216 particles, the amount of pores varying markedly depending on origin and processing of the
217 constituents (Panaitescu and Predeanu 2007; Picon-Hernandez et al. 2008).

218 At least two distinct organic compounds are associated with distinct porosities: one organic
219 compound contains large pores (soil S3) and the other one is denser and displays a porosity looking
220 like that of soil S2 (Fig. 2d). Some particles, called cenospheres, that can be almost entirely porous,
221 were also observed by other authors (Panaitescu and Predeanu 2007; Ghosh et al. 2000).

222 In summary, the microstructure of coal tar is very heterogeneous with some anisotropy in
223 agreement with previous observations by Panaitescu and Predeanu (2007). However, the present
224 work demonstrates for the first time that the pores open to the surface are connected and thus that

225 pore water can be in contact with the internal porosity of coal tar particles. Observations in optical
226 microscopy demonstrate even more easily the presence of a connected pore network (Fig. 2e).
227 Here, the differentiation between coal tar and resin is obvious: organic compounds of coal tar
228 appear in white with some mosaic patterns in relation to coal tar anisotropy while resin appears
229 homogeneous with a medium grey level. The connected internal pore network of coal tar particles
230 is thus well defined by grey-level differences between resin and coal tar organic compounds.
231 Unconnected pores in which resin cannot penetrate are also well defined, appearing black. Optical
232 microscopy, simpler and less expensive than SEM, can give satisfactory results when estimating
233 the amount of porosity within coal tar particles. However, mineral compounds are not so well
234 discriminated compared to SEM observations with a better contrast due to differences in mean
235 atomic number. In addition, magnification is rapidly limited for optical microscopy compared to
236 SEM.

237 SEM observations on soil S3T reveal, in agreement with the distribution of soil fractions
238 (Table 1), that the biotreatment did not modify the initial size of coal tar particles. Like soil S3, soil
239 S3T shows large coal tar particles engulfed in a matrix of small mineral grains (Fig. 2f). However,
240 the volume of the internal pore network of coal tar particles was markedly increased by the
241 biotreatment (Fig. 2g). In order to further assess the connection of the internal pore system of coal
242 tar particles with soil water, polished sections of soil S3T were prepared with less pressure applied
243 to the resin when embedding the soil, the internal pore system of coal tar particles being not always
244 intruded by the resin. With this specific setup, it was possible to observe mineral particles in
245 contact with pores open at the coal tar surface. This is an additional evidence of the presence of an
246 open connected pore network that had developed over the whole volume of coal tar particles during
247 biotreatment.

248 Image analysis indicated that coal tar particles of soil S2 have a small pore volume fraction
249 of $6 \pm 1\%$ while pore volume fractions of $47 \pm 3\%$ and $65 \pm 4\%$ are found for soils S3 and S3T,
250 respectively.

251

252 **Discussion**

253 Microscopic observations of coal tar particles brought some helpful additional data to previous
254 ecotoxicological assays and chemical analyses (Lors et al. 2010, 2011), more especially by
255 revealing the presence of a connected network of pores open to the surface that depended on the
256 type of organic compounds contained in coal tar particles. When an open porosity was found, the
257 coal tar surface potentially in contact with soil water was expected to increase markedly.

258 Additionally, the presence of an open porosity can be beneficial to speed up the rate of
259 biodegradation of coal tar particles. Indeed, the biodegradation of coal tar particles increased the
260 amount of porosity indicating that biodegradation occurred on the whole available surface of coal
261 tar and thus even in the internal porosity of coal tar particles. The relative increase of porosity
262 between soils S3 and S3T due to biotreatment was 1.38. This increase can be related to the
263 microbial consumption of organic compounds ($33\ 000\ \text{mg kg}^{-1}$) contained in coal tar particles. As
264 the volume of coal tar particles remained constant, the proportion of consumption of coal tar can be
265 related to the relative increase of porosity if the density of coal tar is known. Considering an
266 average density of 1.3 for coal tar (Brown et al. 2006), the observed decrease of 36.6% of TOC
267 would lead to increase the porosity of soil S3 by 1.28. This value compares well with 1.38 that
268 corresponds to the relative increase of porosity between soils S3 and S3T.

269 The diffusion of pollutants and mostly PAHs from coal tar particles to soil water depends
270 first on the gradient of PAH concentration between coal tar particles and soil water. Thus,
271 ecoscores have been represented as a function of PAHs/TOC that gives an estimate of PAH
272 concentration in coal tar particles rather than their concentration in bulk soil as presented in Fig 1.
273 This estimate is expected to be pertinent for the three studied soils due to their low content in clay
274 and organic matter, known for having high sorptive affinities to PAHs (Lamichlane et al. 2016).
275 Ecoscores increase with PAHs/TOC: soil S2 now ranges between soils S3 and S3T (Fig. 3,
276 compare with Fig. 1). Thus, PAH concentration in coal tar particles differentiates soil S2 from soil
277 S3 despite a similar concentration of PAHs in both soils. Despite a strong hazard potential, soil S2
278 gave a moderate ecotoxic response as its coal tar particles exhibited a small internal pore volume.
279 This comparison of ecoscores and microscopic observations also confirms that analytical results of
280 solvent extracts are not representative of environmental hazard of PAH-polluted soils (Semple et al.
281 2003).

282 The amount of internal porosity of coal tar particles can also indicate the best strategy for
283 remediation. Indeed, if this amount is low, other techniques than biodegradation may be preferred.
284 The advancement of a biotreatment can also be surveyed by the increase of the internal porosity of
285 coal tar particles in relation to the biodegradation of organic compounds. Moreover, the value of
286 internal porosity can be used as a criterion to determine when the biotreatment can be ended.
287 Despite the necessary statistical approach of microscopy, this technique is the only one that can
288 assess quantitatively and qualitatively the porosity of coal tar particles. Other techniques, such as
289 mercury intrusion porosimetry or adsorption isotherm measurements, are not able to differentiate
290 the surface of organic compounds relative to that of mineral compounds contained in the soil.

291

292 **Conclusion**

293 As already known, the assessment of the environmental hazard of soils polluted by NAPLs and
294 especially by coal tar is complex and a multi-disciplinary approach is thus required. The
295 bioavailability of PAHs is linked to their rates of desorption from coal tar particles to the soil water
296 that depends first on diffusion but also on additional mechanisms. The diffusion of PAHs to soil
297 water can be correlated to the PAH concentration in coal tar particles. It can be estimated in the
298 case of the reported sandy soils by the overall ratio between PAH concentration and the total
299 organic content. Indeed, ecoscores increase almost linearly with PAH concentration in coal tar
300 particles, although this relationship should be verified on a wider array of soils. The rate of release
301 of PAHs is linked to additional parameters, such as the surface area of coal tar in contact with soil
302 water. Microscopic observations of the coarser fraction ($> 200 \mu\text{m}$) of two of the three studied soil
303 samples showed an interconnected pore network opening to the surface of coal tar particles.
304 Biotreatment increased the amount of porosity due to the microbial consumption of some organic
305 compounds contained in coal tar particles. The presence of a pore network increases markedly the
306 surface area of coal tar in contact with soil water and thus the potential release rate of pollutants.
307 Thus, microscopy can be an additional method to chemical analyses and ecotoxicological assays to
308 assess the best strategy for remediation but also to follow the efficiency of a biotreatment. Our
309 study also confirmed that the analysis of PAHs transferred to the water fraction using water instead
310 of solvent extraction could be advised in the perspective of environmental hazard assessment.

311

312 **Acknowledgements** The present study was performed with a financial support from the ADEME
313 (Agence de l'Environnement et de la Maîtrise de l'Énergie, France), which is greatly
314 acknowledged. We thank Total (France) and Charbonnages de France (France) to put industrial
315 sites at our disposal.

Table 1. Distribution of soil particle size fractions (in mass %) in the three studied soils.

Soil fractions	S2	S3	S3T
> 2000 μm	17.19	9.14	9.12
2000-200 μm	55.84	67.93	67.82
200 - 50 μm	23.41	18.16	18.14
50 - 20 μm	1.59	3.05	3.16
20 - 2 μm	1.72	1.39	1.44
< 2 μm	0.25	0.32	0.33

Table 2. PAH and total organic carbon concentrations in each fraction of soil S2.

Concentration (mg kg ⁻¹ of soil)	soil fraction (µm)						Soil = Σ fractions
	> 2000	2000-200	200-50	50-20	20-2.	< 2	
2 ring PAHs	41.6	247.5	109.2	6.2	14.0	1.9	420
3 ring PAHs	191.2	669.0	229.2	8.0	20.4	1.1	1 119
4 ring PAHs	28.3	223.3	97.1	4.2	10.7	0.1	364
5 ring PAHs	100.5	584.7	299.1	9.9	29.3	2.8	1 026
6 ring PAHs	68.4	430.2	228.2	7.3	22.3	1.6	758
Total PAHs	430	2 155	963	36	97	7	3 687
distribution of PAHs	11.66%	58.44%	26.11%	0.96%	2.62%	0.20%	100%
TOC	42 013	325 066	66 786	3 230	4 211	693	442 000
2-4 / 5-6 ratio	1.55	1.12	0.83	1.06	0.88	0.7	1.07
PAHs / TOC (%)	1.02	0.66	1.44	1.10	2.30	1.07	0.83

Table 3. PAH and total organic carbon concentrations in each fraction of soil S3.

concentration (mg kg ⁻¹ of soil)	soil fraction (µm)						Soil = Σ fractions
	> 2000	2000-200	200-50	50-20	20-2	< 2	
2 rings PAHs	2.5	65.3	8.1	0.4	0.4	0.0	77
3 rings PAHs	47.1	1 120.0	141.5	1.3	7.2	3.6	1 321
4 rings PAHs	41.0	1 000.4	129.7	3.3	8.7	7.6	1 191
5 rings PAHs	6.8	179.2	23.3	0.4	1.9	1.6	213
6 rings PAHs	2.5	79.0	9.7	0.2	1.2	1.0	94
Total PAHs	100	2 444	312	6	19	14	2 895
Distribution of PAHs	3.45%	84.42%	10.78%	0.19%	0.67%	0.48%	100%
TOC	6 325	77 617	5 146	335	396	181	90 000
2-4 / 5-6 ratio	9.78	8.47	8.48	8.55	5.31	4.37	8.44
PAHs / TOC (%)	1.58	3.15	6.07	1.68	4.90	7.65	3.22

Table 4. PAH and total organic carbon concentrations in each of soil S3T.

concentration (mg kg ⁻¹ of soil)	soil fraction (µm)						Soil = Σ fractions
