Abstract

Documenting sub-Antarctic glacier variations during the local last glacial maximum is of major interest to better understand their sensitivity to atmospheric and oceanic temperature changes in conjunction with Antarctic ice sheet changes. However, data are sparse because evidence of earlier glacier extents is for most sub-Antarctic islands located offshore making their observation complex. Here, we present 22 cosmogenic ³⁶Cl surface exposure ages obtained from five sites at Kerguelen to document the glacial history. The ³⁶Cl ages from roche moutonnée surfaces, erratics and boulders collected on moraines span from 41.9 ± 4.4 ka to 14.3 ± 1.1 ka. Ice began to retreat on the eastern part of the main island before 41.4 ± 4.4 ka. Slow deglaciation occurred from ~41 to ~29 ka. There is no evidence of advances between 29 ka and the Antarctic Cold Reversal (ACR) period (~14.5-12.9 ka) period. During the ACR, however, the Bontemps and possibly Belvedere moraines were formed by the advance of a Cook Ice Cap outlet glacier and a local glacier on the Presque Ile Jeanne d'Arc, respectively. This glacier evolution differs partly from that of glaciers in New

29 Zealand and in Patagonia. These asynchronous glacier changes in the sub-Antarctic region are however in
30 agreement with sea surface temperature changes recorded around Antarctica, which suggest differences in
31 the climate evolution of the Indo-Pacific and Atlantic sectors of Antarctica.

32

33 **Keywords:** Glacier fluctuations, ^{36}Cl cosmic-ray exposure dating, MIS 2-4, Kerguelen

34

35 **Highlights**

36 • Little is known about glacier fluctuations in sub-Antarctic regions.

37 • We present 22 cosmogenic ^{36}Cl surface exposure ages in Kerguelen Islands.

38 • The ^{36}Cl ages from erratic and moraine boulders span from 41 ka to 14 ka.

39 • Ice began to retreat on the eastern part of the main island before 41.4 ± 4.4 ka.

40 • Slow deglaciation occurred from ~ 41 to ~ 29 ka.

41

42 • This pattern of deglaciation partly differs from that of glaciers in New Zealand and in Patagonia due to
43 different regional climate conditions.

50

51 **1. Introduction**

52 Hodgson et al (2014) published a synthesis of terrestrial and submarine evidence of the extent and timing
53 of the global Last Glacial Maximum (gLGM 26, 500-19, 000 years ago) (Clark et al., 2009) and the onset
54 of deglaciation on the maritime-Antarctic and sub-Antarctic islands in the framework of the Scientific
55 Committee for Antarctic Research (SCAR). Based on the lack of glacier chronologies or indirect evidence
56 of glacier extents from the local LGM (ILGM), Kerguelen archipelago, located in the Indian Ocean (49°S ,
57 69°E ; Fig 1), was classified as an area with a limited ILGM ice extent, but as subject to extensive earlier
58 continental shelf glaciations. The Kerguelen archipelago is, however, the largest currently glaciated area in
59 sub-Antarctic regions with numerous terrestrial glaciers. The Cook Ice Cap (CIC) and smaller glaciers

60 covered a total area of 520 km² in 2009 (Berthier et al., 2009). These glaciers are known to be very sensitive
61 indicators of climate change in the southern polar region. Favier et al (2016) showed that the current high
62 wastage of the largest CIC outlet Ampere glacier was driven by atmospheric drying, which was induced by
63 a latitudinal shift of the storm track over the last decades. This latitudinal storm track shift is mainly driven
64 by the Southern Annular Mode, whose positive phase (SAM+) is associated with a belt of low pressure
65 surrounding Antarctica (Thompson and Wallace, 2000; Thompson et al., 2011). In addition, Jomelli et al
66 (2017) provided chronological evidences of a general glacier retreat since the Late Glacial in Kerguelen and
67 suggested that this glacier retreat was concomitant with warming and snow accumulation decrease in
68 Antarctica, thus demonstrating the sensitivity of the CIC to climate change in the Antarctic region.

69
70 Considering this connection between glaciers in Kerguelen and Antarctic climate, new investigations on
71 glacier extensions during and before the ILGM in Kerguelen is particularly relevant. It raises questions
72 regarding their relative pacing with Antarctic climate and ice sheet changes. Moreover, a comparison of
73 several ice core records from West and East Antarctic Ice Sheets revealed distinct variations, pointing to
74 differences in the climate evolution of the Indo-Pacific and Atlantic sectors of Antarctica (Stenni et al.,
75 2010, 2011). A better knowledge of glacier changes at Kerguelen may be relevant to discussing possible
76 differences in glacier behavior between the Indo-Pacific and Atlantic sectors of sub-Antarctic regions.

77
78 To address these issues, a field campaign organized in the framework of two IPEV(Institut Paul Emile
79 Victor) programs (Kesacco and Glacepreker) was conducted focusing on the geomorphology and the
80 chronology of several glacially formed landscapes and deposits at the margin of the CIC with the aim to
81 document the timing and extent of the LGM in Kerguelen. Here, we present 22 new ³⁶Cl cosmic-ray
82 exposure ages obtained from roche moutonnee surfaces, erratics and boulders collected on moraines over
83 the whole extent of the main island.

84

85

86

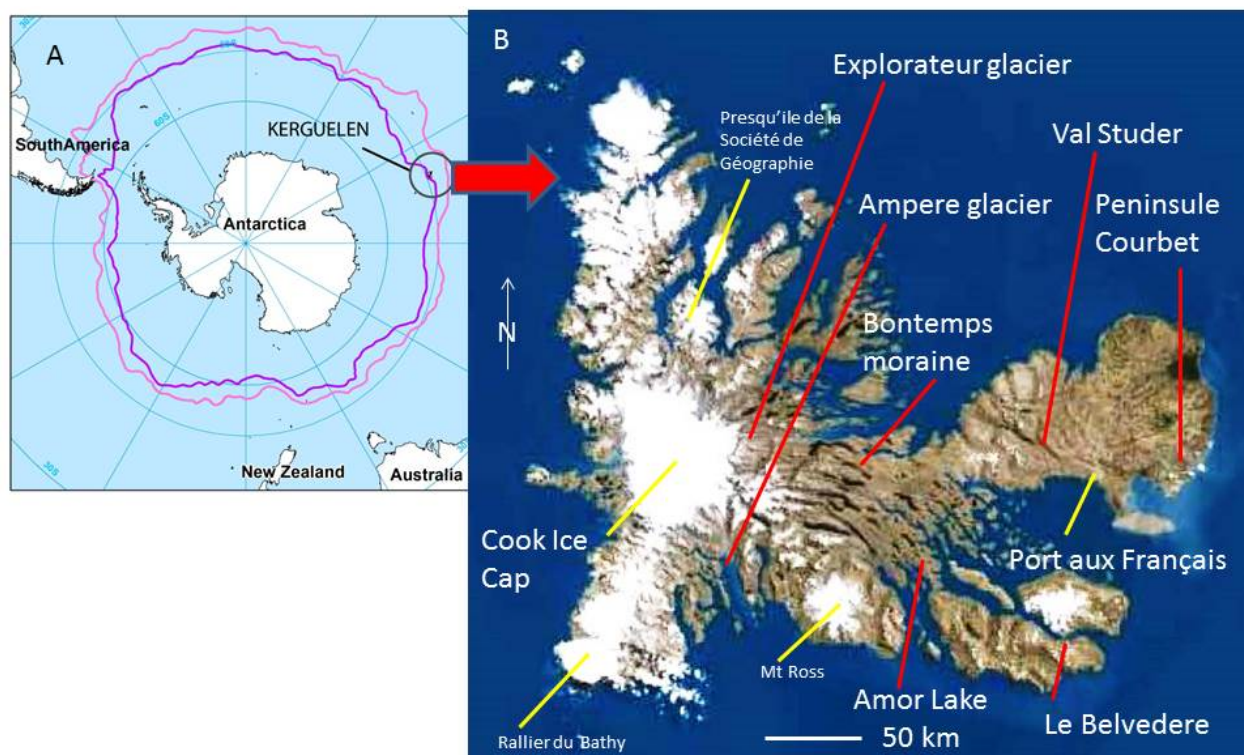

87 **2. Study area**

88 The French Kerguelen basaltic archipelago is located in the southern Indian Ocean (49°N, 69°E) about
89 2000 km north of Antarctica. It is composed of one main island with an area of 6,700 km² and about 300
90 smaller islands (Fig. 1) emerged from the Kerguelen oceanic plateau about 40 Ma ago. It stretches over a
91 distance of about 150 km. The western part of the archipelago is covered by the CIC, the largest ice cap on
92 this island (410 km² in 2011, Verfaillie et al., 2015), which is culminating at 1,030 m above sea level (a.s.l.).

93 Glaciers are also present at the base of three summits, at Mont Ross 1,850 m a.s.l., the highest summit on
94 Kerguelen about 40 km south east of CIC, as well as on the highest slopes of Rallier du Bathy (1100 m a.s.l.)
95 45 km south of CIC and on Presqu'île de la Société de Géographie (1081 m a.s.l.). The eastern part of the
96 archipelago forms an ice free peninsula with a mean elevation of 200 m a.s.l.. However, numerous undated
97 glacial features such as erratic boulders, kettles, and Rogen moraines demonstrate that this area was covered
98 by ice in the past (Hall, 1984). It is probable that evidence of earlier glacier extent exists off shore. To date,
99 a LGM frontal moraine may have been identified from bathymetry off shore from Ampere glacier (Jomelli
100 et al., 2017).

101 There is only one permanent weather station on the Kerguelen Islands, located at the scientific station Port
102 aux Français (PAF) (12 m a.s.l.) with daily values of temperature and precipitation available since 1951.
103 Here the mean annual temperature is 4.6°C with 800 mm of precipitation. However, the precipitation
104 amounts on the main island are affected by a strong W-E gradient due to foehn effect on the eastern side of
105 CIC, which constitutes a barrier to the dominant westerly winds. At CIC, the precipitation amount reaches
106 3,150 mm per year at 250 m a.s.l. (Verfaillie et al., 2015).

107

108

111 mean positions of the sub-Antarctic (pink) and polar (purple) oceanic fronts between 1993 and 2005. B. Red lines

112 show the five cosmogenic sample sites investigated in this study; yellow lines show geographic locations described in
113 the paper.

114

115 **3. Previous glaciological studies on glaciers at Kerguelen**

116 The first glaciological investigations at Kerguelen were realized in the 1970s, during which surface energy
117 and mass balance studies (Poggi, 1977; Vallon, 1977a, 1977b, 1987) were conducted on Ampere glacier.
118 Additionally, satellite images made it possible to assess CIC wastage over the last decades (Berthier et al.,
119 2009; Verfaillie, et al., 2015). During the last six years, new glaciological investigations were conducted at
120 Kerguelen. Ablation stakes were set up in December 2010 and January 2011 and were measured during the
121 next three years to assess the glacier surface mass balance. A total loss of 1.6 meter water equivalent per
122 year (m w.e. a⁻¹) was measured over the ice cap between 1960 and 2011, with a maximum loss of 2.76 m
123 w.e. a⁻¹ on Ampere glacier. From a detection attribution analysis, Favier et al. (2016) demonstrated that
124 precipitation decrease was the first order cause for glacier wastage since the 1960s. Precipitation changes
125 were attributed to a shift of the latitudinal position of the storm track mainly driven by the Southern Annular
126 Mode (SAM) whose positive phase (SAM+) is associated with a belt of low pressure surrounding Antarctica
127 (Thompson and Wallace, 2000; Thompson et al., 2011) and dry conditions at Kerguelen.

128

129 To better understand the long term evolution of glaciers at Kerguelen, 13 cosmogenic ³⁶Cl surface exposure
130 ages were determined at four sites, one located close to Ampere glacier front position and three 20 km away
131 from the CIC (Jomelli et al., 2017). These data were combined with existing radiocarbon ages from
132 terrestrial and marine sediments cores, bathymetric measurements and a relative dating technique that uses
133 the radial growth of *Azorella selago* Hook, a cushion-forming Umbelliferae species growing on the moraine
134 (Frenot et al 1993; 1997). Results revealed that deglaciation started at least ~24 ka ago and that the landscape
135 up to 20 km east of CIC was still partly covered by ice during the Late glacial. Glaciers were shrinking
136 through the Holocene probably until 3 ka with evidence of minor advances during the last millennium
137 (Jomelli et al., 2017).

138

139 **4. Methods**

140 The fieldwork was conducted in different areas of the Kerguelen Islands on the slope east of the CIC in
141 order to complement a previous study (Jomelli et al., 2017) and document earlier glacier extents on the main
142 Island at various altitudes and distances from CIC. Frontal moraines are rare on the main island but erratics
143 and roche moutonnees are very frequent making possible to document past ice extents. Five sites, Peninsula

144 Courbet, Val Studer, Armor Lake, Bontemps valley and Le Belvedere moraine (sample locations in Fig.1
145 and Table 1; note that Armor Lake and Ampere glacier were studied by Jomelli et al., 2017. Their
146 chronologies are discussed at the end of this paper) were visited in order to collect rock samples from glacial
147 moraine boulders, erratic boulders and roche moutonnee surfaces:

148
149 Samples were taken with a hammer and a chisel from preferentially flat surfaces of erratic and moraine
150 boulders and of roche moutonnee. The geographic coordinates were recorded with a handheld GPS device
151 and topographic shielding was measured using a clinometer (Table 1). The altitudes were later determined
152 from shuttle radar topography mission data (SRTM), because they are more accurate than the handheld GPS
153 data (Table 1).

154 The *in situ* ^{36}Cl dating was conducted on the basaltic whole rock samples at CEREGE, Aix-en-Provence,
155 France, similar to the method described in Schimmelpfennig et al. (2011). An aliquot of bulk rock was
156 taken from several samples for major and trace element analysis at the Service d'Analyse des Roches et des
157 Minéraux (SARM, Nancy, France) (Tables 2-3), necessary to estimate the low-energy neutron flux in the
158 samples, which induces the ^{36}Cl production from capture of the low-energy neutrons on ^{35}Cl . Due to low Cl
159 concentrations (Table 4), this production reaction contributed little to the total ^{36}Cl production in most
160 samples (between ~2% and ~9%), except for sample Ker-16 (16%).

161 After crushing and sieving to a grain size fraction of 250-500 μm , the samples were decontaminated from
162 potentially Cl-rich groundmass and atmospheric ^{36}Cl in a diluted suprapur HF/HNO₃ acid mixture
163 (Schimmelpfennig et al., 2009). Following this step, which removed about 40% of the initial samples
164 weight, 2 g aliquots of the rinsed and dried sample grains were taken for analysis of the major elements
165 concentrations by ICP-OES at SARM (Table 3), because Ca, K, Ti and Fe, are the target elements for
166 spallogenic/muogenic production of ^{36}Cl . After addition of a ^{35}Cl -enriched spike (~99%) for isotope dilution
167 (Ivy-Ochs et al., 2004), the samples were totally dissolved in a HF/HNO₃ acid mixture. Two chemistry
168 blanks were processed together with the samples (Table 4). The remaining steps were identical with those
169 described in Schimmelpfennig et al. (2011). Measurement of the $^{36}\text{Cl}/^{35}\text{Cl}$ and $^{35}\text{Cl}/^{37}\text{Cl}$ ratios by isotope
170 dilution accelerator mass spectrometry at the AMS facility ASTER-CEREGE allowed the calculation of the
171 ^{36}Cl and Cl concentrations (Table 4).

172 ^{36}Cl age calculations were done using the Excel® spreadsheet published by Schimmelpfennig et al. (2009),
173 using scaling factors based on the time-invariant "St" method (Stone, 2000) (Table 4) and applying the
174 following ^{36}Cl production rates, referenced to sea level and high latitude (SLHL): 42.2 ± 4.8 atoms ^{36}Cl (g
175 Ca)⁻¹ yr⁻¹ for spallation of Ca (Schimmelpfennig et al., 2011), 148.1 ± 7.8 atoms ^{36}Cl (g K)⁻¹ yr⁻¹ for spallation

176 of K (Schimmelpfennig et al., 2014), 13 ± 3 atoms ^{36}Cl (g Ti) $^{-1}$ yr $^{-1}$ for spallation of Ti (Fink et al., 2000),
177 1.9 ± 0.2 atoms ^{36}Cl (g Fe) $^{-1}$ yr $^{-1}$ for spallation of Fe (Stone et al., 2005), and 626 neutrons (g air) $^{-1}$ yr $^{-1}$ for
178 the production rate of epithermal neutrons from fast neutrons in the atmosphere at the land/atmosphere
179 interface (Phillips et al., 2001). A high-energy neutron attenuation length of 160 g cm $^{-2}$ was used. We
180 assumed bulk rock density of 2.4 g cm $^{-3}$ for all samples. Further relevant input data (sample thicknesses,
181 shielding factors, compositional data) are shown in Tables 1, 2 and 3.

182
183 In Table 4, we present the 1σ uncertainties of the resulting individual ^{36}Cl ages inferred through full
184 propagation of all errors (analytical and production rate errors) as well as of the analytical errors only. In
185 the main text, we report the individual ages with their analytic uncertainties only for the sake of internal
186 comparison between the ages; when presenting the mean of an age population, we report the arithmetic
187 mean and the full error including the production rate error to allow comparison with climate records that
188 were dated with different methods. We determined this full error by computing the standard deviation and
189 adding analytical and production rate errors (represented by the mean of the relative individual age
190 uncertainties) by propagation in quadrature. On the maps, all ages are shown with the full errors, unless
191 otherwise stated. A Chi^2 test was applied to identify potential outliers within an age population.

192
193 The ^{36}Cl ages are presented without erosion or snow cover corrections. Concerning erosion, quantitative
194 information at Kerguelen is not available at present, but during sampling, surfaces with little evidence of
195 erosion were preferentially targeted (degree of weathering and direct evidence on the boulder surface of
196 frost, salt or wind action). Assuming an erosion rate of 5 mm ka would result in a 10% increase of the oldest
197 ^{36}Cl ages (erratic boulders at Peninsula Courbet) and less for the younger ages. This is within the overall
198 uncertainties of the final ^{36}Cl ages and taking it into consideration would not change the conclusions of this
199 study. Potential snow cover effects were not considered in the ^{36}Cl age calculations, because of the modern
200 short annual snow cover duration (~ 1.5 months at 90 m altitude and ~ 3 weeks at 35 m altitude as inferred
201 from glaciological modelling (Verfaillie et al., 2015; Favier et al., 2016)), which would lead to an
202 insignificant snow cover correction.

203

204

205 **5. Results**

206

207 **5.1 Erratic boulders deposited far east of CIC**

208 The ^{36}Cl ages range from ~42 to ~11 ka (Table 1-4) with an ~80% contribution covering the 42-20 ka period.
209 Our dataset can be divided into three groups (erratics, roche moutonnees and moraine landforms) in terms
210 of sampled glacial features and distance from CIC.

211 The first group is composed of the 13 distant erratic boulders located at Peninsula Courbet and Val Studer.
212 Peninsula Courbet is the farthest sampling site located about 85 km east of CIC in our study, at an altitude
213 between 37 m and 57 m a.s.l. (Figs.1, 2, 3; table 1). Most of this peninsula is relatively flat with altitudes
214 lower than 100 m a.s.l. Numerous kettle lakes are visible. They are associated with loosely-spaced ridges or
215 small hills 2-5 m high, mostly covered by sand and gravel with few larger boulders that may correspond to
216 a glacial till. These ridges may correspond to remains of Rogen moraines formed transverse to ice flow in a
217 subglacial position and indicating the presence of an ice sheet flowing eastward. Three samples (Ker 26,
218 Ker 27, Ker 28) were collected from large erratic boulders 8 km north east of PAF (Fig.2). These three
219 erratic are the oldest dated samples in this study. Positioned on a rocky pavement, they yield consistent ^{36}Cl
220 ages of 40.9 ± 2.7 ka, 41.9 ± 2.8 ka and 41.3 ± 2.8 ka, with a mean age of 41.4 ± 4.4 ka (Figs. 2-4, 13).

221 Erratic are rare closer the coast and on northeastern direction. Nevertheless two additional samples (Ker 29
222 and Ker 30) were collected from erratics partly embedded in a sandy gravel pavement 5 and 11 km north
223 east from the previous sampling site, respectively (Fig.2). They yield ages of 30.7 ± 2.0 ka and 26.7 ± 3.0
224 ka.

Fig. 2. Location of ^{36}Cl ages with their arithmetic mean at Peninsule Courbet site. The 1σ uncertainties in the individual ^{36}Cl erratic ages account for analytical and production rate uncertainties, while the uncertainty in the mean includes standard deviation, analytical and production rate uncertainties. The samples in *italic* were rejected as outliers based on a Chi^2 test (see text for details).

According to the Chi^2 test, these ages do not belong to the same age population as the other three dates, but are statistically indistinguishable from each other with a mean of 28.7 ± 4.3 ka. Two explanations are possible: either these two younger boulders were deposited following a later ice advance compared to the deposition of the ~ 41 ka boulders, or they reflect post depositional erosion or exhumation processes. Since there is no firm evidence supporting either of the two scenarios, we assume these two younger boulder ages as outliers (reflecting possible post depositional erosion or exhumation processes) and do not further consider them.

Figure 3. Pictures of some of the sites sampled during the field campaigns. A: erratic boulders Ker-28 at Peninsula Courbet. B: erratic boulders Ker-34 at Val Studer. C: sampling of the roche moutonnee near Armor Lake. D: erratic boulder Ker-38 at Val Studer.

270

271

272 Fig 4. Probability plots of ^{36}Cl boulder ages from Peninsule Courbet. Please note that the gaussian curves
 273 of the individual ages do not include the ^{36}Cl production rate uncertainties (analytical uncertainties only),
 274 while the error of the mean age in the upper left corner box includes the ^{36}Cl production rate uncertainties.
 275 Grey curves are outliers. Vertical blue line and grey band represent arithmetic mean and standard deviation,
 276 respectively (outliers are not included).

277

278 The second sample site is Val Studer, a typical deep U-shaped glacial valley located at 60 km from CIC and
 279 about 16 km from PAF. Three erratic boulders were collected at about 320 m a.s.l. on the southern slope of
 280 Montagne Verte (716 m a.s.l.), the highest summit on the left side of Riviere du Sud. These erratics (Ker
 281 31, 32, and 34) sampled on flat surfaces yield ^{36}Cl ages of 11.06 ± 0.86 ka, 26.5 ± 1.8 ka, and 30.8 ± 2.1 ka
 282 respectively. Rejecting Ker 31 (11.06 ± 0.86 ka) as an outlier based on the Chi^2 test, Ker 32 and Ker 34
 283 give a mean age of 28.6 ± 4.1 ka.

284 About 8 km downslope five other erratic boulders were sampled on the Plateau des Drumlins between 48
 285 and 63 m a.s.l. (Table 1, Fig. 3, 5). These boulders (Ker 35-39) yield ^{36}Cl ages of 40.6 ± 2.7 ka, 24.4 ± 1.7
 286 ka, 38.9 ± 2.7 ka, 31.3 ± 2.1 ka and 27.8 ± 1.9 ka (Fig. 5, 6). All these boulders were also collected on flat
 287 surfaces in order to avoid downslope movements.

288

289

290

291 Fig. 5. Location of ^{36}Cl ages with their arithmetic means at Val Studer site. The 1σ uncertainties in the individual ^{36}Cl
 292 boulder ages account for analytical and production rate uncertainties, while the uncertainties in the means include
 293 standard deviation, analytical and production rate uncertainties. A sample in italic from Montagne Vertes was rejected
 294 as outlier based on the Chi^2 test (see text for details). For the boulders near Plateau des Drumlins there are two possible
 295 groups of outliers; see text for clarification.

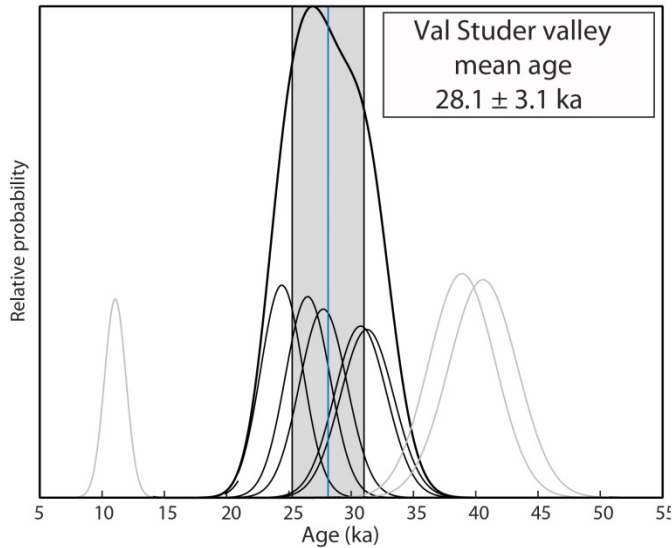

296

297 Based on the Chi^2 test, two sub groups can be distinguished among samples Ker 35-39, leading us to consider
 298 two distinct hypotheses for these low elevation samples. The first hypothesis rejects the three samples Ker
 299 35 (40.6 ± 2.7 ka), Ker 36 (24.4 ± 1.7 ka) and Ker 37 (38.9 ± 2.7 ka) as outliers. Then Ker 38 and Ker 39
 300 yield a mean age of 29.5 ± 3.8 ka (Fig.5). This hypothesis implies a synchronous boulder deposition at the
 301 two elevations in Val Studer valley (Ker 32, Ker 34). The second hypothesis rejects the three samples Ker
 302 36 (24.4 ± 1.7 ka), Ker 38 (31.3 ± 2.1 ka), and Ker 39 (27.8 ± 1.9 ka) as outliers. Then Ker 35 and Ker 37
 303 yield a mean age of 39.7 ± 1.2 ka (standard deviation only) and 39.7 ± 4.0 ka (full uncertainty) (Figs. 5, 6,
 304 13). This second hypothesis implies two distinct depositional periods at Val Studer first at Plateau des
 305 Drumlins, then at Montagnes Vertes. It also implies temporal synchronicity with the boulder ages from
 306 Peninsula Courbet, even supporting two synchronous deposition periods at both sites at ~40 ka and ~29 ka.
 307 However, this second hypothesis is not further discussed due to the lack of evidence of two boulder
 308 deposition periods. Nevertheless, this scenario does not contradict the general conclusions of this study.

309 Finally, considering all ages from the two altitudes in Val Studer valley (Montagnes Vertes and Plateau des
 310 Drumlins), after rejection of Ker 31, Ker 35 and Ker 37 as outliers, yields a mean age of 28.1 ± 3.1 ka
 311 (Figs.5, 6). As this mean value is not statistically different from the first hypothesis presented above (29.5

312 ± 3.8 ka) based on the mean of the two Ker 38-39 samples but based on a larger number of boulders, it will
313 be considered as representative for the Val Studer site in the following text.

5.2 Roches moutonnees at 37 km from CIC

322 The second group of samples comes from five roche moutonnees. Roughly 37 km east of CIC, five samples
323 (Ker, 12, 13, 14, 15 and 16) were collected on the basaltic plateau on the south-western side of Armor Lake.
324 Ker 12, 13 and 14 were sampled at an altitude of 132 m a.s.l and Ker 15 and 16 at 125 m a.s.l. and 53 m
325 a.s.l. respectively (Table 1, Figs.3, 7). These roche moutonnees samples complement two ^{36}Cl ages obtained
326 from erratic boulders located at 176 m and 177 m a.s.l. and dated to a mean age of 24.4 ± 1.1 ka (Jomelli et
327 al., 2017).

328

329 The samples Ker 12-16 yield ^{36}Cl ages of 29.5 ± 2.1 ka, 32.1 ± 2.2 ka, 41.4 ± 2.8 ka, 30.1 ± 2.1 ka and 25.9
330 ± 2.0 ka respectively (Figs. 7, 8). Rejecting Ker 14 (41.4 ± 2.8 ka) as an outlier based on the Chi^2 test, the
331 other samples yield a mean age of 29.4 ± 3.3 ka (full uncertainty). Grouping the ages previously dated by
332 Jomelli et al., (2017) with those of the roches moutonnes and rejecting Ker 14 (41.4 ± 2.8 ka) and Ker 13
333 (32.1 ± 2.2 ka) as outliers, yields a mean age of 26.9 ± 3.0 ka.

334

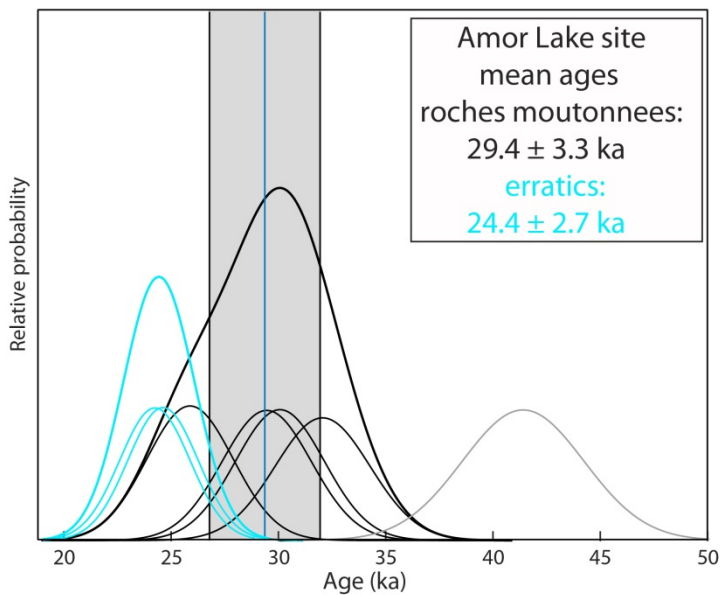

335

336 Fig. 7. Location of ^{36}Cl ages at Amor lake site. Green circles show samples from roche moutonnees with their
 337 arithmetic mean and white circles show erratic boulder ages from Jomelli et al., (2017). The 1σ uncertainties in the
 338 individual ^{36}Cl boulder ages account for analytical and production rate uncertainties, while the uncertainties in the
 339 means includes standard deviation, analytical and production rate uncertainties. The sample in italic was rejected as an
 340 outlier based on the Chi^2 test (see text for details).

341

346 show ages of erratics from Jomelli et al. (2017).

347

348

349

350 5.3 Moraine landforms

351 The last group of ^{36}Cl ages presented in this paper is composed of four boulders on the top of two distinct
352 moraines.

353 In Bontemps valley, the CIC outlet Explorateur glacier formed a prominent moraine located about 26 km
354 down-valley from the current ice front, where it dammed Bontemps Lake, the largest lake on the main
355 island. This moraine, covered by sub-angular large boulders (>50 cm in length), was tentatively dated to the
356 ACR chronozone (13.3 ± 1.4 ka) by Jomelli et al (2017), based on three boulder ages, one of which was
357 rejected as an outlier. In this study, one additional sample (KBT7) was collected from the top of this frontal
358 moraine at 16 m a.s.l (Figs.3, 9) to better constrain the age of this moraine.

359

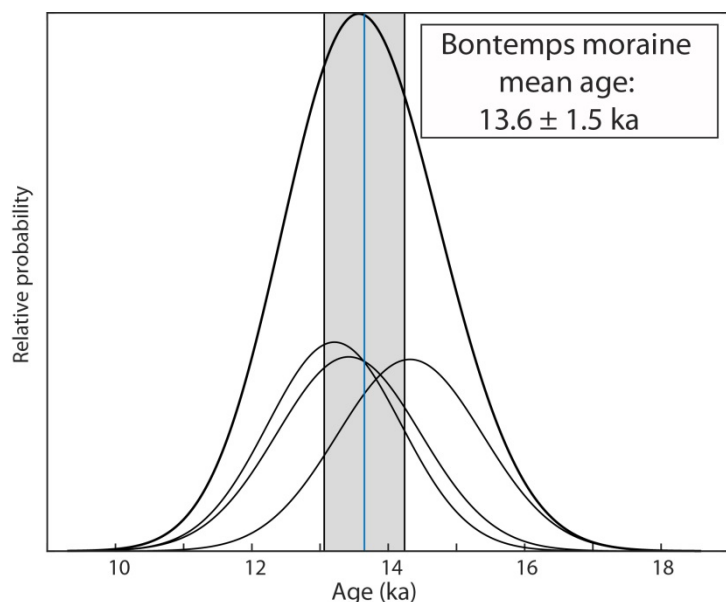

360

361 Fig.9. Sample locations in Bontemps valley with the corresponding individual ^{36}Cl ages. A red circle shows the new
362 sample on Bontemps moraine highlighted by the yellow line, white circles show boulder ages from Jomelli et al.,
363 (2017). Also shown are the arithmetic means for the age population with the 1σ uncertainty including standard

364 deviation, analytical and production rate uncertainties. The sample in *italic* was rejected as an outlier based on the
365 χ^2 test (see text for details).

366
367 KBT7 is dated to 14.3 ± 1.1 ka and is consistent with previous boulder ages from the same moraine KBT5
368 13.2 ± 1.0 ka and KBT6 13.4 ± 1.1 ka (standard deviation only) (Fig. 9, 10, 13). All three samples from
369 Bontemps moraine yield a mean age of 13.6 ± 1.5 ka.

370

371

372 Fig. 10. Probability plots of ^{36}Cl moraine boulder ages from Bontemps moraine. See caption of Fig. 4 for details.

373

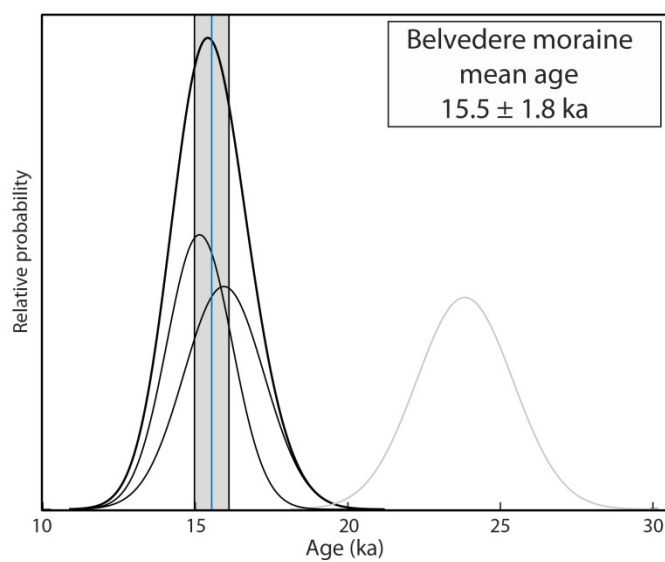

374 Three other samples HBN2, HBN3 and HBN4 were collected at an altitude between 115 and 138 m a.s.l.
375 from boulders of about 70-100 cm height on the crest of the Belvedere moraine, about 72 km from CIC, on
376 the southeastern part of Kerguelen about 32 km south of PAF (Fig. 11). This left lateral moraine, formed by
377 a local glacier is located on the southern slope of a small glacial cirque below the plateau les Haut de
378 Hurlevent. This moraine of about 300 m long and 20 m high, has steep slopes and is covered by subangular
379 boulders.

380 The three samples yield ^{36}Cl ages of 15.1 ± 1.1 ka and 15.9 ± 1.3 ka and 23.8 ± 1.6 ka, respectively. From
381 this dataset, sample HBN4 (23.8 ± 1.6 ka) was rejected as an outlier based on the χ^2 test. This moraine
382 boulder likely was pre-exposed to cosmic radiation and reworked during the last glacier advance. The
383 remaining two consistent moraine boulder ages yield a mean of 15.5 ± 1.8 ka (Figs. 3, 11, 12).

384

385
 386 Fig. 11. Location of ^{36}Cl ages on Belvedere moraine site. The 1σ uncertainties in the individual ^{36}Cl boulder ages
 387 account for analytical and production rate uncertainties, while the uncertainty in the mean includes standard deviation,
 388 analytical and production rate uncertainties. The sample in *italic* was rejected as an outlier based on the Chi^2 test (see
 389 text for details).

 392 Fig. 12. Probability plots of ^{36}Cl boulder ages from Belvedere moraine. See caption of Fig. 4 for details.

393

394

395 **6. Discussion**

396 **6.1 History of glacier fluctuations at Kerguelen from 41 ka to the late glacial**

397 ³⁶Cl cosmic-ray exposure dating of glacial erratics, roches moutonnees and morainic boulders collected at
398 different sites over Kerguelen archipelago provide constraints on the glacier extents on the island from 41
399 ka to the late glacial period. Erratics from Peninsula Courbet, the farthest site east of CIC provide direct
400 evidence that this part of the main island of Kerguelen was deglaciated ~41 ka ago (Fig. 13). These erratics
401 most likely do not represent the maximum glacier position and were probably transported by the ice during
402 a glacier advance that pre-dates ~41 ka ago.

403 Over the time period lasting from ~41 to ~29 ka, glacier shrinkage generally continued, possibly interrupted
404 by stagnation or minor advances. We assume that before ~29 ka, outlet glaciers of CIC (or the glaciers that
405 developed locally) had not retreated beyond the sample sites of Armor Lake and Val Studer for a significant
406 period of time. This is supported by the similarity of the ages of the roches moutonnees at Armor Lake (~29
407 ka) and those of the erratic boulder at Val Studer (~28 ka). If the glaciers had retreated further for a
408 significant period of time, the exposure duration of the roches moutonnees would have been longer than that
409 of the erratics. Moreover, the age of the erratics at Armor Lake (~24 ka) suggests that after ~29 ka the ice
410 might have retreated to an unknown position for at most ~5 ka before readvancing at ~24 ka. In addition,
411 the uncertainties associated with the ages at Val Studer and Armor Lake do not allow us to reach a resolution
412 good enough to highlight possible (a)-synchronies of the CIC outlet glacier fluctuations in this part of the
413 archipelago.

414 After ~24 ka, the CIC outlet glaciers continued to retreat likely until the Antarctic Cold Reversal (ACR)
415 period (14.5-12.9 ka). During this ACR period the Explorateur glacier, a CIC outlet, stagnated or re-
416 advanced forming, 26 km from its current front position the Bontemps moraine at about 13.6 ± 1.5 ka ago.
417 The local glacier located on the Presqu Ile Jeanne d'Arc formed the Belvedere moraine at about 15.5 ± 1.8
418 ka ago, which might have been contemporaneous with the formation of Bontemps moraine given their
419 overlapping age uncertainties.

420

421

422
 423 Fig. 13. Summary of ^{36}Cl ages obtained at different sample sites. Reported mean ^{36}Cl boulder ages account for standard
 424 deviation, analytical and production rate uncertainties. Red = moraine ages; Blue = erratic ages; Green = roche
 425 moutonnee age; dot = this paper; triangle = ages from Jomelli et al (2017) only.

426

427 6.2 Comparison to other sub-Antarctic glacial chronologies

428

429 Comparing our findings from the southern Indian Ocean with other sub-Antarctic glacial chronologies
 430 located in the South Pacific (New Zealand) and South Atlantic regions (Patagonia) reveals intriguing
 431 features (Fig. 14). The presented cosmic-ray exposure ages indicate that glacier retreat occurred in
 432 Kerguelen roughly 41 ka ago with a preceding glacier advance that must have been larger than that during
 433 the gLGM. Unfortunately, the exact location of the corresponding maximum CIC front position is unknown,
 434 as it might be offshore. The exact age of the glacier maximum extent that precedes the subsequent retreat

435 around 41 ka ago remains therefore also unknown. These findings do not fully correspond to what is
436 documented in the two other regions.

437 The glacier evolution at Kerguelen only partly resembles that described in New Zealand. Kelley et al.,
438 (2014) showed that Pukaki and Mt John glaciers in New Zealand started to retreat from a major extent about
439 42 ka ago based on ^{10}Be ages. At Pukaki, the glacier extent during the maximum MIS-3 ice cover was
440 comparable to the subsequent glacier culminations, which occurred between 28 ka and 25 ka, as well as 21
441 ka and 18 ka ago (Kelley et al., 2014). Consequently, in both regions, glaciers were larger during the MIS-
442 3 period than during the gLGM. At Kerguelen, large glacier extent occurred 42 ka ago, but it does not
443 necessarily correspond to a maximum glacial advance. In both regions, comparable subsequent glacier
444 extents occurred between about 28 ka and 19 ka ago, even if field evidence of a clear glacier advance at
445 Kerguelen at 25, 21 and 18 ka ago are still lacking. Moreover, observations covering the more recent periods
446 revealed significant differences in glacier evolution between the two regions (Schaefer et al., 2015; Jomelli
447 et al 2017).

448 Glacier evolution at Kerguelen also differs partly from Patagonia. In Patagonia, there is no clear evidence
449 of large advances at 42 ka (Darvill et al., 2015). Fogwill et al. (2015) showed in a compilation of 59
450 cosmogenic ages (^{10}Be and ^{36}Cl ages) that the culmination of the ice sheet during the ILGM occurred about
451 28 ka ago, i.e. few millennia before the gLGM. However, this ILGM extent was smaller than pre ILGM
452 glacier MIS-3 extents that mostly occurred at roughly 32 ka about 49°S (same latitude as Kerguelen) as well
453 as at higher latitudes (Darvill et al., 2015). Uncertainties associated with the ^{36}Cl ages do not permit to assess
454 synchronous advances with those documented in Patagonia between 32 and 28 ka ago. In addition, field
455 evidence of a clear glacier advance at Kerguelen around 32 ka ago is still lacking. Also, glacier retreat in
456 Patagonia between 28 ka to 19 ka ago was larger than at Kerguelen. These different patterns of glacier
457 fluctuations in sub-Antarctic regions raise questions about the potential drivers of the glacier fluctuations in
458 the southern hemisphere.

459 Several hypotheses have been proposed to explain the major glacier advance during the MIS-3 period but a
460 full understanding of the forcings involved in the glacier evolution at the hemispheric scale remains puzzling
461 (Putnam et al., 2013; Kelley et al., 2014; Darvill et al., 2015; Schaefer et al., 2015).

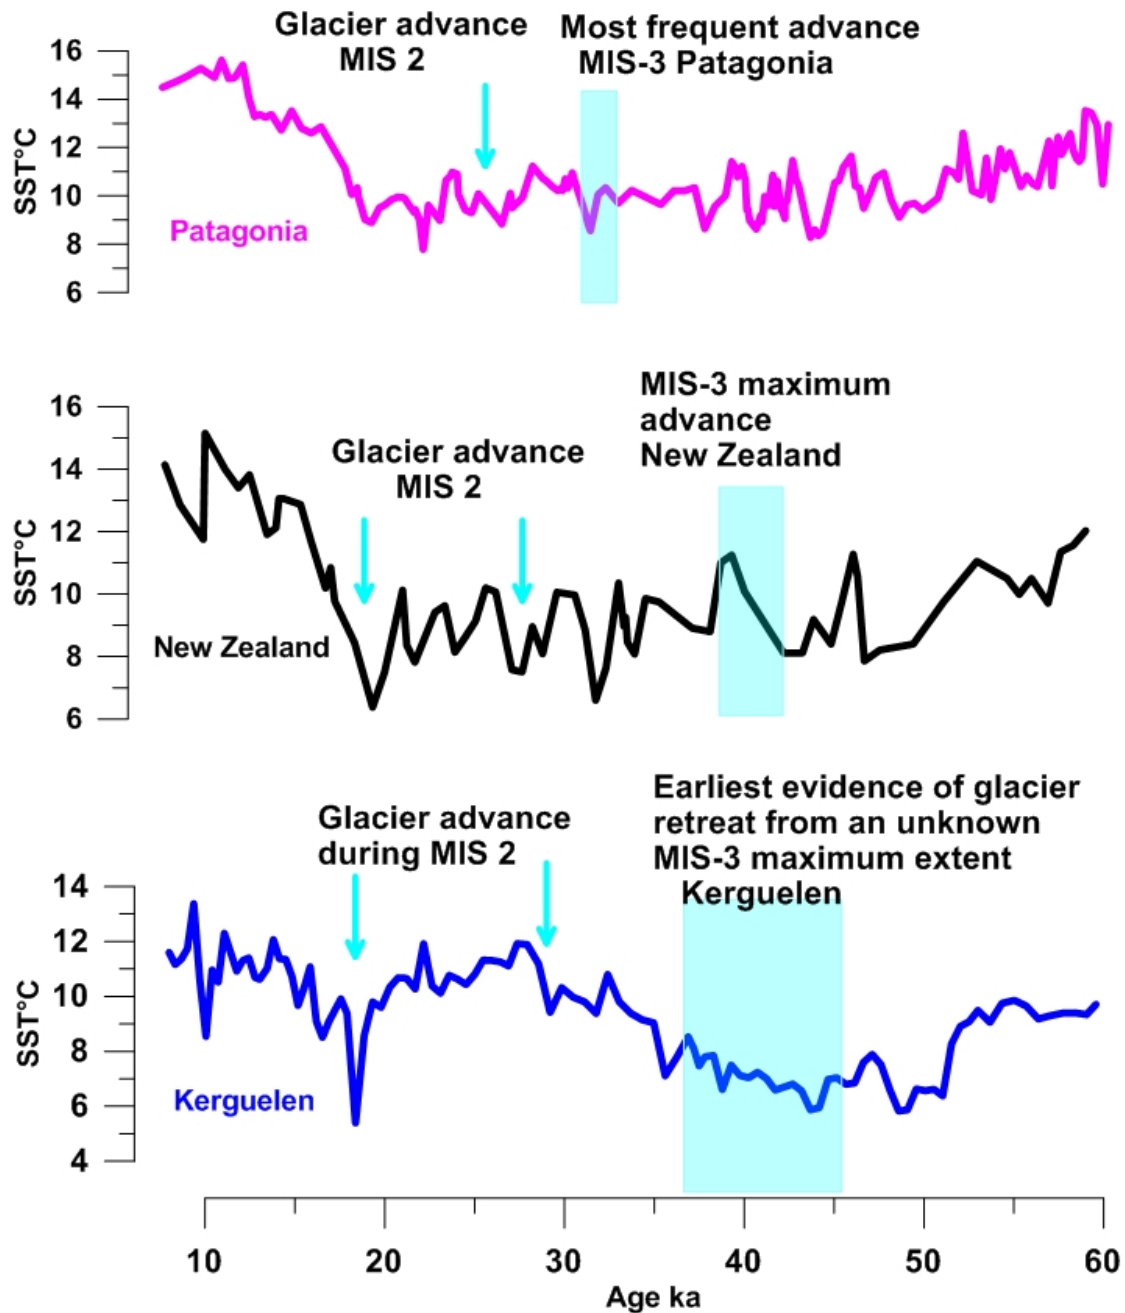

462
463 It is generally assumed as inferred from proxy data, that a northward migration and intensification of the
464 southern westerly wind belt occurs during colder periods in Antarctica resulting in reduced deep ocean
465 ventilation and low atmospheric CO_2 concentrations (Lamy et al., 2010; Fletcher and Moreno, 2011). On
466 the other hand, model studies show contrasting results on the position and strength of the westerly winds

467 during the LGM conditions with either an equatorward or a poleward position (Otto Bliesner et al., 2006;
468 Rojas et al., 2009; Sime et al., 2013).

469
470 Numerous ice core records have been extracted from the west and east Antarctic ice sheets (e.g. Watanabe
471 et al., 2003; EPICA comm members, 2004, 2006; Stenni et al., 2011; Wais Divide, 2015). Every site
472 temperature reconstructions based on $\delta^{18}\text{O}$ of ice cores show a progressive cooler trend during MIS-3 period
473 with a major temperature minimum between 28 and 22 ka corresponding to the gLGM (Stenni et al., 2010;
474 Parrenin et al., 2013; Wais Divide, 2015). These observations are the same in both the Indo-Pacific and the
475 Atlantic sectors. Temperature and snow accumulation changes documented at Wais Divide showed a
476 remarkable concordance with glacier changes at Kerguelen over the last 28 ka (Jomelli et al., 2017).
477 However warm temperature in Antarctica during the pre-gLGM is counterintuitive with large glacier extent
478 at that time observed in different regions of mid southern hemisphere. This suggests an important regional
479 variability during the pre-LGM period. This regional variability is also seen in Antarctic ice core records
480 over Marine Isotopic Stage 3 (MIS 3, 60 to 25 ka) during the succession of Antarctic Isotopic Maxima
481 (AIM) associated with the abrupt Dansgaard-Oeschger events in Greenland. The warming phases of the
482 AIM show strong variability when comparing the Atlantic and Indian-Pacific basins: it is much more rapid
483 (a few centuries) on the Atlantic side. This creates a transient climatic dipole during warming phase of the
484 AIMs with the Atlantic side of Antarctica being warmer than the Indian-Pacific side.

485
486 Interestingly, several sea surface temperature (SST) reconstructions have been produced making possible
487 the documentation of climate conditions in the Indian, Pacific and Atlantic circum-Antarctic regions
488 (Pahnke and Sachs, 2006; Kaiser and Lamy, 2010). These SSTs point to significant differences in the climate
489 evolution of the Indo-Pacific and Atlantic sectors over the last 60 ka (Fig.14). Sub-Antarctic SSTs from N
490 Chatham Rise MD97-2120 sediment core located south east of New Zealand (45°S) show a long period
491 lasting from 48 ka and 28 ka ago with relatively cold conditions (Pahnke and Sachs, 2006). Minima coincide
492 with large glacier extent. On the north west of Kerguelen, SSTs from Cape Basin 1089/TN057 sediment
493 core (41°S) show a different pattern with a progressive warming trend from a minimum 43 ka ago,
494 interrupted by periodic cold peaks (Pahnke and Sachs, 2006). On the east coast of Patagonia, SSTs from the
495 sediment core ODP Site 1233 (41°S) reveal several cold episodes, in particular at 43 ka, 32 ka and 22 ka
496 (Kaiser and Lamy, 2010). A parallel can be drawn between these differences in regional SSTs conditions
497 and reconstructions of surface air temperature or climate of the evaporative source regions from proxy data
498 in various Antarctic ice core records. Indeed and as mentioned above for the surface air temperature
499 reconstruction from water isotopes, water isotopic records ($\delta^{18}\text{O}$ and d-excess) show strong differences
500 during AIM warming phases between ice cores located on the Atlantic side of Antarctica and ice cores

501 located on the Indian – Pacific sides of Antarctica (Stenni et al., 2010; Buiron et al., 2012; Landais et al.,
 502 2015). At Kerguelen uncertainties associated with the ³⁶Cl ages do not permit to assess synchrony between
 503 glacier changes and AIMs but we notice that nine AIMs occurred during MIS 3 period.

504
 505
 506
 507 Fig.14. Comparison between sea surface temperature and major glacier extent during MIS-3 and the ILGM in
 508 Patagonia (after Darvill et al., 2015; Fogwill et al., 2015), Kerguelen (this study) and New Zealand (after Kelley et al.,
 509 2014). Pink curve shows SSTs from the sediment core ODP Site 1233 (41°S) on the east coast of Patagonia, (Kaiser
 510 and Lamy, 2010). Black curve shows Sub-Antarctic SSTs from N Chatham Rise MD97-2120 sediment core (45°S)

511 (Pahnke and Sachs, 2006). Blue curve shows SSTs from Cape Basin 1089/TN057 sediment core (41°S) (Pahnke and
512 Sachs, 2006).

513

514

515

516

517 **7. Conclusion**

518 Twenty-two cosmogenic ^{36}Cl surface exposure ages were collected from five sites on Kerguelen
519 Archipelago on the eastern slope of the Cook Ice Cap. These samples collected from glacial moraine
520 boulders, erratic boulders and roche moutonnee surfaces made it possible to document changes in glacier
521 extent between 42 ka ago and the late glacial period. The data combined with an earlier record from
522 Kerguelen reveal that glaciers retreated from the maximum extent at ~41 ka ago. From ~41 to ~15 ka,
523 deglaciation generally continued, interrupted by several stagnations or minor culminations, at least at ~28-
524 29 ka and ~24 ka ago. A period of glacier advance occurred prior to ~15-14 ago. These glacier changes at
525 Kerguelen are comparable with glacier fluctuations in New Zealand, but differ from those in Patagonia,
526 where the maximum glacier extent occurred about 13 ka later. The reason of such asynchronous pattern is
527 enigmatic so far, but we hypothesize that it is related to differences in the climate evolution of the Indo-
528 Pacific and Atlantic sectors of Antarctica documented by SSTs from sediment cores and surface air
529 temperature and sea ice extent from proxy ice core records around Antarctica. A transient climatic dipole is
530 created during warming phase of the AIMs with the Atlantic side of Antarctica being warmer than the
531 Indian-Pacific side which may partly be responsible for such different regional climate conditions and by
532 repercussion may explain the reason why Kerguelen glaciers exhibited a different evolution compared to
533 other sub Antarctic regions. However, further investigations of the mechanisms responsible for such
534 asynchronous pattern of climate change are needed to better understand the respective role of external and
535 internal forcings and glacier dynamic.

686

687 **Author Contributions:** V.J., D.B., D.V., V.R., C.L. and V.F. conducted the field work on the Island; F.M. produced
688 the cosmogenic data, ASTER Team performed AMS measurements; I.S., V.M., V.R. and V.J. interpreted the
689 cosmogenic ages; A.L. V.J. interpreted the ice core signal; V.J. and I.S. prepared figures and V.J., I.S., V.R., V.F.,
690 D.V. and A.L. contributed to writing the paper.
