## Abstract

Gaussian processes (GP) are widely used as a metamodel for emulating time-consuming computer codes. We focus on problems involving categorical inputs, with a potentially large number  $L$  of levels (typically several tens), partitioned in  $G \ll L$  groups of various sizes. Parsimonious covariance functions, or kernels, can then be defined by block covariance matrices  $\mathbf{T}$  with constant covariances between pairs of blocks and within blocks. However, little is said about the positive definiteness of such matrices, which may limit their practical usage.

In this paper, we exploit the hierarchy group/level and provide a parameterization of valid block matrices  $\mathbf{T}$ , based on a nested Bayesian linear model. The same model can be used when the assumption within blocks is relaxed, giving a flexible parametric family of valid covariance matrices with constant covariances between pairs of blocks. As a by-product, we show that the positive definiteness of  $\mathbf{T}$  is equivalent to the positive definiteness of a small matrix of size  $G$ , obtained by averaging each block.

We illustrate with an application in nuclear engineering, where one of the categorical inputs is the atomic number in Mendeleev's periodic table and has more than 90 levels.

# 1 Introduction

This research is motivated by the analysis of a time-consuming computer code in nuclear engineering, depending on both continuous and categorical inputs, one of them having more than 90 levels. The final motivation is an inversion problem. However, due to the heavy computational cost, a direct usage of the simulator is hardly possible. A realistic approach is to use a statistical emulator or metamodel. Thus, as a first step, we investigate the metamodeling of such computer code. More precisely, we consider Gaussian process (GP) regression models, also called kriging models ([Sacks et al., 1989], [Rasmussen and Williams, 2006]), which have been successfully used in sequential metamodel-based strategies for uncertainty quantification (see e.g. [Chevalier et al., 2014]).

Whereas there is a flourishing literature on GP regression, the part concerned with categorical inputs remains quite limited. We refer to [Zhang and Notz, 2015] for a review. As for continuous inputs, covariance functions or *kernels* are usually built by combination of 1-dimensional ones, most often by multiplication or, more rarely, by addition [Deng et al., 2017]. The question then comes down to constructing a valid kernel on a finite set, which is a positive semidefinite matrix. Some effort has been spent on parameterization of general covariance matrices [Pinheiro and Bates, 1996] and parsimonious parameterizations of smaller classes [Pinheiro and Bates, 2009]. Some block form have also been proposed [Qian et al., 2007], in order to deal with a potential large number of levels. However, their validity was not investigated. Furthermore, to the best of our knowledge, applications in GP regression are limited to categorical inputs with very few levels, typically less than 5.

Guided by the application, we investigate more deeply the so-called *group kernels* cited in Qian et al. [2007], defined by block covariance matrices  $\mathbf{T}$  with constant covariances between pairs of blocks and within blocks. We exploit the hierarchy group/level by revisiting a nested Bayesian linear model where the response term is a sum of a group effect and a level effect. This leads to a parameterization of  $\mathbf{T}$  which is automatically positive definite. Interestingly, the assumption on within blocks can be relaxed, and we obtain a parameterization of a wider class of valid group kernels. The positive definiteness condition of  $\mathbf{T}$  is also explicit: it is equivalent to the positive definiteness of the smaller covariance matrix obtained by replacing each block by its average.

As mentioned above, this work has some connections with Bayesian linear models as well as linear mixed effect models (see e.g. [Lindley and Smith \[1972\]](#), [Smith \[1973\]](#)) in a hierarchical view. Other related works concern hierarchical GPs with a tree structure. For instance, particular forms of group kernels are obtained in multiresolution GP models ([\[Fox and Dunson, 2012\]](#), [\[Park and Choi, 2010\]](#)). Given two resolution levels and a spatial partition  $\mathcal{A} = \cup_i \mathcal{A}_i$  of  $\mathbb{R}^d$ , a parent GP on  $\mathcal{A}$ , corresponding to the lowest resolution, serves as a trend for children GPs on  $\mathcal{A}_i$ , corresponding to the highest resolution. Children GPs are independent conditionally on the parent GP, and have the same covariance structure with a lengthscale parameter decreasing with the diameter of  $\mathcal{A}_i$ . As a result, for a given resolution, the covariance matrix has a block form given by a sum of nested block diagonal covariance matrices. In comparison, the two-resolution (group/level) GP corresponding to a categorical input, does not assume a conditional independence between children, and the block form of covariance matrices can be more general.

The paper is structured as follows. Section [2](#) gives some background on GP regression with mixed categorical and continuous inputs. Section [3](#) presents new findings on group kernels. Section [4](#) illustrates on synthetic examples. Section [5](#) is devoted to the application which motivated this work. Section [6](#) gives some conclusions and perspectives for future research.

## 2 Background and notations

### 2.1 GPs with continuous and categorical variables

We consider a set of  $I$  continuous variables  $\mathbf{x}_1, \dots, \mathbf{x}_I$  defined on a hypercubic domain  $\Delta$ , and a set of  $J$  categorical variables  $u_1, \dots, u_J$  with  $L_1, \dots, L_J$  levels. Without loss of generality, we assume that  $\Delta = [0, 1]^I$  and that, for each  $j = 1, \dots, J$ , the levels of  $u_j$  are numbered  $1, 2, \dots, L_j$ . We denote  $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_I)$ ,  $\mathbf{u} = (u_1, \dots, u_J)$ , and  $\mathbf{w} = (\mathbf{x}, \mathbf{u})$ .

We consider GP regression models defined on the product space

$$\mathcal{D} = [0, 1]^I \times \prod_{j=1}^J \{1, \dots, L_j\},$$

and written as:

$$y_i = \mu(\mathbf{w}^{(i)}) + Z(\mathbf{w}^{(i)}) + \epsilon_i, \quad i = 1, \dots, N. \quad (1)$$

where  $\mu$ ,  $Z$  and  $\epsilon$  are respectively the trend, the GP part and a noise term. There exist a wide variety of trend functions, as in linear models. Our main focus here is on the centered GP  $Z(\mathbf{w})$ , characterized by its kernel

$$k : (\mathbf{w}, \mathbf{w}') \mapsto \text{cov}(Z(\mathbf{w}), Z(\mathbf{w}')).$$

Kernels on  $\mathcal{D}$  can be obtained by combining kernels on  $[0, 1]^I$  and kernels on  $\prod_{j=1}^J \{1, \dots, L_j\}$ . Standard valid combinations are the product, sum or ANOVA. Thus if  $k_{\text{cont}}$  denotes a kernel for the continuous variables  $\mathbf{x}$ ,  $k_{\text{cat}}$  a kernel for the categorical ones  $\mathbf{u}$ , examples of valid kernels for  $\mathbf{w} = (\mathbf{x}, \mathbf{u})$  are written:

$$\begin{aligned} \text{(Product)} \quad k(\mathbf{w}, \mathbf{w}') &= k_{\text{cont}}(\mathbf{x}, \mathbf{x}') k_{\text{cat}}(\mathbf{u}, \mathbf{u}') \\ \text{(Sum)} \quad k(\mathbf{w}, \mathbf{w}') &= k_{\text{cont}}(\mathbf{x}, \mathbf{x}') + k_{\text{cat}}(\mathbf{u}, \mathbf{u}') \\ \text{(ANOVA)} \quad k(\mathbf{w}, \mathbf{w}') &= (1 + k_{\text{cont}}(\mathbf{x}, \mathbf{x}'))(1 + k_{\text{cat}}(\mathbf{u}, \mathbf{u}')) \end{aligned}$$

For consiseness, we will denote by  $*$  one of the operations: sum, product or ANOVA. The three formula above can then be summarized by:

$$k(\mathbf{w}, \mathbf{w}') = k_{\text{cont}}(\mathbf{x}, \mathbf{x}') * k_{\text{cat}}(\mathbf{u}, \mathbf{u}') \quad (2)$$

Then, in turn,  $k_{\text{cont}}$  and  $k_{\text{cat}}$  can be defined by applying these operations to 1-dimensional kernels. For continuous variables, famous 1-dimensional kernels include squared exponential or Matérn [Rasmussen and Williams, 2006]. We denote by  $k_{\text{cont}}^i(x_i, x'_i)$  such kernels ( $i = 1, \dots, I$ ). For a categorical variable, notice that, as a positive semidefinite function on a finite space, a kernel is a positive semidefinite matrix. We denote by  $\mathbf{T}_j$  the matrix of size  $L_j$  corresponding to kernels for  $u_j$  ( $j = 1, \dots, J$ ). Thus, examples of expressions for  $k_{\text{cont}}$  and  $k_{\text{cat}}$  are written:

$$k_{\text{cont}}(\mathbf{x}, \mathbf{x}') = k_{\text{cont}}^1(x_1, x'_1) * \dots * k_{\text{cont}}^I(x_I, x'_I) \quad (3)$$

$$k_{\text{cat}}(\mathbf{u}, \mathbf{u}') = [\mathbf{T}_1]_{u_1, u'_1} * \dots * [\mathbf{T}_J]_{u_J, u'_J} \quad (4)$$

The formulation given by Equations (2), (3), (4) is not the most general one, since kernels are not always obtained by combining 1-dimensional ones.

Nevertheless, it encompasses the GP models used in the literature of computer experiments with categorical inputs. It generalizes the tensor-product kernels, very often used, and the sum used recently by [Deng et al., 2017] on the categorical part. It also contains the heteroscedastic case, since the matrices  $\mathbf{T}_j$  are not assumed to have a constant diagonal, contrarily to most existing works [Zhang and Notz, 2015]. This will be useful in the application of Section 5, where the variance of the material is level dependent.

**Remark 1.** *Combining kernels needs some care to obtain identifiable models. For instance, the product of kernels  $k_1, k_2$  with  $k_i(x_i, x'_i) = \sigma_i^2 e^{-|x_i - x'_i|}$  ( $i = 1, 2$ ), is a kernel depending on only one variance parameter  $\sigma^2 := \sigma_1^2 \sigma_2^2$ . The GP model is identifiable for this new parameter, but not for the initial parameters  $\sigma_1^2, \sigma_2^2$ .*

## 2.2 1-dimensional kernels for categorical variables

We consider here a single categorical variable  $u$  with levels  $1, \dots, L$ . We recall that a kernel for  $u$  is then a  $L$  by  $L$  positive semidefinite matrix  $\mathbf{T}$ .

### 2.2.1 Kernels for ordinal variables

A categorical variable with ordered levels is called ordinal. In this case, the levels can be viewed as a discretization of a continuous variable. Thus a GP  $Y$  on  $\{1, \dots, L\}$  can be obtained from a GP  $Y_c$  on the interval  $[0, 1]$  by using a non-decreasing transformation  $F$  (also called warping):

$$Y(u) = Y_c(F(u)).$$

Consequently, the covariance matrix  $\mathbf{T}$  can be written:

$$[\mathbf{T}]_{\ell, \ell'} = k_c(F(\ell), F(\ell')), \quad \ell, \ell' = 1, \dots, L. \quad (5)$$

When  $k_c(\mathbf{x}, \mathbf{x}')$  depends on the distance  $|\mathbf{x} - \mathbf{x}'|$ , then  $k(\ell, \ell')$  depends on the distance between the levels  $\ell, \ell'$ , distorted by  $F$ . In the general case,  $F$  is piecewise-linear and defined by  $L - 1$  parameters. However, a parsimonious parameterization may be preferred, based on the cdf of a flexible probability distribution such as the Normal or the Beta. We refer to [McCullagh, 1980] for examples in regression and to [Qian et al., 2007] for illustrations in computer experiments.

**Remark 2.** Notice that usual continuous kernels have non-negative values, which is a necessary condition if they are valid radial kernels in all dimensions. As a consequence, the kernels for ordinal variables built by warping do not allow negative correlations between levels.

### 2.2.2 Kernels for nominal variables

For simplicity we present here the homoscedastic case, i.e. when  $\mathbf{T}$  has a constant diagonal. It is immediately extended to situations where the variance depends on the level, by considering the correlation matrix.

**General parametric covariance matrices.** There are several parameterizations of positive-definite matrices based on the spectral and Choleky decompositions. The spectral decomposition of  $\mathbf{T}$  is written

$$\mathbf{T} = \mathbf{P}\mathbf{D}\mathbf{P}^\top \quad (6)$$

where  $\mathbf{D}$  is diagonal and  $\mathbf{P}$  orthogonal. Standard parameterizations of  $\mathbf{P}$  involve the Cayley transform, Eulerian angles, Householder transformations or Givens rotations, as detailed in [Khuri and Good, 1989] and [Shepard et al., 2015]. Another general parameterization of  $\mathbf{T}$  is provided by the Cholesky decomposition:

$$\mathbf{T} = \mathbf{L}\mathbf{L}^\top, \quad (7)$$

where  $\mathbf{L}$  is lower triangular. When the variance  $[\mathbf{T}]_{\ell,\ell}$  does not depend on the level  $\ell$ , the columns of  $\mathbf{L}$  have the same norm and represent points on a sphere in  $\mathbb{R}^L$ . A spherical parameterization of  $\mathbf{L}$  is then possible with one variance term and  $L(L-1)/2$  angles, representing correlations between levels [see e.g. Pinheiro and Bates, 1996].

**Parsimonious parameterizations.** The general parametrizations of  $\mathbf{T}$  described above require  $O(L^2)$  parameters. More parsimonious ones can be used, up to additional model assumptions. Among the simplest forms, the compound symmetry (CS) - often called exchangeable - covariance matrix assumes a common correlation for all levels [see e.g. Pinheiro and Bates, 2009]. The CS matrix with variance  $v$  and covariance  $c$  is defined by:

$$[\mathbf{T}]_{\ell,\ell'} = \begin{cases} v & \text{if } \ell = \ell' \\ c & \text{if } \ell \neq \ell' \end{cases}, \quad c/v \in (-1/(L-1), 1). \quad (8)$$

This generalizes the kernel obtained by substituting the Gower distance  $d$  [Gower, 1982] into the exponential kernel, corresponding to  $c/v = e^{-d^2} > 0$ . The CS covariance matrix treats equally all pairs of levels, which is an important limitation, especially when  $L \gg 1$ . More flexibility is obtained by considering groups of levels. Assume that the  $L$  levels of  $u$  are partitioned in  $G$  groups  $\mathcal{G}_1, \dots, \mathcal{G}_G$  and denote by  $g(\ell)$  the group number corresponding to a level  $\ell$ . Then a desired parameterization of  $\mathbf{T}$  is given by the block matrix (see e.g. Qian et al. [2007]):

$$[\mathbf{T}]_{\ell, \ell'} = \begin{cases} v & \text{if } \ell = \ell' \\ c_{g(\ell), g(\ell')} & \text{if } \ell \neq \ell' \end{cases} \quad (9)$$

where for all  $i, j \in \{1, \dots, G\}$ , the terms  $c_{i,i}/v$  are within-group correlations, and  $c_{i,j}/v$  ( $i \neq j$ ) are between-group correlations. Notice that additional conditions on the  $c_{i,j}$ 's are necessary to ensure that  $\mathbf{T}$  is a valid covariance matrix, which is developed in the next section.

### 3 Block covariance matrices for levels grouping

We consider the framework of Section 2.2.2 where  $u$  denotes a categorical variable whose levels are partitioned in  $G$  groups  $\mathcal{G}_1, \dots, \mathcal{G}_G$  of various sizes  $n_1, \dots, n_G$ . Without loss of generality, we assume that  $\mathcal{G}_1 = \{1, \dots, n_1\}$ ,  $\mathcal{G}_2 = \{n_1 + 1, \dots, n_1 + n_2\}$ , .... We are interested in parsimonious parameterizations of the covariance matrix  $\mathbf{T}$ , written in block form:

$$\mathbf{T} = \begin{pmatrix} \mathbf{W}_1 & \mathbf{B}_{1,2} & \cdots & \mathbf{B}_{1,G} \\ \mathbf{B}_{2,1} & \mathbf{W}_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{B}_{G-1,G} \\ \mathbf{B}_{G,1} & \cdots & \mathbf{B}_{G,G-1} & \mathbf{W}_G \end{pmatrix} \quad (10)$$

where the diagonal blocks  $\mathbf{W}_g$  contain the within-group covariances, and the off-diagonal blocks  $\mathbf{B}_{g,g'}$  are constant matrices containing the between-group covariances. We denote:

$$\mathbf{B}_{g,g'} = c_{g,g'} \mathbf{J}_{n_g, n_{g'}}, \quad g \neq g' \in \{1, \dots, G\}$$

where  $\mathbf{J}_{s,t}$  denotes the  $s$  by  $t$  matrix of ones. This means that the between-group covariances only depends on groups (and not on levels).

We will also consider the particular case where diagonal blocks  $\mathbf{W}_g$  are CS covariance matrices with variance  $v_g$  and covariance  $c_g$ . In this subclass, the between-group and within-group covariances only depends on groups (and not on levels). When the variance term is the same for all groups, we obtain block matrices of the form (9) as a special case.

Although the block matrices of the form (10) may be covariance matrices, they are not positive semidefinite in general. In the next section, we provide a proper characterization as well as a *parameterization* of such matrices which automatically fulfills the positive semidefinite conditions.

We will use the following additional notations: for a given integer  $L \geq 1$ ,  $\mathbf{I}_L$  is the identity matrix of size  $L$ ,  $\mathbf{J}_L$  is the matrix of ones of size  $L$ ,  $\mathbf{1}_L$  is the vector of ones of size  $L$ . Finally, for a vector or a matrix  $\mathbf{M}$ , we denote by  $\overline{\mathbf{M}}$  the real number equal to the average of its coefficients.

### 3.1 A Gaussian model for CS covariance matrices

We first focus on the case of a CS matrix. We denote by

$$\mathbf{\Gamma}_L^{\text{CS}}(v, c) = (v - c)\mathbf{I}_L + c\mathbf{J}_L \quad (11)$$

the CS matrix with a common variance term  $v$  and a common covariance term  $c$ . It is well-known that  $\mathbf{\Gamma}_L^{\text{CS}}(v, c)$  is positive definite if and only if

$$-(L - 1)^{-1}v < c < v. \quad (12)$$

For instance, one can check that the eigenvalues of  $\mathbf{\Gamma}_L^{\text{CS}}(v, c)$  are  $v + (L - 1)c$  with multiplicity 1 (eigenvector  $\mathbf{1}_L$ ) and  $v - c$  with multiplicity  $L - 1$  (eigenspace  $\mathbf{1}_L^\perp$ ). Notice that a CS matrix is positive definite for a range of negative values of its correlation term.

Then we consider the following Gaussian model:

$$\eta_\ell = \mu + \lambda_\ell, \quad \ell = 1, \dots, L \quad (13)$$

where  $\mu \sim \mathcal{N}(0, v_\mu)$  with  $v_\mu > 0$ , and  $\lambda_1, \dots, \lambda_L$  are i.i.d. random variables from  $\mathcal{N}(0, v_\lambda)$ , with  $v_\lambda > 0$ , assumed to be independent of  $\mu$ .

A direct computation shows that the covariance matrix of  $\boldsymbol{\eta}$  is the CS covariance matrix  $\mathbf{\Gamma}_L^{\text{CS}}(v_\mu + v_\lambda, v_\mu)$ . Clearly this characterizes the subclass of

positive definite CS covariance matrices  $\mathbf{\Gamma}_L^{\text{CS}}(v, c)$  such that  $c$  is non-negative. The full parameterization, including negative values of  $c$  in the range  $(-(L-1)^{-1}v, 0)$ , can be obtained by restricting the average of level effects to be zero, as detailed in the next proposition.

**Proposition 1.** *When  $\boldsymbol{\eta}$  and  $\boldsymbol{\lambda}$  are related as in (13), the covariance of  $\boldsymbol{\eta}$  conditional on zero average errors  $\bar{\boldsymbol{\lambda}} = 0$  is a CS matrix with variance  $v = v_\mu + v_\lambda[1 - 1/L]$  and covariance  $c = v_\mu - v_\lambda/L$ . Conversely, given a CS covariance matrix  $\mathbf{C}$  with variance  $v$  and covariance  $c$ , there exists a representation (13) such that  $\mathbf{C}$  is the covariance of  $\boldsymbol{\eta}$  conditional on zero average errors  $\bar{\boldsymbol{\lambda}} = 0$  where  $v_\mu = v/L + c[1 - 1/L]$  and  $v_\lambda = v - c$ .*

### 3.2 Parameterization of centered covariance matrices

The usage of Model (13) to describe CS covariance matrices involves Gaussian vectors that sum to zero. This is linked to centered covariance matrices, i.e. covariance matrices  $\mathbf{F}$  such that  $\bar{\mathbf{F}} = 0$ , as detailed in the next proposition. We further give a parameterization of centered covariance matrices.

**Proposition 2.** *Let  $\mathbf{F}$  be a covariance matrix of size  $L \geq 2$ . Then,  $\mathbf{F}$  is centered iff there exists a Gaussian vector  $\mathbf{z}$  on  $\mathbb{R}^L$  such that  $\mathbf{F} = \text{cov}(\mathbf{z} | \bar{\mathbf{z}} = 0)$ . In that case, let  $\mathbf{A}$  be a  $L \times (L-1)$  matrix whose columns form an orthonormal basis of  $\mathbf{1}_L^\perp$ . Then  $\mathbf{F}$  is written in an unique way*

$$\mathbf{F} = \mathbf{A} \mathbf{M} \mathbf{A}^\top \quad (14)$$

where  $\mathbf{M}$  is a covariance matrix of size  $L-1$ .

In particular if  $\mathbf{F} = v[\mathbf{I}_L - L^{-1}\mathbf{J}_L]$  is a centered CS covariance matrix, then  $\mathbf{M} = v\mathbf{I}_{L-1}$ , and we can choose  $\mathbf{z} \sim \mathcal{N}(0, v\mathbf{I}_L)$ .

The choice of  $\mathbf{A}$  in Prop. 2 is free, and can be obtained by normalizing the columns of a  $L \times (L-1)$  Helmert contrast matrix (Venables and Ripley [2002], §6.2.):

$$\begin{bmatrix} -1 & -1 & -1 & \cdots & -1 \\ 1 & -1 & -1 & \cdots & -1 \\ 0 & 2 & -1 & \cdots & -1 \\ \vdots & 0 & 3 & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & -1 \\ 0 & 0 & \cdots & 0 & L-1 \end{bmatrix}$$

### 3.3 A hierarchical Gaussian model for block covariance matrices

Let us now return to the general case, where the levels of  $u$  are partitioned in  $G$  groups. It will be convenient to use the hierarchical notation  $g/\ell$ , indicating that  $\ell$  belongs to the group  $\mathcal{G}_g$ . Then, we consider the following hierarchical Gaussian model:

$$\eta_{g/\ell} = \mu_g + \lambda_{g/\ell}, \quad g = 1, \dots, G, \quad \ell \in \mathcal{G}_g \quad (15)$$

where for each  $g$  the random variable  $\mu_g$  represent the *effect of the group  $g$* , and the random variables  $\lambda_{g/1}, \dots, \lambda_{g/n_g}$  represent the *effects of the levels* in this group. We further assume:

- The vector  $\boldsymbol{\mu}$  is normal  $\mathcal{N}(0, \boldsymbol{\Gamma}_\mu)$ .
- The vectors  $\boldsymbol{\lambda}_{g/}$  are normal  $\mathcal{N}(0, \boldsymbol{\Gamma}_{\lambda_g})$ .
- The vectors  $\boldsymbol{\lambda}_{1/}, \dots, \boldsymbol{\lambda}_{G/}$  are independent.
- The vectors  $\boldsymbol{\mu}$  and  $\boldsymbol{\lambda}$  are independent.

As an extension of Prop. 1, the next proposition and Cor. 1 show that (15) gives a one-to-one parameterization of positive semidefinite matrices of the form (10) with CS diagonal blocks, under the additional assumption that the average of level effects is zero in each group. More generally, we obtain a large parametric family of positive semidefinite matrices of the form (10).

**Proposition 3.** *The covariance matrix of  $\boldsymbol{\eta}$  conditional on  $\{\overline{\boldsymbol{\lambda}_{g/}} = 0, g = 1, \dots, G\}$  has the form (10) with, for all  $g, g' \in \{1, \dots, G\}$ :*

$$\begin{aligned} \mathbf{W}_g &= [\boldsymbol{\Gamma}_\mu]_{g,g} \mathbf{J}_{n_g} + \mathbf{F}_g, \\ \mathbf{B}_{g,g'} &= [\boldsymbol{\Gamma}_\mu]_{g,g'} \mathbf{J}_{n_g, n_{g'}}, \end{aligned} \quad (16)$$

where  $\mathbf{F}_g$  is a centered positive semidefinite matrix equal to  $\text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}_{g/}} = 0)$ . Therefore  $\mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g}$  is positive semidefinite for all  $g = 1, \dots, G$ . Conversely, consider a positive semidefinite matrix  $\mathbf{T}$  having the block form (10) such that  $\mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g}$  is positive semidefinite for all diagonal blocks  $g$ . Let  $\tilde{\mathbf{T}}$  be the  $G \times G$  matrix obtained by averaging each block of  $\mathbf{T}$ . Then there

exists a representation (15) such that  $\mathbf{T}$  is the covariance of  $\boldsymbol{\eta}$  conditional on zero average errors  $\overline{\boldsymbol{\lambda}}_{g/} = 0$ , ( $g = 1, \dots, G$ ), with:

$$\begin{aligned}\boldsymbol{\Gamma}_\mu &= \tilde{\mathbf{T}}, \\ \text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0) &= \mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g}.\end{aligned}$$

**Corollary 1.** Positive semidefinite matrices of the form (10) with CS diagonal blocks exactly correspond to covariance matrices of  $\boldsymbol{\eta}$  in (15) conditional on the  $G$  constraints  $\overline{\boldsymbol{\lambda}}_{g/} = 0$  when  $\text{cov}(\boldsymbol{\lambda}_{g/}) \propto \mathbf{I}_{n_g}$ .

As a by-product, we obtain a simple condition for the validity of block covariance matrices of the form (10). Interestingly, it only involves a small matrix whose size is the number of groups.

**Proposition 4.** Let  $\mathbf{T}$  be a matrix having the block form (10) such that  $\mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g}$  is positive semidefinite for all  $g = 1, \dots, G$ . Then

- (i)  $\mathbf{T}$  is positive semidefinite if and only if  $\tilde{\mathbf{T}}$  is positive semidefinite.
- (ii)  $\mathbf{T}$  is positive definite if and only if  $\tilde{\mathbf{T}}$  is positive definite and the diagonal blocks  $\mathbf{W}_g$  are positive definite for all  $g = 1, \dots, G$ .

Furthermore, we have

$$\mathbf{T} = \mathbf{X} \tilde{\mathbf{T}} \mathbf{X}^\top + \text{diag}(\mathbf{W}_1 - \overline{\mathbf{W}}_1 \mathbf{J}_{n_1}, \dots, \mathbf{W}_G - \overline{\mathbf{W}}_G \mathbf{J}_{n_G}) \quad (17)$$

where  $\mathbf{X}$  is the  $n \times G$  matrix

$$\mathbf{X} := \begin{pmatrix} \mathbf{1}_{n_1} & 0 & \dots & 0 \\ 0 & \mathbf{1}_{n_2} & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \mathbf{1}_{n_G} \end{pmatrix}.$$

**Remark 3.** All the results depend on the conditional distribution  $\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0$ . Thus there is some flexibility in the choice of  $\boldsymbol{\Gamma}_{\lambda_g}$ , since several matrices  $\boldsymbol{\Gamma}_{\lambda_g}$  can lead to the same conditional covariance matrix  $\text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0)$ .

**Remark 4** (Groups of size 1). Prop. 3 is still valid for groups of size 1. Indeed if  $n_g = 1$ , then  $(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0)$  is degenerate and equal to 0. Thus  $\mathbf{F}_g = \mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_1 = 0$  is positive semidefinite.

### 3.4 Related works

Model (15):

$$\eta_{g/\ell} = \mu_g + \lambda_{g/\ell},$$

shares similarities with two-way Bayesian models and linear mixed effect models (see e.g. Lindley and Smith [1972]), with Gaussian priors for the effects  $\boldsymbol{\mu}$  and  $\boldsymbol{\lambda}_{g/\cdot}$ . The centering constraints  $\overline{\boldsymbol{\lambda}_{g/\cdot}} = 0$  are also standard identifiability conditions in such models. Furthermore, the particular case of CS covariance matrices corresponds to the exchangeable assumption of the corresponding random variables. Typically, in the framework of linear modelling, Model (15) could be written as

$$y_{g,\ell} = m + \mu_g + \lambda_{g,\ell} + \varepsilon_{g,\ell},$$

with additional grand mean  $m$  and errors  $\varepsilon_{g,\ell}$ .

However, if the framework is similar, the goal is different. In linear modelling, the aim is to quantify the effects by estimating their posterior distribution  $(\boldsymbol{\mu}, \boldsymbol{\lambda})|\mathbf{y}$ . On the other hand, we aim at investigating the form of the covariance matrix of the response part  $\mu_g + \lambda_{g/\ell}$ , or, equivalently, the covariance matrix of the *likelihood*  $\mathbf{y}|\boldsymbol{\mu}_g + \boldsymbol{\lambda}_{g/\ell}$ .

### 3.5 Summary and comments

The results of the previous sections show that a wide class of valid block covariance matrices can be parameterized by a family of covariance matrices of smaller sizes. This class is formed by positive definite matrices of the form (10) such that  $\mathbf{W}_g - \overline{\mathbf{W}_g} \mathbf{J}_{n_g}$  is positive semidefinite for all  $g = 1, \dots, G$ . It contains the case where diagonal blocks are CS covariance matrices. The algorithm is summarized below.

1. Generate a covariance matrix  $\boldsymbol{\Gamma}_\mu$  of size  $G$ .
2. For all  $g = 1, \dots, G$ ,  
 If  $n_g = 1$ , set  $\mathbf{F}_g = 0$ , else:
  - Generate a covariance matrix  $\mathbf{M}_g$  of size  $n_g - 1$ .
  - Compute a centered matrix  $\mathbf{F}_g = \mathbf{A}_g \mathbf{M}_g \mathbf{A}_g^\top$ , where  $\mathbf{A}_g$  is a  $n_g \times (n_g - 1)$  matrix whose columns form an orthonormal basis of  $\mathbf{1}_{n_g}^\perp$ .

3. For all  $1 \leq g < g' \leq G$ , compute the within-group blocks  $\mathbf{W}_g$  and between-group blocks  $\mathbf{B}_{g,g'}$  by Eq. (16).

In steps 1 and 2, the covariance matrices  $\mathbf{\Gamma}_\mu$  and  $\mathbf{M}_g$  can be general, and obtained by one of the parameterizations of §2.2.2. However, some specific form, such as CS matrices, can also be chosen. Depending on the number of groups and their sizes, different levels of parsimony can be obtained. Table 1 summarizes some possibilities.

Notice that it may be hard to choose the parametric setting  $\mathbf{M}_g, \mathbf{\Gamma}_\mu$  in order to account for a specified constraint of the block matrix  $\mathbf{T}$ , such as homoscedasticity. An alternative to over-parameterization is to use the economic constraint on  $\mathbf{T}$  of Prop. 4. Indeed, positive definiteness on  $\mathbf{T}$  is equivalent to positive definiteness of the small matrix  $\tilde{\mathbf{T}}$  of size  $G$ .

<i>Parametric setting</i>		<i>Resulting form of <math>\mathbf{T}</math></i>		<i>Number of parameters</i>

## 4 Examples

Before considering the application in nuclear engineering, we consider two toy functions with one continuous input and one categorical input, which reproduce two specificities of that application. The first function mimics a situation where the output variance depends on the level of a categorical input. The second one investigates level grouping when the number of levels is large.

## 4.1 Example 1 (An heretoscedastic case)

Consider the deterministic function

$$f(x, u) = \begin{cases} \cos\left(\frac{6.8\pi x}{2}\right) & \text{if } u = 1 \\ -2 \cos\left(\frac{7.0\pi x}{2}\right) & \text{if } u = 2, \\ \frac{1}{2} \cos\left(\frac{7\pi x}{2}\right) & \text{if } u = 3 \end{cases}$$

where  $x \in [0, 1]$  and  $u \in \{1, 2, 3\}$ . The expression of  $f$  is adapted from [Han et al., 2009] by scaling the three output curves  $f(\cdot, u)$  according to the level of  $u$ . Thus the output variance clearly depends on the level. As visible in Figure 1, these three curves are strongly dependent, with a positive link between  $f(x, 1)$  and  $f(x, 3)$ , and negative between  $f(x, 1)$  and  $f(x, 2)$ .

Figure 1: Test function 1.  $f(x, 1)$  in black,  $f(x, 2)$  in red and  $f(x, 3)$  in green. The design points correspond to one realization of a sliced LHD.

The aim is to compare the accuracy of four GP models by reconstructing  $f$  with few evaluations. For all of them, a Matérn 5/2 kernel [Rasmussen and Williams, 2006] is chosen for  $x$ . The first GP model (IND) consists in three independent GPs corresponding to the levels of  $u$ . The other ones have tensor product kernels, with three different covariance matrices  $\mathbf{T}$  for  $u$ . The first two ones assume a constant variance:  $\mathbf{T}$  is defined by a CS covariance

structure (Eq. 8), or by a general spherical parameterization (SPH) (See Section 2.2.2). Finally, we consider a heteroscedastic spherical parameterization (H-SPH) where the covariance matrix is defined by a general variance vector, and a spherical parameterization of the correlation matrix.

In order to benefit from the strong link between levels, we use a design that spreads out the points between levels. For instance, the information given by  $f(0, 1)$  may be useful to estimate  $f(x, 2)$  and  $f(x, 3)$  at 0, without computing  $f(0, 2)$  and  $f(0, 3)$ . More precisely, we have used a (random) sliced Latin hypercube design (SLHD) [Qian, 2012] with 5 points by level, for a total budget of 15 points. Parameter estimation is by maximum likelihood. As the likelihood surface may be multimodal, we have launched several optimizations with different starting points chosen at random in the domain. Model accuracy is measured over a test set formed by a regular grid of size 1000, in terms of  $Q^2$  criterion. The  $Q^2$  criterion has a similar expression than  $R^2$ , but is computed on the test set:

$$Q^2 = 1 - \frac{\sum_i (y_i - \hat{y}_i)^2}{\sum_i (y_i - \bar{y})^2}, \quad (18)$$

where the  $y_i$  denote the observations (on the test set),  $\bar{y}$  their mean,  $\hat{y}_i$  the predictions. It is negative if the model performs worst than the mean, positive otherwise, and tends to 1 when predictions are close to true values. Finally, the process is repeated 100 times, in order to assess the sensitivity of the result to the design.

We observe that the heteroscedastic model H-SPH clearly outperforms the other ones. As expected, the estimated variances (2.5, 5.3, 1.4) for this model are level-dependent, whereas a constant variance is wrongly estimated around 2 by CS and SPH. Moreover, we have represented in Figure 3 an estimation of the correlations between levels, deduced from the parameterized covariance matrix  $T$ . For representativeness, we have chosen one of the 100 designs used to generate Figure 2, such that the corresponding  $Q^2$  is the closest to the median of the 100  $Q^2$  values. We can see that the strong dependence link of  $f(\cdot, u)$  between the levels of  $u$  is only recovered correctly by H-SPH, with a poor estimation of correlation parameters for the other ones.

## 4.2 Example 2 (Levels grouping)

The second function is defined as:

$$g(x, u) = \cos \left( 7\pi \frac{x}{2} + p(u)\pi - \frac{u}{20} \right)$$

Figure 2:  $Q^2$  criterion for four GP models, based on 100 repetitions of the design.

with  $x \in [0, 1]$ ,  $u \in \{1, \dots, 13\}$  and  $p(u) = (0.4 + \frac{u}{15}) \mathbb{1}_{u>9}$ . As visible in Figure 4, there are two groups of curves corresponding to levels  $\{1, \dots, 9\}$  and  $\{10, \dots, 13\}$  with strong within-group correlations, and strong negative between-group correlations.

We aim at reconstructing  $g$  with five GP models based on levels grouping. The first one uses a CS covariance matrix, corresponding to a single group. The second one considers the two groups  $\{1, \dots, 9\}$  and  $\{10, \dots, 13\}$ . The third model, based on the five groups  $\{1, \dots, 9\}$ ,  $\{10\}$ ,  $\{11\}$ ,  $\{12\}$ ,  $\{13\}$ , has two variants: (a) when the inter-groups correlation is constant and (b) in the general case. The fourth model uses the spherical parameterization of  $T$ , leading to 13 groups, and the last one considers an ordinal parameterization for  $T$ . The design of experiments is a 39-points SLHD. The remaining simulation settings are the same as in Example 1.

The estimated correlation parameters are shown in Figures 5. The right correlation structure is well recovered with two groups and five groups, with different between-groups correlations. The model with thirteen groups involves the estimation of 90 parameters, which is hard to achieve, especially with 39 points. This is visible in the erratic values of the estimated correlations values, which seem not meaningful. On the opposite, considering only one group or five groups with a common between-group correlation oversimplifies and fails at recovering the right correlations. The ordinal ker-

Figure 4: Test function  $g$ .

nel recovers the two blocs of curves, but cannot detect negative correlation between them (Remark 2).

In Figure 6, we can see that the best tradeoff between prediction accuracy and parsimony is obtained with two groups. whereas it reduces the number of observations by group. Notice the rather good performance of the ordinal model, at the cost of a larger number of parameters: the warping was parameterized by an affine function (see Section 2.2.1). This is noticeable since negative correlations are not possible (see above). This may be due to the larger number of within-group levels combinations, which reduces the influence of the negative between-group correlations.

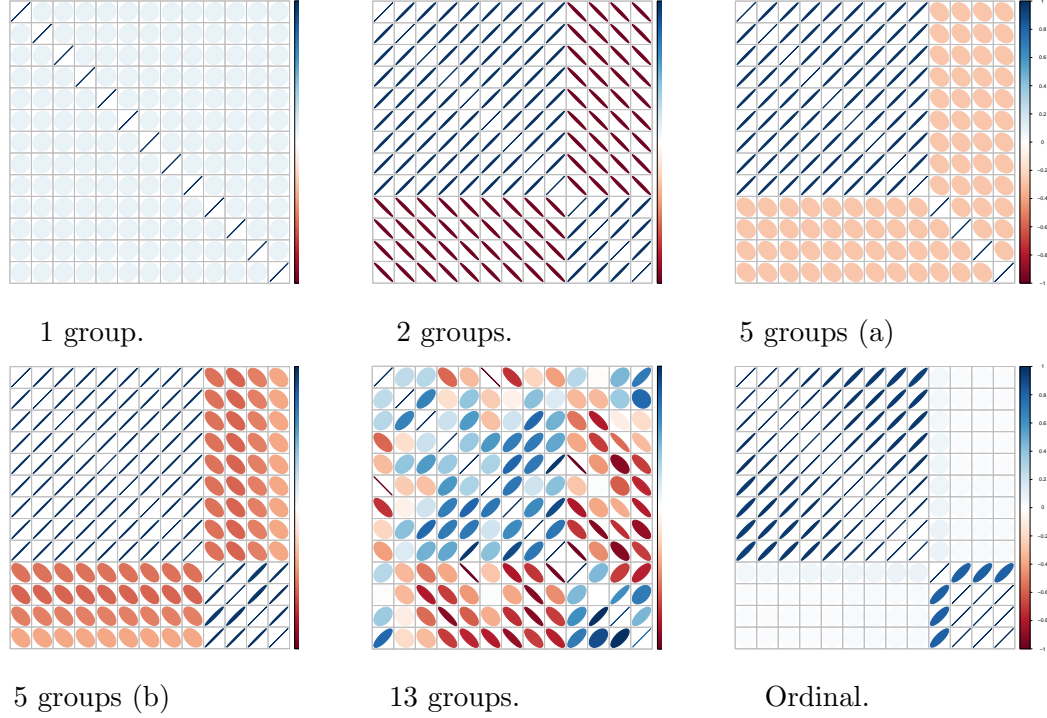

Figure 5: Estimated correlation parameters among levels for  $g$ , based on a representative design of experiments (design with median  $Q^2$ ).

## 5 Application in nuclear engineering

### 5.1 Position of the problem

As presented in Introduction, this research is originally motivated by the solving of an inverse problem confronting experimental measurements in nuclear engineering and time-consuming numerical simulation. More precisely, this analysis concerns the identification of the mass  $m$  of  $^{239}\text{Pu}$  that is present in a particular waste container using a non-destructive nuclear detection technique such as the gamma spectrometry [Knoll, 2010]. In that case, at each energy level  $E$ ,

$$m \times \epsilon(E; \mathcal{E}) = y^{\text{SG}}(E), \quad (19)$$

where  $y^{\text{SG}}(E)$  is the quantity of interest provided by the gamma transmitter, and  $\epsilon(E; \mathcal{E})$  is the attenuation coefficient, which depends on the source envi-

Figure 6:  $Q^2$  of six GP models, based on 100 repetitions of the design. Number of parameters used (bloxplot order): 5, 7, 10, 19, 90, 16.

ronment denoted by  $\mathcal{E}$ . In practice, only discrete values of  $E$  are of interest, corresponding to the natural energy levels of  $^{239}\text{Pu}$ :

$$E \in \{94.66, 129.3, 203.6, 345.0, 375.1, 413.7\} \text{ (keV)}. \quad (20)$$

Then, based on previous studies [Guillot, 2015], the real source environment is parameterized by the following input variables:

- An equivalent geometric shape for the nuclear waste: sphere ('sph'), cylinder ('cyl') or parallelepiped ('par').
- An equivalent material for this waste, characterized by its chemical element with atomic number in  $\{1, \dots, 94\}$ ,
- The bulk density of the waste, in  $[0, 1]$ ,
- The distance of measurement between the container and the measurement device, in  $[80, 140]$  (cm),
- The mean width and lateral surfaces (in logarithmic scale) crossed by a gamma ray during the rotation of the object.

After normalization, the characteristics of the input space can be summed up in Table 2.

Name of the input	Variation domain
Distance	[0,1]
Density	[0,1]
Width	[0,1]
Surface	[0,1]
Energy	$\{1, 2, 3, 4, 5, 6\}$
Shape	$\{\text{sph, cyl, par}\}$
Chemical element	$\{1, \dots, 94\}$

Table 2: Description of the input variables for the nuclear application.

To recapture the notation of the previous sections, let  $\mathbf{x}$  and  $\mathbf{u}$  be the vectors gathering respectively the continuous and categorical inputs, and  $\mathbf{w} = (\mathbf{x}, \mathbf{u})$ . For a given value of  $\mathbf{w}$ , Monte Carlo simulation codes as MCNP [Goorley et al., 2013] can be used to model the measured scene and approach the value of  $\epsilon(\mathbf{w}) = \epsilon(E, \mathcal{E})$ . The mass  $m$  can eventually be searched as the solution of the following optimization problem:

$$(m^*, \mathbf{w}^*) = \arg \min_{m, \mathbf{w}} \|\mathbf{y}^{\text{obs}} - m \times \epsilon(\mathbf{w})\|, \quad (21)$$

where  $\|\cdot\|$  is the classical Euclidian norm,  $\epsilon(\mathbf{w})$  and  $\mathbf{y}^{\text{obs}}$  respectively gather the values of  $\epsilon$  and  $y^{\text{SG}}$  at the six values of  $E$  that are used for the measurements. To solve (21), it is therefore necessary to compute  $\epsilon$  at a high number of points. However, each evaluation of the MCNP code can be extremely demanding (between several minutes to several hours CPU for one evaluation). Thus, surrogate models have to be introduced to emulate the function  $\mathbf{w} \mapsto \epsilon(\mathbf{w})$ , which is now investigated in the frame of Gaussian process regression. We refer to Clement et al. [2018] for the second step, namely the treatment of the inversion problem.

## 5.2 Model settings

For pedagogical purpose, a dataset of large size  $N = 5076$  has been computed with the MNCP code. The construction of the design of experiments was guided by the categorical inputs, such that each of the  $6 \times 3 \times 94 = N/3$  combinations of levels appears 3 times. It was completed by a Latin hypercube of size  $N$  to define the values of the four continuous inputs.

From this full dataset, a training set of size  $n = 3 \times 94 = 282$  is extracted by selecting at random 3 observations by chemical element. The remaining  $N - n$  points serve as test set.

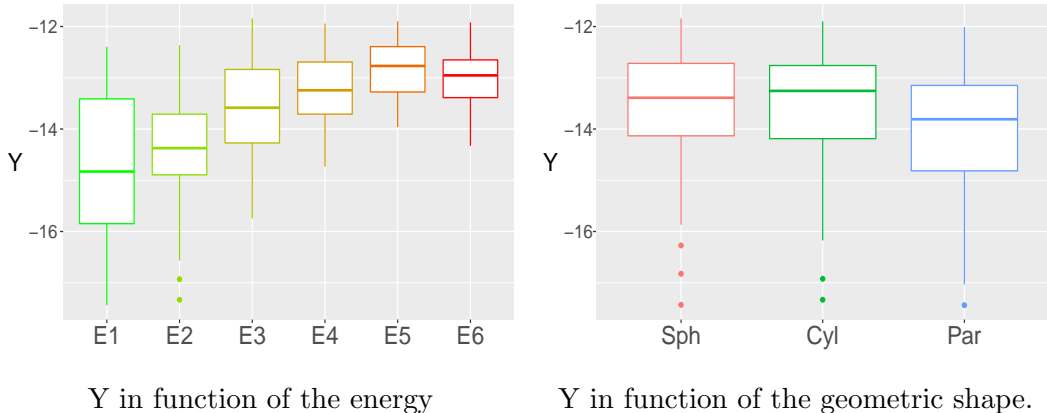

Figure 7:  $Y$  in function of the energy and geometric shape.

Model settings are now motivated by a graphical analysis. In Figure 7, the output is displayed in function of the energy and the geometric shape. We observe that successive energy levels correspond to close values. This fact confirms that the energy is ordinal and we use the warped kernel defined by Eq. (5). The influence of the geometric shape is less obvious, and we have chosen an exchangeable (CS) covariance structure for it.

In Figure 8,  $Y$  is displayed in function of the 94 chemical elements, ordered by atomic number. Two important facts are the high number of levels and heteroscedasticity. For this purpose, the 94 chemical elements are divided into 5 groups, provided by expert knowledge and represented by colors. This partition suggests to use a group kernel of the form (10), where the within-group blocks  $\mathbf{W}_g$  are CS covariance matrices. In order to handle heteroscedasticity, the variance of  $\mathbf{W}_g$  is assumed to depend on the group number  $g$ .

The influence of continuous variables can be observed by panels (not represented), and does not reveal useful information for our purpose. A Matérn 5/2 kernel is set for all continuous inputs, as we expect the output to be a regular function of the continuous inputs. Indeed, for this kernel, the corresponding Gaussian process is two times mean-square differentiable. Finally, three candidate kernels for  $\mathbf{w}$  are obtained by combining the kernels of input variables defined above, by sum, product or ANOVA (see Section 2).

Figure 8:  $Y$  in function of chemical elements, ordered by atomic number.

### 5.3 Results

Following the model settings detailed above, Figure 9, Panel 3, presents the results obtained with 60 random designs of size  $n$  and three operations on kernels. Furthermore, we have implemented three other kernels for the chemical element, in order to compare other model choices for this categorical input. In the first panel, we grouped all the 94 levels in a single group. In the second one, we kept the 5-group kernel but forced the between-group covariances to have a common value. Finally, in the fourth panel, we considered that the levels were ordered by their atomic number, and used the warped kernel of Eq. (5) with a Normal transform.

Figure 9:  $Q^2$  of several GP models, based on 60 random designs, corresponding to different model choices for the chemical element. First panel: Single group. Second panel: 5 groups, with a common between-group covariance. Third panel: 5 groups. Fourth panel: Ordered levels. Total number of parameters used in the panel order: ‘prod’ = (12, 21, 30, 14), ‘add’ = ‘prod’ + 6, ‘anova’ = ‘prod’ + 7.

First, comparing the three operations on kernels, we remark that in all the panels, additive kernels provide the worst results. This suggests the existence of interactions between different inputs of the simulator. Second, the ANOVA combination produces slight improvements, compared to the standard tensor-product, both in terms of accuracy and stability with respect to design choice.

Now, comparing the four panels, we see that gathering the levels in a single group is the least efficient strategy. The 5-group kernel gives very good performances, especially when the between-group covariances vary freely: constraining them to be equal degrades the result. Surprisingly here, the ordinal kernel gives the best performance. Indeed, for this application it was not intuitive to the experts that the chemical element can be viewed as an ordinal variable, simply sorted by its atomic number. This is confirmed by the correlation plots of Figure 10, corresponding to a model with a median  $Q^2$  score. We can see that the estimated correlations between levels seems to decrease as the difference between levels increases, an indication that the levels may be ordered by their atomic number.

Finally, we report several post-processing results. First, the estimated transformation of energy levels (Figure 11a) is concave and flat near high values, which corresponds to the behaviour observed in Figure 7 (left panel). In addition, the last three levels lead to similar results (Figure 11). This corresponds to the fact that when the energy is high, the gamma ray almost always crosses the nuclear waste, leading to a high value for the output. Second, the estimated correlation among the sphere, the cylinder and the parallelepiped is very high ( $c = 0.9$ , Figure 12). This justifies considering a covariance structure for that categorical input, rather than using three independent GP models for all the three levels.

## 6 Conclusion

In the framework of GP regression with both continuous and categorical inputs, we focused on problems where categorical inputs may have a potentially large number of levels  $L$ , partitioned in  $G \ll L$  groups of various sizes. We provided new results about parsimonious block covariance matrices, defined by a few within- and between-group covariance parameters.

(a) 5 groups (common between-group covariance)

(b) 5 groups (general)

Figure 10: Estimated correlation parameters among the chemical element.

(a) Transformation.

(b) Correlations.

Figure 11: Estimated correlation parameters for the energy.

Figure 12: Estimated correlation parameters for the geometric shape.

We revisited a two-way nested Bayesian linear model, where the response term is defined as a sum of a group effect and a level effect. We obtained a flexible parameterization of block covariance matrices which automatically satisfy the positive definiteness conditions. As a particular case, we recover situations where the within-group covariance structures are compound symmetry, with possible negative correlations. Furthermore, we showed that the positive definiteness of a given block covariance matrix can be checked by verifying that the small matrix of size  $G$  obtained by averaging each block is positive definite. This criterion can be useful if the proposed block matrix has a desirable constraint, such as homoscedasticity, which is not directly handled by the proposed parameterization.

We applied these findings on several toy functions as well as an application in nuclear engineering, with 2 continuous inputs, 3 categorical inputs, one of them having 94 levels corresponding to chemical numbers in Mendeleev’s table. In this application, 5 groups were defined by experts. The results, measured in terms of prediction accuracy, outperform those obtained with oversimplifying assumptions, such as gathering all levels in a same group. On the other hand, when the categorical input can be viewed as an ordinal one, plugging the right order into warped kernels has lead to slightly better results in our experiments.

There are several perspectives for this work. Firstly, one future direction is to find a data-driven technique to recover groups of levels. This may be not an easy task, due to the small number of observations available in the context of GP regression. Similarly, if there is an order between levels, can we infer it from the data? Secondly, the trend of the GP models has been fixed to a constant. More complex forms, based on linear models, could be explored.

## Software information and acknowledgements

Implementations have been done with the R packages `mixgp` and `kergp` [Deville et al., 2015]. Illustrations use `ggplot2` [Wickham, 2009] and `corrplot` [Wei and Simko, 2016].

This research was conducted within the frame of the Chair in Applied Mathematics OQUAIDO, gathering partners in technological research (BRGM,

CEA, IFPEN, IRSN, Safran, Storengy) and academia (CNRS, Ecole Centrale de Lyon, Mines Saint-Etienne, University of Grenoble, University of Nice, University of Toulouse) around advanced methods for Computer Experiments.

## Appendix

*Proof of Proposition 1.* The vector  $(\boldsymbol{\lambda}, \lambda_1 + \dots + \lambda_L)$  is a centered Gaussian vector with covariance matrix

$$v_\lambda \begin{pmatrix} \mathbf{I}_L & \mathbf{1}_L \\ \mathbf{1}_L^\top & L \end{pmatrix}.$$

Hence the conditional distribution of  $\boldsymbol{\lambda}$  knowing  $\bar{\boldsymbol{\lambda}} = 0$  is a centered Gaussian vector with covariance matrix

$$\text{cov}(\boldsymbol{\lambda} \mid \bar{\boldsymbol{\lambda}} = 0) = v_\lambda [\mathbf{I}_L - \mathbf{1}_L L^{-1} \mathbf{1}_L^\top] = v_\lambda [\mathbf{I}_L - L^{-1} \mathbf{J}_L].$$

Then, by using the independence between  $\mu$  and the  $\lambda_\ell$ 's, we deduce

$$\begin{aligned} \text{cov}(\boldsymbol{\eta} \mid \bar{\boldsymbol{\lambda}} = 0) &= v_\mu \mathbf{J}_L + v_\lambda [\mathbf{I}_L - L^{-1} \mathbf{J}_L] \\ &= v_\lambda \mathbf{I}_L + [v_\mu - L^{-1} v_\lambda] \mathbf{J}_L. \end{aligned}$$

We recognize the CS covariance matrix  $\boldsymbol{\Gamma}_L^{\text{CS}}(v, c)$  with  $v = v_\mu + (1 - L^{-1})v_\lambda$  and  $c = v_\mu - L^{-1}v_\lambda$ . As a covariance matrix, it is positive semidefinite. Furthermore, we have  $c < v$  and  $c + (L - 1)^{-1}v = v_\mu[1 + (L - 1)^{-1}] > 0$ , and the conditions of positive definiteness (12) are satisfied.

Conversely, let  $\mathbf{C}$  be a positive definite CS matrix  $\boldsymbol{\Gamma}_L^{\text{CS}}(v, c)$ . Then we have  $-(L - 1)^{-1}v < c < v$ , and we can define  $v_\mu = L^{-1}[v + (L - 1)c]$  and  $v_\lambda = v - c$ . From the direct sense, we then obtain that the covariance matrix of  $\boldsymbol{\eta} \mid \bar{\boldsymbol{\lambda}} = 0$  is  $\boldsymbol{\Gamma}_L^{\text{CS}}(v, c) = \mathbf{C}$ .  $\square$

*Proof of Proposition 2.* The first part of the proposition is obtained by remarking that if  $\mathbf{F} = \text{cov}(\mathbf{z})$ , then  $\bar{\mathbf{F}} = \text{cov}(\bar{\mathbf{z}})$ . Thus, assuming that  $\mathbf{z}$  is centered,  $\bar{\mathbf{F}} = 0$  is equivalent to  $\bar{\mathbf{z}} = 0$  with probability 1.

For the second part, notice that  $\bar{\mathbf{z}} = 0$  means that  $\mathbf{z}$  is orthogonal to  $\mathbf{1}_L$ . Thus, one can write the expansion of  $\mathbf{z}$  in the orthonormal basis  $\mathbf{1}_L^\perp$  defined by  $\mathbf{A}$ . Denoting by  $\mathbf{t}$  the  $(L - 1)$ -vector of coordinates, we have  $\mathbf{z} = \mathbf{A}\mathbf{t}$ . This gives  $\mathbf{F} = \text{cov}(\mathbf{A}\mathbf{t}) = \mathbf{A} \text{cov}(\mathbf{t}) \mathbf{A}^\top$ , and (14) follows with  $\mathbf{M} = \text{cov}(\mathbf{t})$ .

To prove unicity, observe that, by definition,  $\mathbf{A}^\top \mathbf{A} = \mathbf{I}_{L-1}$ ,  $\mathbf{A}^\top \mathbf{1}_L = 0$ . Starting from  $\mathbf{F} = \mathbf{A} \mathbf{M} \mathbf{A}^\top$ , and multiplying by  $\mathbf{A}^\top$  on the left and by  $\mathbf{A}$  on the right, we get  $\mathbf{M} = \mathbf{A}^\top \mathbf{F} \mathbf{A}$ , showing that  $\mathbf{M}$  is unique. Now, let  $\mathbf{F} = v[\mathbf{I}_L - L^{-1} \mathbf{J}_L]$ . Since  $\mathbf{J}_L = \mathbf{1}_L \mathbf{1}_L^\top$ , we obtain

$$\mathbf{M} = \mathbf{A}^\top \mathbf{F} \mathbf{A} = v[\mathbf{A}^\top \mathbf{A} - L^{-1}(\mathbf{A}^\top \mathbf{1}_L)(\mathbf{1}_L^\top \mathbf{A})] = v\mathbf{I}_{L-1}.$$

As a by-product, notice that resubstituting  $\mathbf{M}$  into  $\mathbf{F} = \mathbf{A} \mathbf{M} \mathbf{A}^\top$  gives  $\mathbf{A} \mathbf{A}^\top = \mathbf{I}_L - L^{-1} \mathbf{J}_L$ .

Finally, if  $\mathbf{z} \sim \mathcal{N}(0, v\mathbf{I}_L)$ , then the properties of conditional Gaussian vectors lead immediately to  $\text{cov}(\mathbf{z} | \bar{\mathbf{z}} = 0) = \mathbf{F}$ .  $\square$

*Proof of Proposition 3.* The expressions of  $\mathbf{W}_g$  and  $\mathbf{B}_{g,g'}$  are obtained directly by using the independence assumptions about  $\boldsymbol{\mu}$  and the  $\boldsymbol{\lambda}$ 's. Notice that  $\mathbf{F}_g$ , the covariance matrix of  $\boldsymbol{\lambda}_{g/}$  knowing  $\overline{\boldsymbol{\lambda}_{g/}} = 0$ , is centered by Proposition 2. This gives  $\mathbf{W}_g - \overline{\mathbf{W}_g} \mathbf{J}_{n_g} = \mathbf{F}_g$ , which is positive semidefinite.

Conversely, let  $\mathbf{T}$  be a positive semidefinite matrix of the form (10), such that  $\mathbf{W}_g - \overline{\mathbf{W}_g} \mathbf{J}_{n_g}$  is positive semidefinite for all  $g = 1, \dots, G$ . Let  $\tilde{\mathbf{T}}$  be the matrix obtained from  $\mathbf{T}$  by averaging each block. Then  $\tilde{\mathbf{T}}$  is also a positive semidefinite matrix. Indeed, since  $\mathbf{T}$  is positive semidefinite, it is the covariance matrix of some vector  $\mathbf{z}$ . Then  $\tilde{\mathbf{T}}$  is the covariance matrix of  $\tilde{\mathbf{z}}$ , the vector obtained from  $\mathbf{z}$  by averaging by group:  $\tilde{\mathbf{z}}_g = n_g^{-1} \sum_{\ell \in G_g} \mathbf{z}_\ell$ . Thus there exists a centered Gaussian vector  $(\mu_g)_{1 \leq g \leq p}$  whose covariance matrix is

$$\boldsymbol{\Gamma}_\mu = \tilde{\mathbf{T}}.$$

Now, for  $g = 1, \dots, G$ , define

$$\mathbf{F}_g = \mathbf{W}_g - [\boldsymbol{\Gamma}_\mu]_{g,g} \mathbf{J}_{n_g} = \mathbf{W}_g - \overline{\mathbf{W}_g} \mathbf{J}_{n_g}.$$

Observe that  $\overline{\mathbf{F}_g} = 0$ , and by assumption  $\mathbf{F}_g$  is positive semidefinite. Hence, from Proposition 2, there exists a centered Gaussian vector  $(\lambda_{g/j})_{1 \leq j \leq n_g}$  such that

$$\mathbf{F}_g = \text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}_{g/}} = 0).$$

We can assume that  $\boldsymbol{\lambda}_{1/}, \dots, \boldsymbol{\lambda}_{G/}$  are independent, and  $\boldsymbol{\mu}$  and  $\boldsymbol{\lambda}$  are independent. Finally, we set  $\eta_{g/\ell} = \mu_g + \lambda_{g/\ell}$ . By the direct sense and (16), we obtain that  $\mathbf{T}$  is the covariance matrix of  $\boldsymbol{\eta}$  conditional on  $\{\overline{\boldsymbol{\lambda}_{g/}} = 0, g = 1, \dots, G\}$ .  $\square$

*Proof of Corollary 1.* Let  $\mathbf{T}$  be a positive semidefinite matrix of the form (10) with CS diagonal blocks. Then the diagonal CS matrices are positive semidefinite, leading to  $v_g - c_g \geq 0$ . Thus,

$$\mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g} = (v_g - c_g)(\mathbf{I}_{n_g} - n_g^{-1} \mathbf{J}_{n_g})$$

is a positive semidefinite CS matrix. Hence, by Prop. 3,  $\mathbf{T}$  is obtained from Model (15), with  $\text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0) = (v_g - c_g)(\mathbf{I}_{n_g} - n_g^{-1} \mathbf{J}_{n_g})$ . By Prop. 2 (last part), we can choose  $\boldsymbol{\Gamma}_{\lambda_g} = v_{\lambda_g} \mathbf{I}_{n_g}$ , with  $v_{\lambda_g} = v_g - c_g \geq 0$ .

Conversely, if  $\boldsymbol{\Gamma}_{\lambda_g} = v_{\lambda,g} \mathbf{I}_{n_g}$ , then by Prop. 2,  $\mathbf{F}_g = \text{cov}(\boldsymbol{\lambda}_{g/} | \overline{\boldsymbol{\lambda}}_{g/} = 0)$  is a CS covariance matrix. The result follows by Prop. 3.  $\square$

*Proof of Proposition 4.* The direct sense of (i) has already been derived in the proof of Prop. 3. Furthermore, inspecting that proof, we see that if  $\tilde{\mathbf{T}}$  is positive semidefinite, then  $\mathbf{T}$  admits the representation (15). Thus  $\mathbf{T}$  is a covariance matrix, and positive semidefinite.

For (ii), a proof is available in [Roustant and Deville, 2017]. Notice that we need to add the condition that  $\mathbf{W}_g$  is positive definite for all  $g = 1, \dots, G$ . However, adding an equivalent condition for (i), namely that  $\mathbf{W}_g$  is positive semidefinite, was not necessary. Indeed, it is a consequence of the fact that  $\mathbf{W}_g - \overline{\mathbf{W}}_g \mathbf{J}_{n_g}$  is positive semidefinite and that  $\tilde{\mathbf{T}}$  is positive semidefinite, which implies  $\tilde{\mathbf{T}}_{g,g} = \overline{\mathbf{W}}_g \geq 0$ .

Finally, Eq. (17) is direct.  $\square$
