7

Abstract Knowledge of the fundamental parameters of the poly(lactic acid) (PLA) molecular chain and resulting macroscopic properties is important for successful application of this polymer in different domains. Rheological data show that PLA has the typical properties of a linear and semi-stiff polymer chain. The stereochemical composition of the atactic polymer chain does not impact the rheological, mechanical, and barrier properties of PLA. Most commercial PLA grades contain a large majority of L-lactic acid units, in which case the polymer is named PLLA. PLLA at room temperature is a brittle glassy polymer and its main fracture mechanism is crazing. Above the glass transition, semicrystalline PLLA shows extensive cavitation. Uniaxial deformation above, but near, the glass transition temperature leads to the formation of a mesophase, responsible for strain hardening. At higher temperatures, strain hardening is caused by induced crystallization. The PLLA oxygen barrier properties are comparable to those of polystyrene (PS). The water vapor barrier properties are higher than those of PS because of the higher polarity of the polymer chain. An increase in barrier properties can be obtained by specific crystallization techniques, multilayer strategies, or the addition of (nano) fillers.

46 1 Introduction

47 The objective of the present chapter is to summarize the fundamental and
 48 application-relevant properties of poly(lactic acid) (abbreviated PLLA when the
 49 L-lactic acid content is much greater than the D-lactic acid content). Rheology, in
 50 particular, gives insight into the fundamental characteristics of the macromolecular
 51 chain, which can be linked to its macroscopic features. The flexibility and physical
 52 dimensions of the macromolecular chain influence its entanglement capacity and,
 53 therefore, the melt viscosity and processing ability. Furthermore, mechanical prop-
 54 erties such as high ductility are obtained when the macromolecular chains can
 55 accommodate deformation at the imposed time scale. The barrier properties are
 56 conditioned by the chemical structure of the polymer chain and the free volume
 57 present in the material. Understanding and control of those parameters are key for
 58 the successful application of PLLA in different fields.

59 We would like to recall here some fundamentals on the structure of PLLA (more
 60 details can be found in other chapters of this book). PLLA is a semicrystalline
 61 polyester with a glass transition temperature (T_g) of around 60°C. The monomer of
 62 PLLA, lactide, has two chiral centers, which allows the synthesis of PLA macro-
 63 molecules with different stereochemistries. Microbial production of lactic acid
 64 yields primarily the stereoisomer L-lactic acid, which is therefore the principal
 65 reactant for formation of the lactide ring. In this chapter, the stereochemistry of
 66 PLA will therefore be indicated by the molar percentage of the minor stereoisomer,
 67 D-lactic acid (% D), in the macromolecular chain. In cases where the stereochem-
 68 istry of adjacent chiral centers in the macromolecule is controlled, the polymer
 69 chain presents specific tacticity, that is, specific orderliness of the succession of the
 70 configurational repeating units in the main chain (IUPAC definition). Briefly, in

isotactic macromolecules, all substituents are located on one side of the main chain. In PLA the substituent is the methyl group, and the isotactic polymer is composed of either 100% L-lactic acid or 100% D-lactic acid. In syndiotactic polymers, the substituents are alternately located at one and the other side of the main chain. In the case of PLA, the polymer could have, for example, an alternating structure of L-lactic acid and D-lactic acid units (L-D-L-D). Heterotactic polymers are constituted of a regular succession of diads or triads; for PLA the succession is DD-LL-DD-LL. In atactic polymers, the sequence of L- and D-lactic acids is not controlled. This is the case for most commercial polymers, where, in addition, the quantity of D-lactic acid in the chain is small (typically below 5 mol%). In some academic studies, however, the tacticity of PLA was controlled and, in these cases, the tacticity is specifically indicated in the text.

The proportion of D- and L-lactic acid units in the polymer chain has primary importance for the crystallization properties of PLA. The use of racemic proportions of PDLA and PLLA yields the formation of stereocomplexes that crystallize at temperatures different from the crystallization temperatures of the homopolymers. Furthermore, PLA presents a crystalline polymorphism. The most usual crystalline form is the α -polymorph, characterized by a left-handed 10_3 helix and a pseudo-orthorhombic or orthorhombic unit cell. At low crystallization temperatures (typically below 110°C), a disordered α -polymorph with larger unit cell dimensions is obtained. This polymorph was originally named the “ α' -form,” but recent literature proposes that it be renamed “ δ -polymorph.” In the present chapter, we will stick to the initial name and use the denomination “ α' -form” for this polymorph.

2 Rheology of PLA

2.1 Solution Rheology

Garlotta [1] has presented an overview of PLA properties in solution, showing that there are conflicting data in the literature concerning solution rheology. In response, Dorgan et al. [2] investigated very systematically the fundamental properties of PLA using a multimethod strategy by comparing data from solution rheology, light scattering, and melt rheology. PLAs with 0 and 20% D-lactic acid and different chain lengths were synthesized and the solution rheology parameters analyzed in chloroform (CHCl_3), tetrahydrofuran (THF), and mixtures of dichloromethane (CH_2Cl_2) and acetonitrile (CH_3CN). Analysis of the intrinsic viscosity ($[\eta]$) of the macromolecules as a function of the solvent and the molecular weight averages (M) allowed the Mark–Houwink parameters (K and α) to be obtained with the help of the Mark–Houwink equation:

$$[\eta] = KM^\alpha. \quad (1)$$

t1.1 **Table 1** Mark–Houwink parameters for PLA in THF

t1.11 ^aThe authors used different types of PLLA purchased from NatureWorks and pooled the data obtained

K Mark–Houwink front factor, α Mark–Houwink exponent

107 The Mark–Houwink parameters depend on the polymer–solvent system, where
 108 the exponent α is characteristic for the solvent quality and polymer flexibility. The
 109 value $\alpha = 0.5$ indicates a theta solvent. A high value, such as $\alpha = 0.8$, indicates a
 110 good solvent and a stiff polymer chain. Dorgan et al. [2] showed that the relative
 111 percentage of the optical co-monomers in the PLA chain did not impact the
 112 fundamental rheological parameters. The Mark–Houwink plot of PLA was linear,
 113 which implies that PLA behaves as a linear polymer with random coil conformation
 114 in the tested solvents. Table 1 gives the solution rheology constants of PLA in THF.
 115 The exponents of the Mark–Houwink plot were between 0.5 and 0.8, which shows
 116 good-solvent conditions. Chile et al. [3] studied PLA with controlled tacticity and
 117 concluded that only the isotactic chain of PLA developed higher $[\eta]$ than the other
 118 types of tacticity (compare entries for isotactic and other PLA samples in Table 1).
 119 The creation of branched and star-like structures decreased $[\eta]$ of PLA [4] com-
 120 pared with the linear polymer chain of equivalent molecular weight. The value of
 121 $[\eta]$ decreased from 35.7 mL/g (linear chain $M_w 1.97 \times 10^3$, solvent CHCl_3) to
 122 24.2 mL/g (star-shaped chain $M_w 1.94 \times 10^3$).

123 The characteristic ratio (C_∞) of the unperturbed polymer chain in dilute solution
 124 was calculated from the Stockmayer–Fixman fit of $[\eta]$ for the acquisition of the
 125 front factor K_Θ in several common solvents [2]. The front factor describes the
 126 unperturbed chain dimensions in dilute solution and can be obtained from the
 127 Mark–Houwink fit in theta conditions. The Stockmayer–Fixmann fit is a means to
 128 retrieve K_Θ . It reads:

$$\frac{[\eta]}{M^{1/2}} = K_\Theta + bM^{1/2}, \quad (2)$$

129 where b is a solvent-dependent factor. The front factor can depend slightly on
 130 temperature, but is independent of solvent. With the help of K_Θ , C_∞ can be
 131 calculated:

$$C_\infty = \left(\frac{K_\Theta}{\Phi} \right)^{2/3} M_{1/2}^{1/2}, \quad (3)$$

Table 2 Dilute solution constants for PLA (pooled data of PLA with 0, 20 and 50% D), adapted from [2]

	C_{∞}	6.74 ± 0.67	6.29 ± 0.57	6.08 ± 0.46

^aFor comparison, data are repeated from Table 1

K , α Mark-Houwink parameters, K_{Θ} , b Stockmayer-Fixman parameters, C_{∞} characteristic ratio

with Φ being the Flory constant (2.55×10^{23}), M_1 the relative molar mass per backbone bond (24.02), and \bar{l}^2 the mean squared backbone length (2.05 \AA^2) of PLA. C_{∞} is a measure of chain rigidity, as it corresponds to the ratio of the mean squared end-to-end distance of the freely joined chain ($\langle R^2 \rangle$) over the sum of the squared segment length ($N\bar{l}^2$), $C_{\infty} = \frac{\langle R^2 \rangle}{N\bar{l}^2}$. The C_{∞} value for an ideal random chain would be equal to one; the higher the value of C_{∞} , the stiffer the polymer chain. The corresponding data are given in Table 2.

Several authors have measured the dependence of the hydrodynamic radius (R_h) of PLLA on the molecular weight using the solvent THF [5, 6]. The relationships obtained were $R_h = 0.017M_w^{0.56}$ and $R_h = 0.016M_w^{0.56}$, which are typical for random coil polymers in good solvent. The influence of tacticity on the scaling relationship seemed to be negligible, except maybe a small effect for the isotactic sample [3].

2.2 Melt Rheology

To understand the PLLA processing ability and flow in melt processes, analysis of the viscoelastic behavior as a function of temperature is useful. Master curves of the viscoelastic behavior of PLLA spanning from the glass to the melt can be obtained by applying the time–temperature superposition principle. The viscoelastic moduli of a polymer depend on the measurement frequency and temperature. If the measurement frequency is sufficiently low, the characteristic times for polymer relaxation are shorter than the measuring time and the viscous character of the polymer is preponderant. At high frequencies, polymer relaxation can only occur at small length scales and the elastic character is thus dominant. This interdependency can be used to obtain master curves of the viscoelastic behavior of polymers over a wide range of temperature and frequency by shifting isothermal frequency sweep curves with the help of shift factors. The laws of Williams–Landel–Ferry (WLF) and Arrhenius establish the equivalence between the frequency (time) and the temperature. The WLF equation applies to long-range relaxation movements, whereas the Arrhenius equation applies to local relaxations. One of the difficulties

160 in measuring the viscoelastic behavior of PLA is the low thermostability of the
 161 polymer, which results in degradation during rheological measurement in the melt.
 162 Therefore, the data for PLA often fail to comply with the time–temperature
 163 superposition principle. Palade et al. [7] developed a method, now often employed,
 164 using tris(nonylphenyl)phosphite (TNPP) as stabilizer to suppress thermo-
 165 hydrolysis of PLA.

166 A typical master curve of the linear viscoelasticity of PLA is shown in Fig. 1
 167 [6]. The vertical shift factors used for its construction ranged from 0.98 to 1.03,
 168 which is consistent with values for linear polymers [8]. The horizontal shift factors
 169 followed the law of Arrhenius and were independent of molecular weight. The
 170 activation energy of flow was 177 kJ/mol. The terminal zones approached the
 171 typical slopes of 1 and 2 Pa s, which are predicted by the scaling relationships.
 172 Table 3 summarizes the viscoelastic plateau moduli (G_N^0), measured by several
 173 authors. The pooled data for atactic PLA showed that the quantity of D-lactic acid
 174 did not seem to correlate with the measured plateau modulus and entanglement
 175 length (M_e). However, the tacticity of the macromolecular chain seemed to have
 176 some influence on the parameters, where the syndiotactic polymer showed a lower
 177 stiffness and a higher entanglement length.

Fig. 1 Master curve of the linear viscoelastic moduli, G' and G'' , and the complex viscosity (η^*) of PLA (50% D) at the reference temperature 150°C. Reproduced with permission from Othman et al. [6], Journal of Rheology, AIP Publishing LLC

Table 3 Viscoelastic properties of PLA melts

PLA sample	M_w (g/mol)	T (°C)	$G_N^0 \times 10^5$ (Pa)	M_e (g/mol)	Reference
4% D	750,000	180	5		[7]
50% D	165,000	150	9 ± 2	4,400	[6]
2% D		180	5	8,700	[9]
0% D		200		10,500 ^a	[10]
Pooled data, different % D		140	1	3,959	[2]
Heterotactic (60% tacticity)	172,000	150	0.58	6,900	[3]
Heterotactic (96% tacticity)	191,000	150	0.52	7,700	[3]
Syndiotactic (86% tacticity)	150,000	150	0.34	11,800	[3]
Isotactic (71% tacticity)	123,000	150	0.97	4,100	[3]

^aEstimated with the help of the Stockmayer–Fixman fit and the characteristic ratio G_N^0 viscoelastic plateau modulus, M_e entanglement length

The dimensions of the linear PLA chains in the melt were characterized in detail by Dorgan et al. [2]:

- Mean-squared backbone length: 2.05 \AA^2
- Flory constant Φ : 2.55×10^{23}
- Mean-squared radius $\left\langle r_g^2 \right\rangle / M$: 0.574 \AA^2
- Critical entanglement length M_c : 9,211 g/mol (383 backbone bonds)
- Characteristic ratio C_∞ : 6.7 ± 0.7 (140°C)
- Packing length p : 2.51 \AA
- Tube diameter d_t : 47.7 \AA

The C_∞ of PLA obtained from the melt is consistent with the value measured in solution. In the melt, PLA is therefore a highly flexible polymer, comparable to other linear polymers such as polyethylene oxide ($C_\infty = 5.6$) or isotactic polypropylene ($C_\infty = 6.2$) [11]. No influence of the optical co-monomer composition on C_∞ was found within experimental uncertainty, although theoretical analysis predicted some small influence [12].

PLA melts are non-Newtonian fluids, exhibiting shear thinning at high shear rates. The zero-shear viscosity was determined from the measurement of viscosity in the limit of low frequencies, with zero-shear viscosity values typically in the range of 10^2 – 10^4 Pa s for typical commercial polymers (M_w 140–160 kg/mol) (see Table 4). A summary of the data collected on the relationship between zero-shear viscosity and molecular weight is given in Table 4. Most of the power indexes given in recent literature correspond to the theoretical value of 3.4 for truly random materials. The pre-exponential factors (K_η) were rather low, which reflects low melt viscosity. The scaling law was independent of the optical composition of heterotactic and atactic polymers, within measurement uncertainty. However, the tacticity of the macromolecules had some impact on the melt rheology, where isotactic PLA had higher zero-shear viscosity and syndiotactic PLA lower zero-shear viscosity than heterotactic PLA [3]. Semicrystalline PLLA had a slightly higher melt viscosity than amorphous PLLA [13]. However, the PLLA melt

^aChile et al. [3] used Othman's [6] parameters for the description of their heterotactic samples

207 viscosity and melt strength were low, which is a drawback for its application in the
 208 fields of foaming and film extrusion [14–18]. A number of methods were experi-
 209 mentally tested for increasing both properties, such as blending and use of in situ
 210 crosslinking by various peroxides or epoxides during processing [14–18]. Peroxides
 211 induce branching of PLLA chains, which increases the zero-shear melt viscosity
 212 [14, 16]. However, branched polymers showed higher shear thinning in the high
 213 frequency range [16]. Analysis of branched PLLA chains having a controlled
 214 molecular structure (two-arm or three-arm branching or a mix of two-arm and
 215 three-arm branched macromolecules) confirmed the positive impact of branching
 216 on the zero-shear viscosity [19]. Stereocomplex technology can also help to
 217 increase the PLA melt viscosity [20]. The connection between stereocomplexed
 218 domains could be varied from chain entanglement to direct molecular bridging by
 219 changing the content of stereocomplex (from 10 to 23%). Both the stereocomplex
 220 crystals and the crosslinked network reinforced the PLA matrix, resulting in an
 221 increase in melt viscosity [20].

222 The Cox–Mertz rule, which states the equivalence of dynamic and steady shear
 223 viscosities, was shown to be valid for PLLA with different optical co-monomer
 224 compositions (2 and 4% D) over a very wide viscosity range, extending into the
 225 shear thinning region [7].

2.3 Extensional Rheology and Melt Strength

227 The extensional rheology of PLLA showed good superposition with the linear
 228 viscoelastic envelope at low Hencky strain rates, where Hencky strain = ln
 229 (length/(initial length)). At higher Hencky strain rates (from 1 to 10 s⁻¹) a shear
 230 hardening effect was found for PLLA at various D-lactic acid contents (2, 4, and
 231 50%) [6, 7]. The shear hardening effect faded at high temperatures. Analysis of
 232 stretched PLLA melts showed the absence of stress-induced crystallization. Strain
 233 hardening occurred when the longest relaxation times of the polymer chains were
 234 longer than the characteristic times of deformation. This was caused by the pres-
 235 ence of a long-chain tail in the PLLA molecular weight distribution. The behavior
 236 could be successfully predicted by the Kaye–Bernstein–Kearsley–Zapas (K–BKZ)

Fig. 2 Elongational viscosity as a function of time for (a) linear PLLA and long chain branched PLLA (75-TN three-arm branch with DP 75; 75-BTN two-arm and three-arm branch with DP 75) at an elongational rate of 0.3 s^{-1} and (b) 75-TN at different elongational rates at 180°C . Reprinted with permission from Wang et al. [19], Industrial & Engineering Chemistry Research. Copyright 2016 American Chemical Society

constitutive equation [6]. Furthermore, the molecular architecture influenced the onset time of strain hardening, as shown in Fig. 2 [19].

Dean et al. [14] investigated the efficiency of peroxides for increasing the PLLA melt strength by crosslinking. They measured the Gottfert Rheotens melt strength of PLLA modified with lauroyl peroxide and showed an increase in force from approximately 0.017 to 0.06 N when using 1% of lauroyl peroxide. Al-Itry et al. [17] worked with an epoxy-modified acrylic copolymer (Joncryl™) and used the Cogswell method to show the positive action of the chain extender on the PLLA melt strength. The elongational viscosity increased tenfold from approximately 25,000 to 225,000 Pa s (180°C) with the addition of 1% Joncryl™. They also showed the positive impact of Joncryl™ on the PLLA blow extrusion stability and the widening of the processing window. The use of Joncryl™ allowed both formation of large bubbles and high film take-up ratios.

2.4 Conclusion

PLLA is a linear and rather rigid polymer, which adopts a random coil structure in good solvents. The tacticity of the polymer main chain has a low influence on its parameters in solution and in the melt, with the exception of the isotactic structure. Indeed, isotactic structures, but also branched structures, showed increased melt viscosity. One of the drawbacks of PLLA is its low melt strength. In this context, the increase in melt viscosity by controlling the tacticity of the PLLA main chain and the creation of branched and star-like structures is one of the research directions that will be followed in the future. The second strategy is the use of polymer additives, such as crosslinkers, during PLLA processing. In this respect, improvements in the processing ability have been obtained and a number of chemical companies now provide specific additives for PLLA.

262 3 Mechanical Properties of PLLA

263 3.1 Hot Drawing

264 Hot drawing of PLLA (i.e., deformation at temperatures higher than T_g) corre-
 265 sponds generally to processing situations in fiber spinning or biaxial stretching
 266 during film drawing or bottle blowing. An example of the stress–strain curves of
 267 semicrystalline PLLA under hot drawing is given in Fig. 3. The curves show an
 268 initial linear slope, then a yield peak, subsequent lowering of the slope of the stress–
 269 strain curve, and finally the onset of strain hardening.

270 The primary damage mechanism in semicrystalline PLLA upon hot drawing is
 271 cavitation and crystalline lamella damage and slip [21]. Cavitation is the formation
 272 of nano- to micrometer-sized voids in the amorphous phase or at the interface of the
 273 amorphous and crystalline phases. It implies a volume change of the polymer.
 274 Cavities occur around the yield point and a macroscopic manifestation of the
 275 phenomenon is stress whitening [22]. Cavities have no internal structure, in contrast
 276 to crazes. They are therefore unable to transfer stresses and elongate in the load
 277 direction upon drawing [22]. Investigation of the behavior of PLLA under hot
 278 drawing showed that stretching temperatures near T_g (70°C) promoted the initiation
 279 of cavitation before yielding and favored destruction of the ordered lamellar
 280 structure with an increase in stretching strain [21]. The supposed mechanism is
 281 sketched in Fig. 4. The cavities appeared and extended perpendicular to the
 282 stretching direction before yielding. The amorphous phase was only stretched
 283 slightly in this case (Fig. 4a). At further stretching deformation, more cavities
 284 appeared and their orientation changed from perpendicular to parallel to the load
 285 direction (Fig. 4b). The crystalline lamellae fractured, which destroyed the ordered
 286 lamellar structure (Fig. 4c). At high stretching temperature (90°C, far from the glass

Fig. 4 Structure evolution of annealed PLLA with strain at different stretching temperatures. The low temperature conditions in Zhang's work were 70°C and the high temperature conditions 90°C. *O-Y* is the pre-yielding zone, *Y-S* the necking, and *S-F* the strain-hardening zone. Reproduced with permission from Zhang et al. [21], Polymer, Elsevier

transition), crystallite deformation and lamellae slip occurred without cavitation (Fig. 4d, e). In the strain-hardening zone, some orientated cavities along the stretching direction appeared and the lamellae fractured (Fig. 4f). The number and size of cavities and the imperfection of the lamellae are, however, smaller when the drawing temperature is higher [21].

Figure 5 (reproduced from [23]) shows a typical stress-strain curve for uniaxial drawing of initially amorphous PLLA. PLLA showed rubber-like behavior up to a critical strain level, which increased with the temperature. The yield peak, which was observed in the hot-drawing experiments using semicrystalline PLLA, was absent. Strain hardening occurred at the critical strain level and became softer at higher temperatures.

Two mechanisms can explain the occurrence of the strain-hardening phenomenon observed upon hot drawing of amorphous PLLA: (1) orientation-induced crystallization and (2) orientation of the amorphous phase. Analysis of the stretched PLLA samples showed that the drawing conditions governed the occurrence of either mechanism [24]. Figure 6 shows a phase diagram and sketch of the supposed molecular mechanisms in the case of molecular orientation and strain-induced crystallization [24]. At low drawing temperature or high drawing rates, entangled clusters are connected to each other by oriented and taut chains, which are not necessarily parallel. In that case, the experimental conditions did not allow

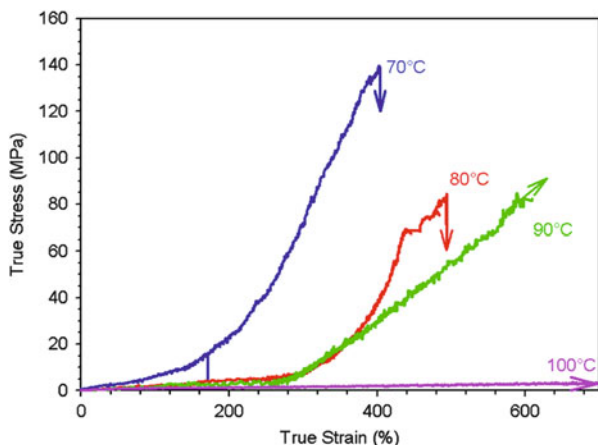

Fig. 5 True stress–strain curves for PLLA (4.3% D) films at different temperatures under uniaxial drawing (strain rate 0.04 s^{-1} , crosshead speed 50 mm/min). Reprinted with permission from Stoclet et al. [23], *Macromolecules*. Copyright 2016 American Chemical Society

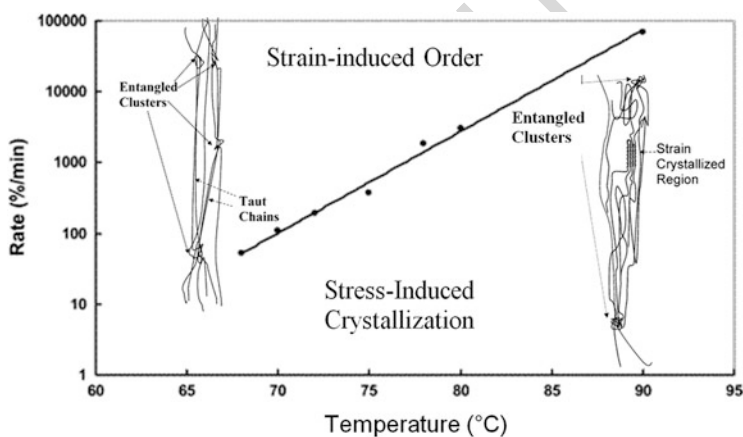

Fig. 6 Phase diagram for structure formation during uniaxial deformation of PLLA and sketch of the molecular deformation model. Adapted from Figures 17 to 19 of Mulligan et al. [24]

307 crystallization because of the lack of time for chain relaxation and arrangement in
 308 the crystallographic register. Mulligan et al. [24] interpreted this structure as
 309 nematic-like ordering. At higher temperatures or lower strain rates, the polymer
 310 chains, which were at intermediate orientation states, could crystallize as a result of
 311 adequate relaxation times (Fig. 6).

312 Stoclet et al. [23] shed novel light on the strain-induced ordering of amorphous
 313 PLLA chains upon drawing at temperatures above, but near to, T_g (70°C). With the
 314 help of in situ small-angle X-ray scattering (SAXS) experiments during uniaxial
 315 drawing, the authors showed the formation of a mesomorphic phase at the onset of

strain hardening. The mesomorphic phase was characterized by reduced interchain distance with regards to the spacing of the amorphous macromolecules. The higher cohesiveness of the mesomorphic domains generated physical crosslinking in the amorphous phase, leading to strain hardening. The mesomorphic phase was reported to be thermally stable up to 90°C. Upon drawing at intermediate temperatures (80°C), PLLA formed a mesomorphic phase and strain-induced crystallites. The ability of PLLA to form ordered phases (i.e., mesomorphic phase or crystallites) is directly linked to its stereoregularity. A critical value of 8% D was found, above which no ordering was induced, neither mesomorphic nor thermal, nor mechanically induced crystallization [25].

3.2 Cold Drawing

PLLA is a semicrystalline polymer and glassy at room temperature, therefore it presents brittle fracture behavior. The main deformation mechanisms of glassy polymers are crazing and shear banding. Crazing implies the formation of small voids (defects) in the amorphous phase, which are generally nucleated on surfaces. The voids are bridged by highly elongated fibrils and grow into crazes upon breakage of the fibrils. Crazes, in contrast to cavities, develop perpendicular to the draw direction, where the stress is concentrated on the edges. The formation of microvoids and crazes is also accompanied by volume change and begins around the yielding peak [26, 27]. Brittle fracture is finally caused by microcracks originating from breaking crazes [28]. The ductile behavior of polymer glasses exhibits yielding. Yield can be caused either by multiple crazes or by shear yielding (i.e., plastic flow without crazing). Whereas crazing occurs in materials at temperatures below T_g , shear yielding can be observed at a wide range of temperatures. The condition of shear yielding is that the critical shear stress for yielding is lower than the stress required to initiate and propagate crazes [28].

The second mechanism, shear banding, does not involve a polymer volume change. It consists in shear of the amorphous phase along slip planes that are oriented at approximately $\pm 45^\circ$ to the draw direction. The shear processes can be localized (fine slip) or diffuse (coarse slip). Slip occurs by the generation and propagation of dislocations between planes. A fine slip produces high deformation of the macromolecules and propagates quickly. In semicrystalline polymers, crystallographic fine slips cause the rotation of lamella planes in relation to the direction of the macromolecules. Therefore, fine slips cause rotation and thinning of the crystalline lamellae. Not much plasticity is created in that case and the fracture is brittle. Coarse slips are caused by the superposition of several fine slips. These slips propagate less quickly and produce more plasticity. The crystallographic coarse slips are responsible for the formation of block structures and lead to fragmentation of lamellae [22, 28].

Figure 7 presents typical stress–strain curves for tensile testing of PLLA (4.3% D) at different drawing temperatures [26]. At higher experimental temperatures, PLLA

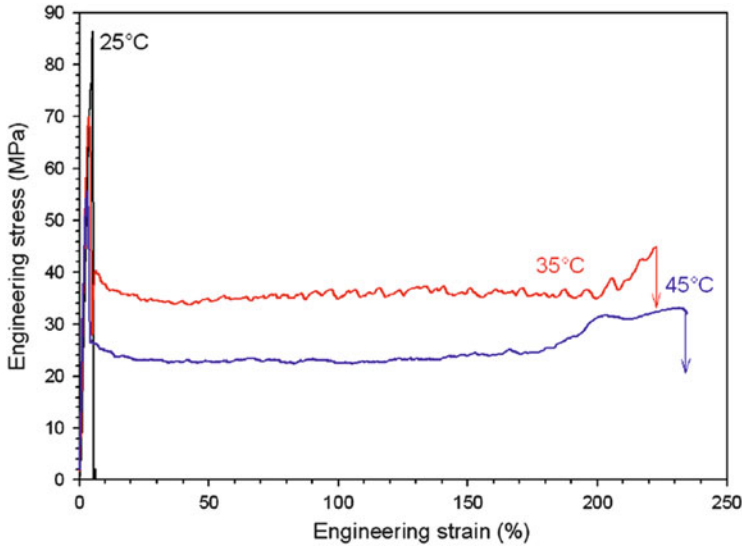

Fig. 7 Stress–strain curves for PLLA (4.3% D) drawn at different temperatures (strain rate 0.04 s^{-1} , $L_0 = 22 \text{ mm}$, crosshead speed 52.8 mm/min). Reproduced with permission from Stoclet et al. [26], Polymer, Elsevier

357 showed ductile behavior, proceeding by the nucleation and propagation of a
 358 neck. Stoclet et al. analyzed the ductile regime in detail using in situ SAXS experi-
 359 ments [26]. PLLA showed the presence of shear bands and shear-band nucleated
 360 crazes during deformation in the linear domain. Upon further elongation, those
 361 shear-band nucleated crazes (at 45° to the load direction) intersected and nucleated
 362 standard crazes (perpendicular to the load direction). In the ductile deformation
 363 region after necking, the preferred plastic deformation mechanism of PLLA was
 364 standard crazing. The shear banding mechanism is generally observed for polymers
 365 with a high entanglement density, whereas crazing is observed for polymers with a
 366 low entanglement density. The entanglement length of PLLA ($M_e = 4,000$; Table 3)
 367 was intermediate between PS (main deformation mechanism crazing, $M_e = 19,100$
 368 [29]) and PC (main deformation mechanism shear banding, $M_e = 2,490$ [29]),
 369 which might explain its mixed plastic deformation mechanism [26].

370 Stoclet et al. [26] suggested furthermore that the presence of voids at low defor-
 371 mation could be linked to the high aging rate of PLLA. Indeed, unaged PLLA was
 372 very ductile (Fig. 8) [30, 31], but it rapidly evolved towards brittle behavior.

373 Physical aging yields rearrangement of macromolecules to a denser and more
 374 ordered structure with a denser chain packing. The lost free volume and chain
 375 flexibility brings about higher yield stress and lower ductility [30].

376 In the brittle regime, which corresponds to the majority of use situations for
 377 PLLA, the crazes are nucleated before the yield point. At high crosshead speeds
 378 (as in the work of Stoclet et al. [26]) or low temperatures, failure generally occurs
 379 before yielding because the yield stress is higher than the critical stress for fibril
 380 break down [26]. The crazes turn then into cracks before the yield peak is reached.

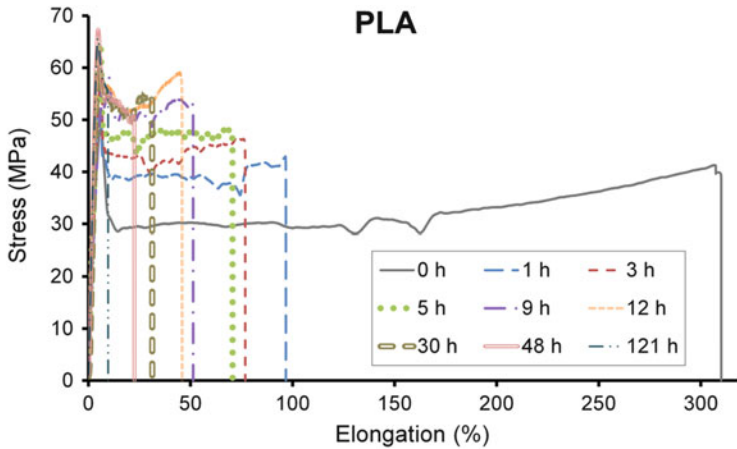

Fig. 8 Stress–strain (elongation) curves for amorphous PLLA at different aging times (23°C, 5 mm/min). From Ruellan et al. [31], personal communication

At lower crosshead speeds, such as 5 mm/min, yielding can be observed [27, 32, 33] 381
with a yield stress typically around 50 MPa. 382

Table 5 shows a collection of typical data on the tensile properties of PLLA 383
compared with other polymers. PLLA typically has an elongation at break of 5% 384
and a yield strength of 60 MPa. Its features are similar to those of polystyrene (PS), 385
but lower than those of polyethylene terephthalate (PET). The polyolefins show a 386
lower stress at yield than PLLA but the strain at break of low-density polyethylene 387
(LDPE) and high-density polyethylene (HDPE) are higher than that of PLLA. 388
Compared with another biobased polymer, poly(hydroxybutyrate) (PHB), PLLA 389
shows better mechanical properties with higher modulus of elasticity and stress at 390
yield (Table 5). 391

No impact of the percentage of D-lactic acid in the macromolecular chain could 392
be observed (Table 5). The molecular weight had moderate influence on the tensile 393
properties, when analyzed in the frame of a single sample set (Table 5, sample set 394
[34]). The crystallization of neat PLLA increased brittleness, which can be 395
observed in sample sets from different studies [27, 33–35]. Annealing at different 396
temperatures was reported to have an effect on the tensile properties. Samples 397
crystallized at 110°C had higher tensile strength but lower elongation at break 398
compared with amorphous samples, whereas annealing at 150°C caused lowering 399
of both characteristics [35]. Cocca et al. also showed the importance of the crystal 400
polymorph of PLLA on the mechanical properties. PLLA crystallized in the 401
 α -polymorph had higher Young's modulus and lower strain at break than PLLA 402
crystallized in the α' -polymorph [36]. 403

404 3.3 Toughening PLLA

405 Improving the toughness of PLLA for increasing its applicative domains is a very
 406 active research field. Roughly, four different techniques are employed: (1) biaxial
 407 stretching, (2) external plasticizing with plasticizers, (3) blending with other poly-
 408 mers, and (4) internal plasticizing by reactive extrusion.

409 Biaxial stretching is a processing method that allows the orientation of polymer
 410 films, leading to an important change in the microstructure. A number of processes
 411 result in de facto bi-oriented structures, such as film blowing, cable drawing, and
 412 cast film bi-orientation. Bi-oriented PLLA is today commercially available for

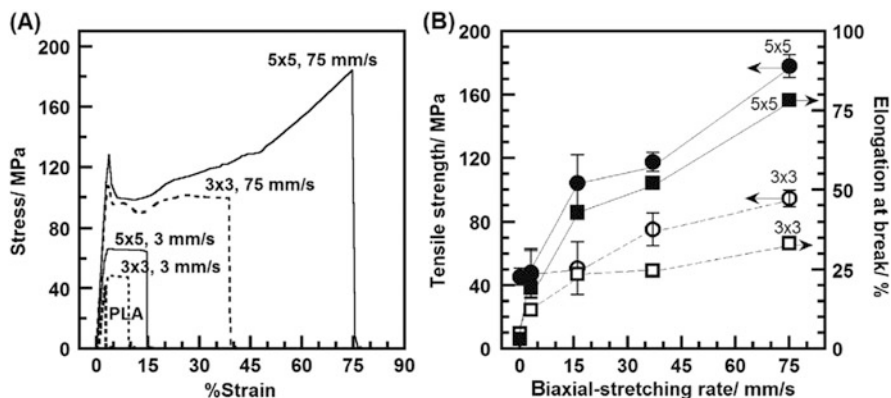

Fig. 9 Stress–strain curves (a) and tensile mechanical properties (b) of bi-oriented (90°C and preheating) PLLA (6% D, M_w 166 kg/mol). Reproduced with permission from Jariyasakoolroj et al. [52], Polymer, Elsevier

food packaging and other applications with an announced toughness of up to 180% 413
 elongation at break in the machine direction and 100% in the transverse direction 414
 (NatureWorks webpage [38]). The biaxial stretching of PLLA has been investigated 415
 by several authors [46–52], demonstrating the orientation of strain-induced or 416
 pre-existing crystallites in plane using either simultaneous or sequential stretching 417
 techniques. High stretching ratios (5×5) and stretching rates (75 mm/s) were 418
 favorable for a high toughness of PLLA (Fig. 9), because of the isotropic orientation 419
 of very small crystalline lamellae (α' -form), which developed from the irregular 420
 amorphous phase over the mesomorphic phase [52]. 421

The influence of plasticizers on the mechanical properties of PLLA has been 422
 extensively studied and recently reviewed [53, 54]. Numerous external monomeric 423
 and oligomeric plasticizers were tested, the most prominent of which were 424
 poly(ethylene glycol) (PEG) [27, 41, 55–61] of variable molecular mass and citrate 425
 derivatives such as acetyl tributyl citrate (ATBC) [41, 59, 61–65]. Significant 426
 modifications of the mechanical properties were generally obtained at a plasticizer 427
 content of approximately 20 wt%, where T_g of the formulated materials was close to 428
 the tensile testing temperature. For example, at 20 wt% ATBC content in PLLA, the 429
 material presented a stress at break between 23.1 and 30 MPa and a strain at break 430
 above 298% [59, 61, 63, 65]. To preserve claims on biodegradability and biobased 431
 carbon content in plasticized PLLA, biobased and biodegradable molecules were 432
 extensively screened as plasticizers [53]. Epoxidized soybean oil [66–69] or epoxi- 433
 dized palm oil [69–71] were tested with some success. More recently, it was shown 434
 that the use of deodorizer distillates, which are a by-product of the vegetable oil 435
 industry, improved astonishingly the ductility of PLLA. The strain at break could be 436
 increased up to 130%, while the T_g of the formulated material remained higher than 437
 room temperature (45°C) and the yield strength at 24 MPa [39, 42]. Annealing of 438
 plasticized PLLA generally has a negative effect on toughness [33, 39, 40]. 439
 Piorkowska et al. [40] studied the mechanism involved and proposed that growing 440

441 crystalline lamellae expelled the plasticizer into the surrounding amorphous matrix.
442 If plasticizer diffusion in the amorphous phase is not quick enough, this can lead to
443 accumulation of the plasticizer next to the crystalline lamellae and, thus, weakening
444 of the interface between the amorphous and crystalline phases, causing premature
445 failure. The same authors also showed that, in some cases, phase separation
446 between plasticizer and PLLA matrix can be positive for the mechanical properties
447 of annealed samples, because the phase-separated plasticizer nodules can facilitate
448 plastic deformation.

449 To toughen PLLA by melt blending, the most popular additions are biodegrad-
450 able polyesters, mainly poly(caprolactone) (PCL), poly(butylene succinate) (PBS),
451 and different members of the poly(hydroxyalkanoate) (PHA) family [54, 72]. For
452 example, the inclusion of 10% PBS in PLLA caused an increase in the elongation at
453 break of up to 120%. The impact of blend structure on the tensile properties was
454 studied by Boufarguine et al. [73] with the help of the layer-multiplying
455 co-extrusion process. This process consists of division of the extrusion flow and
456 its reassembly in specially designed mixing elements, leading to multiplication of
457 the number of co-extruded polymer layers. The increase in the number of PLLA and
458 poly(hydroxybutyrate valerate) PBHV layers (in total 129 layers) allowed an
459 elongation at break of 70%, which was more than the double the value obtained
460 using a dry blend methodology (30%). The dry blend methodology consists of the
461 mixing of polymer pellets offline and feeding them together into the extruder. Many
462 alternative blending strategies exist for improving toughness, such as use of
463 aliphatic-aromatic copolymers [e.g., poly(butylene adipate-*co*-terephthalate),
464 PBAT], commercial acrylates, natural and synthetic rubbers, and impact modifiers
465 [54]. Reactive extrusion processes were also recently reviewed [54, 74]. Reactive
466 melt blending often relies on the reactivity of isocyanates reacting with the
467 hydroxyl and carboxyl groups of PLLA and thereby improving compatibility of
468 the two polymers. However, other functional chemical groups have also been used.
469 Reactive grafting of citrates by maleic anhydride functionalized PLLA allowed an
470 increase in strain at break comparable to that of externally plasticized PLLA, but
471 without exudation of the plasticizer, even after 6 months of aging [75].

472 Blending of PLLA with a number of additives is also a possibility for improving
473 the impact strength. Table 6 gives an overview of different results concerning this
474 property, which is of interest for thermoformed containers and durable applications
475 such as automotive parts. The impact strength of pristine PLLA (13 J/m) is low
476 compared with that of other polymers, although the tensile modulus of PLLA is
477 high (see Table 6). For example, the notched Izod impact strength of PS is 27 J/m
478 and that of PET 56 J/m (data taken from [54]). The low impact strength is generally
479 caused by low chain mobility in the polymer, which results in insufficient energy
480 absorption and dissipation. The impact energy leads therefore to rapid failure
481 propagation by breaking intermolecular bonds (from [76]). Annealing could
482 increase the impact strength of pristine PLLA [34], but could have a negative effect
483 on formulated samples [77]. Plasticizing, polymer blending, and the use of impact
484 modifiers were tested with the aim of increasing impact strength. A number of
485 commercial impact modifiers have been developed for PLLA. They are generally
486 low- T_g elastomers or core-shell polymers. Core-shell polymers typically consist of

a rubbery (low- T_g) core surrounded by a glassy shell with good interfacial adhesion with the PLLA matrix. The impact modifiers are dispersed as microdomains in PLLA. The microdomains are able to absorb and dissipate mechanical energy upon impact or to retard or stop initiation and propagation of cracks. The average size of microdomains of impact modifiers in PLLA ranged in most studies between 0.1 and 5 μm [54, 76, 78–80]. Table 6 gives a selection of some results from the review of Liu et al. [54] and others collected from recent literature. It represents data obtained using the different toughening techniques, that is, plasticizing, polymer blending, and use of commercial impact modifiers. The decrease in microdomain size was, in general, positive for impact strength [54]. Interfacial adhesion between the impact modifier and the PLLA matrix is key to a successful increase in impact strength. The use of a compatibilizer can significantly enhance the material's properties. An example can be found in the study of Hashima et al. [77]. In this study, the use of a compatibilizer helped to improve PLLA impact strength up to 92 kJ/m² (Table 6). The drawback of the use of impact modifiers is a decrease in the modulus and stiffness of PLLA. For example, the modulus of PLLA in Bouzouita's study diminished from 3.2 to 2.3 GPa [79]. In conclusion, as already pointed out by Liu et al. [54], increasing PLLA impact strength while maintaining high stiffness still

505 remains a challenge. Furthermore, the effects of parameters such as the crystallinity
506 degree and the stereochemistry of PLLA still need to be investigated.

507 **3.4 Conclusion**

508 The mechanical properties of PLLA are intermediate between those of PS and PET,
509 which makes PLLA suitable for applications such as rigid containers, cases and
510 housings, service ware, and toys. The principal mechanisms responsible for
511 mechanical failure of PLLA have been intensively investigated in recent years
512 and much knowledge is now established. PLLA presents brittle fracture at room
513 temperature (at around 5% strain), which can be explained by a mixed mechanism
514 of crazing and shear banding. At temperatures higher than T_g , PLLA shows
515 extensive yielding and strain hardening. To overcome the limitations of the brittle
516 fracture and low impact strength, a number of strategies for toughening PLLA have
517 already been tested, such as bi-orientation, external and reactive plasticizing, and
518 melt blending with other polymers or commercial additives for increased impact
519 strength. Although there are already successful toughened PLLA products obtained
520 by bi-orientation and formulation with plasticizers and impact modifiers, research
521 in the field is very active, seeking novel additives (preferentially biobased and/or
522 biodegradable) and using melt blending strategies and reactive extrusion.

523 **4 Barrier Properties of PLLA**

524 The sorption/diffusion model [82] describes the permeability to gas and vapors in
525 polymers. Permeability is influenced by different intrinsic factors of a given
526 polymer, such as the free volume fraction (FFV) of the polymer, T_g , cohesive
527 energy density (CED), degree of crystallinity, molecular orientation, and copoly-
528 merization. A schematic representation of the different structural length scales that
529 are important for the transport of permeants in dense materials is shown in Fig. 10.
530 At the macroscopic length scale (Fig. 10a), the design of the global material
531 architecture (blend structures, multilayers, etc.) influences the barrier properties.
532 In particular, multilayer structures allow the barrier properties of two different
533 polymers to be combined. The permeability (P) of the material in that case is
534 roughly given by the following relationship:

$$\frac{1}{P} = \frac{w_1}{P_1} + \frac{w_2}{P_2}, \quad (4)$$

535 where w_1 and w_2 are the weight fractions of both polymers in the materials and
536 P_1 and P_2 their respective permeabilities. At smaller length scales (Fig. 10b), the
537 presence and morphology of impermeable obstacles in the pathway of diffusion
538 changes the transport properties. Those obstacles create a more tortuous and longer

Fig. 10 Different length scales relevant for barrier properties: (a) macroscopic length scale of the material architecture (multilayer, blend, etc), (b) microscopic to nanoscopic length scale relevant for the tortuosity of the diffusive pathway circumventing obstacles (crystallites, fillers), and (c) macromolecular length scale of the hopping of permeants from one free volume void to another in the amorphous phase

pathway for the diffusive transport of solutes and, as a result, decrease the macroscopic diffusion coefficient. On the molecular scale (Fig. 10c), diffusion proceeds by successive hops of the permeant from one void in the polymer matrix to another. At high temperatures (above T_g), voids are redistributed rapidly and the diffusion rate is governed by the creation of voids of sufficient size for the permeant. In glassy polymers, the probability of the formation of voids of sufficient size is much smaller. The permeants therefore spend most of the time in one void, and only rarely local density fluctuations cause the opening of a tunnel which allows hopping of permeants from one void to the other. The overall diffusive transport is much slower than in melts or rubbers, but higher than extrapolation from the rubber state would predict because of the excess free volume in glasses [83–85].

PLLA barrier properties need to be improved for most applications, and in particular for food packaging [86–88]. Therefore, strategies for improvement using all the above-mentioned length scales have already been employed. The multilayer approach can achieve a broad range of properties that are not available for any of the individual materials/layers alone. Multilayer films can be prepared by co-extrusion, film lamination, or using a layer-by-layer approach. Co-extrusion consists of the simultaneous extrusion of two or more polymer layers and their assembly in the molten state. By contrast, film lamination is the combination of two or more films using an adhesive. The increase in tortuosity of the diffusive pathway inside PLLA has been pursued using two different approaches: (1) increasing polymer crystallinity, because the crystallites are impermeable to small molecules, and (2) adding fillers or nanofillers to the material [89]. The filler materials tested include clay and silicate nanoplatelets, silica nanoparticles (SiO_2), carbon nanotubes, graphene, cellulose-based nanofibers or nanowhiskers, and other inorganics.

565 4.1 Gas Barrier Properties

566 Oxygen has high applicative importance and, not surprisingly, most literature
 567 studies on gas barrier properties are concerned with the oxygen permeability,
 568 $P(O_2)$, of PLLA. Table 7 summarizes some experimental data on the oxygen perme-
 569 ability of PLLA compared with petrochemical polymers. PLLA performance is
 570 similar to that of PS and below the performance of PET.

571 $P(O_2)$ values between 1.3 and $2.0 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$ at 30°C for amorphous
 572 PLLA have been reported, depending on the L/D ratio [90–92]. The oxygen trans-
 573 port coefficients of PLLA, whatever the L/D ratio, are sensitive to the measurement
 574 temperature and relative humidity (RH). Auras et al. [46] showed that at 0% RH,
 575 the oxygen permeability and solubility coefficients increased with temperature.
 576 Mensitieri et al. [93] investigated the coupled effects of water vapor and $P(O_2)$
 577 and showed that PLLA, like other biopolymers, had lower oxygen barrier perfor-
 578 mance than petrochemical polymers, and that its performance was negatively
 579 influenced by its moisture susceptibility. The addition of plasticizers for the
 580 improvement of mechanical properties led to an increase in $P(O_2)$ as a result of
 581 higher mobility of the polymer chain and higher free volume brought by the
 582 plasticizer to the polymer matrix [33, 94]. In some cases, low molecular weight
 583 molecules can also fill in free volume, in which case they are positive for the

t7.1 **Table 7** Oxygen permeability of petrochemical polymers and biopolyesters [90–92, 96, 97]

barrier properties. This was demonstrated by the use of low molecular weight lactic acid oligomers. The blending of PLLA with 25 wt% of lactic acid oligomers reduced the $P(O_2)$ by 22% [95].

Tailoring of the PLLA microstructure for an increase in its barrier properties has been widely investigated in recent years [91, 92, 98]. Dong et al. [99] reported a small increase in the oxygen barrier properties of bi-axially stretched and annealed PLLA. The initial $P(O_2)$ was $2.03 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$. After drawing with a stretching ratio of 3.5, the $P(O_2)$ decreased to $1.53 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$. In the case of stretched and annealed samples, the $P(O_2)$ decreased from 1.83×10^{-18} (stretching ratio 1 and annealed) to $1.31 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$ (stretching ratio 3.5 and annealed) [99].

The effect of crystallinity on PLLA oxygen barrier properties was studied by several authors [33, 100–103]. However, there were a number of conflicting results, for which no clear relationship between PLLA crystallinity degree and barrier properties could be shaped. This situation was encountered in the case of several glassy polymers, as shown by Kanehasi et al. [104]. Guinault et al. [102] carried out a systematic study of the PLLA barrier properties as a function of the crystallinity degree. Their main results are shown in Fig. 11. The $P(O_2)$ of PLLA was either stable or even increased with increasing crystallinity degree (Fig. 11). Guinault et al. [102] showed that, in the case of crystallization of PLLA in α' -form crystallites, high percentages of dedensified rigid amorphous fraction were created in the amorphous phase. This produced a pathway of accelerated gas transport around the crystalline lamellae. The oxygen permeability coefficient of PLLA containing α -form crystallites was lower than that of PLLA containing α' -form crystallites [101],

608 because crystallization from the melt produced less dedensified amorphous phase
 609 [102]. To increase the gas barrier properties of PLLA, high tortuosity needs to be
 610 achieved and the formation of dedensified amorphous phases should be avoided.

611 Bai et al. [105] studied the $P(\text{O}_2)$ of PLLA with an original crystalline morpho-
 612 logy, described as parallel-aligned shish-kebab-like crystals, with the aid of N,N' ,
 613 N'' -tricyclohexyl-1,3,5-benzene-tricarboxylamide (trade name TMC-328), a highly
 614 active nucleating agent. As shown in Fig. 12, the oxygen barrier performance of
 615 PLLA with such parallel-aligned shish-kebab-like crystals was more than two
 616 orders of magnitude higher than that of PLLA with spherulitic crystals. The
 617 growing crystalline lamellae interlocked at the boundary regions and thereby
 618 formed a very densely packed structure, which decreased the gas permeability.
 619 An increase in the concentration of nucleating agent from 0.2 to 0.5 wt% impacted
 620 the oxygen permeability. The PLLA with 0.5 wt% TMC sheet had a $P(\text{O}_2)$ of
 621 $1.989 \times 10^{-20} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$, about 500 times lower than that of the amorphous
 622 PLLA sheets ($9.692 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$) [105].

623 The second option for improving PLLA barrier properties, which has been
 624 widely studied, is an increase in tortuosity of the permeant pathway by the incor-
 625 poration of inert, nanoscale fillers into PLLA [106–110]. The nanoscale particles
 626 need to have at least one dimension that is smaller than 100 nm, which yields a high
 627 aspect ratio (length/diameter = 100–500). The most widely used nanofillers are
 628 montmorillonites (MMTs). MMTs are hydrated alumina-silicate layered clays with
 629 a high surface area and large aspect ratio (50–1,000). Exfoliation of clay minerals in
 630 the polymer is of high importance for obtaining the desired high aspect ratio and a
 631 positive impact on the barrier properties. Furthermore, at a constant clay content,
 632 the permeability coefficient was reported to decrease as the length of the clay

particles increased [107, 111]. Using nanoclays such as organomodified MMT, Cloisite 25A (quaternary ammonium salt modified MMT), Cloisite 30B (alkyl quaternary ammonium salt bentonite), and organo-modified synthetic fluorine mica the permeability coefficient was globally divided by a factor of 2 or 3, depending on the type of nanoclay and the efficiency of exfoliation [112–114].

Guo et al [115] studied the $P(O_2)$ of PLLA and different nanocomposites using MMT, organomodified MMT, halloysite nanotubes, and organomodified halloysite nanotubes. They showed that the largest decrease in $P(O_2)$ was obtained using organomodified MMT. The halloysite nanotubes had no impact on the $P(O_2)$ of PLLA [115]. Picard et al. [107] reported a decrease in $P(O_2)$ of annealed crystalline films containing 4 wt% of MMT with respect to the amorphous reference PLLA film. They showed that the organomodified clays had a tortuosity effect in the matrix. A more important role of the nanofillers, however, was their effect as nucleating agents, which helped to achieve a high crystallinity degree for PLLA and thereby to decrease the $P(O_2)$ [107]. PLLA blended with 1 wt% of surface-modified nanoparticles by in situ polymerization of L-lactide using two different nanoparticles (nanosilica and Cloisite R 15A, an organomodified MMT) showed an increase both in crystallinity (up to 70%) and in barrier properties [116]. $P(O_2)$ was reduced by 80% and carbon dioxide and water vapor permeabilities were reduced by 50 and 45%, respectively, in comparison with pure PLLA [116].

Graphene and graphene oxide have been recently investigated as inorganic nanofillers for PLLA. To achieve a good dispersion of these nanofillers, Ambrosio-Martin tested pre-incorporation of graphene sheets by in situ melt polycondensation with lactic acid oligomers [117]. This procedure enhanced the barrier properties. Reductions of up to 45 and 41% in oxygen and water permeabilities, respectively, were reported. Graphene oxide is similar to graphene but the presence of some oxide groups allows better compatibility with the polar polymer matrix. Pinto et al. [118] reported that $P(O_2)$ decreased from 3.76×10^{-18} for pristine PLLA to $1.34\text{--}1.49 \times 10^{-18} \text{ m}^3 \text{ m}^{-2} \text{ s Pa}$ for PLLA containing 0.2–0.6 wt% of graphene oxide. These authors obtained the same results for PLLA loaded with 0.2–0.6 wt% of graphene nanoplatelets.

In the framework of biobased and biodegradable materials, the increase in PLLA barrier properties was also attempted using organic and biobased materials. Tripathi and Katiyar [119] studied biocomposites obtained using microspheres composed of arabic gum grafted with lactic acid (LA-g-GA). A decrease in $P(O_2)$ by a factor of 10 was achieved independently of the amount of LA-g-GA (3, 5, 8, and 10%). Bionanocomposites of PLLA were also developed using cellulose nanostructures. Cellulose microfibrils (MFCs) have nanosized diameters (2–20 nm depending on the origin) and lengths in the micrometer range. The crystalline parts of MFCs can be isolated by several mechanical and chemical treatments, with the aim of obtaining cellulose nanocrystals (CNCs) or nanowhiskers. The lengths of CNC nanostructures range from 200 nm up to 1–2 μm and about 8–50 nm or less in diameter, which results in high aspect ratios [120–123]. Sanchez-Garcia et al. [124, 125] compared the effect of the same content of MFCs and CNCs. The addition of 5 wt% of MFCs had no effect on the gas barrier properties of PLLA

678 bionanocomposites whereas 5 wt% of CNCs slightly decreased (factor 2) the $P(O_2)$.
679 This result was also shown by Espino et al. [121].

680 Furthermore, different strategies for the fabrication of multilayer materials with
681 improved barrier properties were investigated. A bilayer sample composed of
682 filtered 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO)-radical oxidized cellulose
683 nanofibers and PLLA was studied by Fukuzumi et al. [126]. Under dry conditions,
684 the $P(O_2)$ of the multilayer system decreased by two orders of magnitude compared
685 with neat PLLA. Martucci and Ruseckaite [127] proposed three-layer sheets based
686 on glycerol-plasticized gelatin as the inner layer and PLLA as the outer layers. A
687 decrease of $P(O_2)$ from 1.24×10^{-18} for neat PLLA to $0.81 \times 10^{-18} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$
688 for the three layers was reported. Svagan et al. [128] employed a layer-by-layer
689 approach, using electrostatic forces to assemble alternating layers of MMT and
690 chitosan on extruded PLLA film surfaces. When 70 MMT/chitosan bilayers were
691 applied, the oxygen permeability was reduced by 99 and 96%, respectively, at
692 20 and 50% RH [128]. Novel processing techniques, such as layer-by-layer fabri-
693 cation or layer-multiplying co-extrusion, permit the fabrication of materials with
694 large numbers of layers having nanometer thickness (often between 20 and
695 100 nm). In these cases, the interface area in the multilayer material is very large
696 and interface effects or interdiffusion of polymers at the interface have an effect on
697 the material properties. Liu et al. [129] showed the potential of such materials to
698 improve barrier properties. Boufarguine et al. [73] produced PLLA-PHBV multi-
699 layer films (129 layers) by layer-multiplying co-extrusion. They showed that the
700 multiplication of the layer number had a positive effect on the helium permeability,
701 compared with the three-layer PLLA-PHBV-PLLA configuration. The helium
702 permeability decreased from 120×10^{-18} to 77.6×10^{-18} and $74.3 \times 10^{-18} \text{ m}^3$
703 $\text{m/m}^2 \text{ s Pa}$ for materials having 129 and 3 layers, respectively.

704 The carbon dioxide permeability coefficient of PLLA is $2.5 \times 10^{-18} \text{ m}^3 \text{ m/m}^2$
705 s Pa , which is lower than that of LDPE and PS (95 and $17 \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$,
706 respectively) [92]. PET is a better barrier against CO_2 as its permeability coefficient
707 is as low as $0.5 \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$. The CO_2 permeability was shown to increase with
708 L-lactic acid content and temperature [46]. The crystallization of PLLA induced a
709 decrease in the carbon dioxide permeability coefficient [130, 131]. According to
710 Sawada et al. [103], the decrease in CO_2 permeability with an increase in crystal-
711 linity can only be achieved at a crystallinity degree higher than 40%.

712 The nitrogen permeability of PLLA is $3.8 \times 10^{-19} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$, which is lower
713 than the values for PS ($5.9 \times 10^{-19} \text{ m}^3 \text{ m/m}^2 \text{ s Pa}$) and LDPE ($73 \times 10^{-19} \text{ m}^3 \text{ m/m}^2$
714 s Pa) at 25°C but higher than that of unplasticized PVC ($0.88 \times 10^{-19} \text{ m}^3 \text{ m/m}^2$
715 s Pa) [92]. The L/D ratio did not affect the nitrogen permeability of PLLA [132]. The
716 crystallinity effect has also been evaluated for this gas and it seems that the nitrogen
717 permeability decreased with the increase in crystallinity degree of PLLA [103].

718 The gas selectivity of PLLA membranes depends on the chosen gas. Lehermeier
719 et al. [133] showed that the separation factor of CH_4 and CO_2 , equal to 10, was not
720 dependent on the crystallinity or L/D ratio. Only a change in temperature made it
721 possible to increase this factor. Sawada et al. [103] confirmed the inefficiency of
722 crystallinity on the permselectivity, but also showed that the diffusivity and solu-
723 bility selectivity were not influenced by the crystallinity. The gas permselectivity in

PLLA is larger than 120 for H₂/N₂, 6 for O₂/N₂, 23 for CO₂/N₂, 27 for CO₂/CH₄, 724
 and 1 for CH₄/N₂ [103]. The permselectivity of PLLA is twice that of LDPE and 725
 PVC for O₂/N₂ and CO₂/N₂ [134]. The solubility coefficients of O₂, N₂, CO₂, and 726
 CH₄ decreased monotonically with increasing crystallization temperature: PLLA- 727
 70 > PLLA-80 > PLLA-90 > PLLA-150 [135]. 728

4.2 Water Vapor Permeability of PLLA

729

Table 8 summarizes the water vapor transmission rate (WVTR) of PLLA compared 730
 with other commodity polymers. The WVTR is a water vapor permeability measure 731
 widely used in academic and industrial literature. Table 9 also gives the perme- 732
 ability values in international standard units. PLLA has the highest water vapor 733
 permeability, P(H₂O), of the polyesters. To promote PLLA as a biobased packaging 734
 for aqueous food products, an improvement in the water vapor barrier must be 735
 achieved. The design target is to close the gap between the P(H₂O)s of PLLA and 736
 PET. 737

Table 8 Comparison of water vapor transmission rates for PLLA and other polymers, compiled 18.1
 from [46, 50, 125, 137, 139, 143]

Polymer	Water vapor transmission rate at 23°C and 85% RH (g mm/m ² day)

738 There are some contradictory results in the literature on the effect of temperature
 739 and RH on the $P(\text{H}_2\text{O})$ of PLLA. Auras et al. [46] showed a decrease in perme-
 740 ability with increasing temperature whereas Shogren reported an increase
 741 [136]. Siparsky et al. [137] showed that the diffusion coefficients increased and
 742 the solubility coefficients decreased with the temperature at 90% RH, which was
 743 contradicted by Holm et al. who showed higher values of moisture sorption at
 744 higher temperatures [138]. Furthermore, the conclusions on the effect of the
 745 crystallinity degree on the barrier properties were different in different studies. In
 746 some works, a higher crystallinity degree caused a slight improvement in the barrier
 747 properties [69, 136, 139] and in others not [137]. These discrepancies in the data
 748 show that the mechanism of water transport in PLLA is still not completely
 749 understood [140]. In particular, the presence of water clusters in the PLLA matrix
 750 and their potential to diffuse in cluster form are still controversial [141]. Indeed,
 751 water can cluster inside the PLLA matrix, which changes the structure of the
 752 diffusing unit. Water diffusion in the form of clusters would reduce the rate of
 753 diffusion compared with the diffusion of single molecules. Davis et al. [142]
 754 described non-Fickian diffusion of water in PLLA. At small time intervals, water
 755 transport was driven by the diffusion coefficient, whereas with long experiment
 756 times non-Fickian diffusion occurred as a result of slow polymer relaxation and
 757 swelling by water sorption. The diffusion coefficients were shown to be constant
 758 with water activity and concentration and to increase with temperature.

759 The strategies used to improve $P(\text{H}_2\text{O})$ were essentially the same as used for
 760 improving $P(\text{O}_2)$. Delpouve et al. [50] showed that biaxial stretching had a positive
 761 impact on $P(\text{H}_2\text{O})$ in that it reduced the diffusion coefficient at high stretching
 762 ratios. However, if a thermal annealing treatment was added after biaxial stretching,
 763 the positive effect of the treatment on the barrier properties was lost. Similar to the
 764 case of oxygen barrier properties, thermal crystallization was not efficient enough
 765 to induce sufficient tortuosity in the permeant pathway. Slackening of the orienta-
 766 tion in the amorphous phase after thermal annealing of the biaxially stretched
 767 samples could be one reason for the regression of barrier properties observed
 768 between oriented and annealed PLLA [144]. Cocca et al. reported that crystalliza-
 769 tion of PLLA in the α -polymorph was more efficient at increasing water barrier
 770 properties than α' -form crystallites [36]. Tsuji et al. [145] studied the crystalline
 771 structure and $P(\text{H}_2\text{O})$ of poly(L-lactide)/poly(D-lactide) blend films. The results
 772 showed that the stereoregularity of the composite structure improved the water
 773 vapor barrier properties. Nanocomposites were also fabricated with the aim of
 774 decreasing $P(\text{H}_2\text{O})$. For example, biodegradable PLLA/poly(trimethylene-

carbonate)/laponite (2 wt%) composite films achieved an improvement in $P(\text{H}_2\text{O})$. 775
The value of $P(\text{H}_2\text{O})$ decreased from 4.57×10^{-13} to 3.23×10^{-13} $\text{kg m/m}^2 \text{ s Pa}$ 776
[146]. A small improvement in $P(\text{H}_2\text{O})$ was also obtained using chemically grafted 777
cellulose nanocrystals as nanofillers in PLLA [123]. Deposition of alternate layers 778
of chitosan and processed cellulose nanocrystals on PLLA films and bottles was 779
studied by Halasz et al. [147]. Using the layer-by-layer (LbL) technique, PLLA was 780
coated with four bilayers of chitosan and cellulose nanocrystals. An improvement 781
in $P(\text{H}_2\text{O})$ of 29 and 26% was obtained for PLLA films and bottles, 782
respectively [147]. 783

4.3 Permeability of Organic Vapors Through PLLA

784

The transport of organic compounds in PLLA has been the subject of only a few 785
studies, although it is of importance in food packaging applications. Ethylene, a 786
compound accelerating fresh food ripening, plays an important role in the storage of 787
fresh fruits. The ethylene permeability of amorphous PLLA has been tested and 788
evaluated to be 6.8×10^{-18} $\text{m}^3 \text{ m/m}^2 \text{ s Pa}$ [133]. This value is higher than the 789
ethylene permeability of PET (3.0×10^{-20} $\text{m}^3 \text{ m/m}^2 \text{ s Pa}$) [133] but lower than the 790
value for LDPE (2.2×10^{-17} $\text{m}^3 \text{ m/m}^2 \text{ s Pa}$) [91]. Increasing the crystallinity of 791
PLLA induced a decrease in ethylene permeability [103, 133]. 792

The transport coefficients for ethyl acetate, an aroma booster found in a large 793
variety of aroma formulations, were calculated from sorption of ethyl acetate in 794
PLLA. The ethyl acetate permeability of PLLA was 5.34×10^{-19} $\text{kg m/m}^2 \text{ s Pa}$ at 795
 30°C and 0.3 activity. This value was higher than that for PET but lower than those 796
of PP and LDPE. However, the ethyl acetate solubility coefficient in PLLA, 797
 6.17×10^{-3} $\text{kg m}^{-3} \text{ Pa}^{-1}$ at 30°C and 0.3 activity, was higher than that of the 798
other polymers [148]. This result was comparable to the value reported by 799
Colomines et al. [100] for an amorphous PLLA with 99% L-lactide content at 800
 25°C and 0.5 activity. Moreover, increasing the crystallinity of PLLA provoked a 801
decrease in the ethyl acetate solubility coefficient at 0.5 and 0.9 activity 802
[33, 100]. The permeability of limonene through PLLA was estimated at a maximal 803
value of 9.96×10^{-21} $\text{kg m/m}^2 \text{ s Pa}$ at 45°C and with a limonene partial pressure of 804
258 Pa. The permeability value of this more hydrophobic molecule is lower than 805
that of ethyl acetate in PLLA and those measured for PET, PP, and LDPE 806
[148, 149]. 807

A study of scalping aroma compounds by PLLA during high-pressure treatment 808
evidenced a lower uptake of organic molecules by PLLA compared with LDPE. 809
Indeed, ethyl hexanoate and limonene were more sorbed in the more apolar matrix, 810
LDPE. By contrast, the more polar molecules 2-hexanone and ethyl butanoate were 811
more sorbed by the more polar polymer matrix PLLA [150–152]. 812

The barrier properties of PLLA towards organic compounds depend on the 813
diffusion and solubility coefficients of the given organic molecule. Colomines 814
et al. [100] and Courgneau et al. [33] studied ethyl acetate sorption in PLLA at 815
activities up to 0.5 in Colomines's paper and 0.2 in Courgneau's paper. At these 816

Fig. 13 Solubility coefficients of aroma compounds for different grades of PLLA compared with polyolefins. Data were taken from [151]

817 high activities, the sorption of ethyl acetate into PLLA induced morphological
 818 changes in the polymer structure, namely plasticization and induced crystallization.
 819 These changes could lead to several discrepancies in solubility coefficient data in
 820 the literature at various activities. Nevertheless, Auras et al [148], and Salazar et al.
 821 [152] demonstrated that, whatever the methodologies used, the solubility coeffi-
 822 cients of ethyl acetate in PLLA were close to $6.17 \times 10^{-3} \text{ kg m}^{-3} \text{ Pa}^{-1}$ at 30°C .
 823 These results showed that, at low activity, data could be compared and the solubility
 824 coefficient was independent of partial pressure following Henry's law. At low
 825 activity, the sorption of ethyl acetate in PLLA films is similar to that reported for
 826 PET, LDPE, and PP. In the case of ethyl hexanoate, its solubility coefficient in
 827 different grades of PLLA is ten times lower than in bi-axially oriented polypropyl-
 828 ene (biOPP), PP, and LDPE (Fig. 13). Benzaldehyde presented a solubility coeffi-
 829 cient in PLLA that was ten times higher than that in PP [152], which could lead to
 830 solvent-induced crystallization and plasticization and, thus, changes in PLLA
 831 barrier properties [152]. The high affinity of PLLA for molecules with aromatic
 832 functions can be explained by the miscibility of PLLA with aromatic solvents such
 833 as toluene and benzene [153, 154]. In mixture, the presence of benzaldehyde favors
 834 the interaction and sorption of other organic compounds in PLLA [152].

835 4.4 Nonvolatile Compounds

836 The barrier properties of PLLA against oil products have been rarely studied.
 837 Rapeseed oil and oil-in-water emulsions were packed in PLLA trays and stored
 838 for 30 days at 40°C . For emulsions with 40% oil content, sorption of oil was very
 839 low ($<5 \text{ mg/dm}^2$ of material) whereas the sorption reached 10 mg/dm^2 of material

when PLLA was in contact with rapeseed oil. PET samples immersed in olive oil for 10 days at 40°C sorbed 33 mg/dm². These results, obtained with the same experimental procedure, indicate that PLLA could be an alternative candidate to PET for the conditioning of oil and fatty products [152].

4.5 Conclusion

Barrier properties are of importance for a number of applications, especially packaging. For the preservation of packed goods, low permeability to water, oxygen, and organic vapors is often required. However, these objectives are contradictory in that a high oxygen barrier can be reached by polar materials, whereas polar materials are not a barrier to water vapor. Therefore, numerous strategies have been used to create obstacles to permeation inside the polymer matrix. Crystallization of semicrystalline polymers can be efficient in this respect but, in the case of PLLA, thermal crystallization does not necessarily lead to improvements in barrier properties because of the formation of dedensified phases in the polymer matrix. Controlling crystallite morphology is very important and the most interesting increases in barrier properties could be obtained by shish-kebab-like structures. An alternative strategy is the fabrication of nanocomposites. Incorporation of nanofillers had two effects: (1) an increase in the tortuosity of the diffusive pathway of molecules and, more importantly, (2) an increase in PLLA crystallinity because of the nucleating effect. Strategies using multilayer materials were also efficient, and novel processing methods allowing the creation of multilayers with a large number of layers have shown promising results for the improvement of barrier properties in other polymers. In conclusion, improvement of PLLA barrier properties is still an active research topic and approaches for tailoring crystalline morphology and use of fillers or multilayers will be investigated.
