Abstract

Schistosomes are the causative agents of schistosomiasis, a Neglected Tropical Disease affecting over 230 million people worldwide. Additionally to their major impact on human health, they are also models of choice in evolutionary biology. These parasitic flatworms are unique among the common hermaphroditic trematodes as they have separate sexes. This so-called « evolutionary scandal » displays a female heterogametic genetic sex-determination system (ZZ males and ZW females), as well as a pronounced adult sexual dimorphism. These phenotypic differences are determined by a shared set of genes in both sexes, potentially leading to intralocus sexual conflicts. To resolve these conflicts in sexually selected traits, molecular mechanisms such as sex-biased gene expression could occur, but parent-of-origin gene expression also provides an alternative. In this work we investigated the latter mechanism, *i.e.* genes expressed preferentially from either the maternal or the paternal allele, in *Schistosoma mansoni* species. To this end, transcriptomes from male and female hybrid

adults obtained by strain crosses were sequenced. Strain-specific Single Nucleotide Polymorphism (SNP) markers allowed us to discriminate the parental origin, while reciprocal crosses helped to differentiate parental expression from strain specific expression. We identified genes containing SNPs expressed in a parent-of-origin manner consistent with paternal and maternal imprints. While the majority of the SNPs were identified in mitochondrial and Z-specific loci, the remaining SNPs found in male and female transcriptomes were situated in genes that have the potential to explain sexual differences in schistosomes parasites. Furthermore, we identified and validated four new Z-specific scaffolds.

Keywords: Parent-of-origin gene expression, Sexual dimorphism, Intralocus sexual conflict, Male-Female coevolution, *Schistosoma mansoni*.

Introduction

Schistosomiasis, also known as bilharzia, is a highly prevalent tropical disease affecting over 200 million people worldwide (Engels et al. 2002). It mainly occurs in developing countries and ranks second in term of parasite morbidity and mortality after malaria (King 2010). This chronic infection is caused by different species of the *Schistosoma* genus, blood flukes, with a complex lifecycle involving two obligatory hosts. *Schistosoma mansoni* responsible of intestinal schistosomiasis uses *Biomphalaria* genus as mollusc intermediate host, and humans or rodents as vertebrate definitive hosts. In the vertebrate host, males and females form monogamous couples, and sexually reproduce (Beltran and Boissier 2008). The produced eggs are released out of the host *via* the faeces and, in contact with freshwater, hatch to liberate free-swimming larvae called miracidium. These miracidia actively search and infect their intermediate hosts, transform into two successive intra-molluscan stages (*i.e.*

sporocysts), which produce by asexual multiplication thousands of vertebrate-infecting larvae (*i.e.* cercaria).

Besides the medical importance of this parasite for human health, it is also a very interesting model in terms of evolutionary biology due to its original sexual features. Among the 18,000 to 24,000 hermaphroditic species recorded in Trematodes, only the *Schistosomatidae* family (~100 species) has evolved separate sexes and has thus been qualified as an “evolutionary scandal” by Claude Combes in 1991 (Combes 1991). This gonochorism is accompanied by a pronounced dimorphism between sexes (Basch 1990; Loker and Brant 2006). These differences between males and females exist on different scales ranging from a molecular, to a behavioural level, and have been documented in several studies (see Moné and Boissier 2004 for review). Larval stages are morphologically indistinguishable and one striking difference at the adult stage is the worm musculature (muscular adult male vs. a thin adult female), as well as the presence of a gynaecophorous canal, and a large oral sucker in males allowing them to carry and shelter their female mating partner (Beltran and Boissier 2008; Beltran and Boissier 2009) Sexes are genetically determined during egg fertilization with a ZZ/ZW chromosomal system where females are heterogametic (Grossman et al. 1981). In *S. mansoni*, females have a W chromosome characterized by large pseudo-autosomal regions as well as W-specific sequences almost entirely composed of heterochromatic satellite-type repeats (Protasio et al. 2012; Lepesant et al. 2012). No W-specific protein-coding genes were identified so far (Criscione et al. 2009). Thus, in spite of the observed sexual dimorphism at the adult stage, males and females share a common set of protein-coding genes. There are 782 genes specific to the Z chromosome and are thus found twice in the ZZ males and only once in the ZW females. Studies on ZW female heterogametic systems frequently report a lack of dosage compensation that equalizes Z-linked transcript levels in males and females (Graves 2015). It is also the case in *S. mansoni* adults where Z-linked expression is reduced relative to

autosomal expression in females but not in males (Vicoso and Bachtrog 2011). However, it is not known if specific genes may be escaping the dosage compensation mechanism in schistosome males, therefore being potentially responsible for male-biased gene expression and accentuating phenotypic differences between sexes. If selection for a particular trait at a particular locus favours different alleles in males *vs.* females (*i.e.* sexual antagonism) one would expect to find a mechanism to resolve these intralocus sexual conflicts. Gonochoric species usually “solve” these conflicts through sex-biased expression of the sexually antagonistic genes (Ingleby et al. 2015; Lipinska et al. 2015). In schistosomes, sex-biased gene expression was intensively studied at the whole transcriptome level (Picard et al. 2016; Anderson et al. 2015; Fitzpatrick et al. 2008; Fitzpatrick et al. 2005; Lu et al. 2016), but other molecular mechanisms such as parent-of-origin gene expression have never been investigated. In diploid gonochoric organisms, sexual reproduction leads to the presence of two copies of each gene in each somatic cell of an individual, one inherited from the mother (*i.e.* matrigenes) and the other from the father (*i.e.* patrigenes). Usually both copies of a gene cooperate and are expressed at equal levels allowing compensation of the function in case of deleterious mutation, but in some cases gene expression is restricted to one of the parental alleles leading to paternally *versus* maternally preferential or exclusive gene expression (*aka* parent-of-origin gene expression, or genomic imprinting) (Reik and Walter 2001). Different theories have been proposed to explain the evolution of genomic imprinting and the effects of such gene expression in the offspring. The sexual antagonism (Day and Bonduriansky 2004; Patten et al. 2014; Bonduriansky 2007) or maternal-offspring coadaptation (Wolf and Hager 2006) theories suggest that genomic imprinting has the potential to modify resemblance of an individual to its parents (Patten et al. 2014). The sexual antagonism theory, proposes that as fathers and mothers have passed the filter of sex-specific selection (alleles successfully transmitted to progeny), it is thus more likely that male offspring will benefit from paternally

expressed alleles for male traits, while female offspring will benefit from maternally expressed alleles for female traits (Day and Bonduriansky 2004). It is therefore predicted that phenotypic traits benefiting males or females, as for example muscular bodies for males, would be preferentially expressed from the paternal alleles. In schistosomes we therefore expect paternal genes coding for growth enhancers or muscle development to be preferentially expressed in males, and maternal expression in females for traits under sexually antagonistic selection.

Based on the maternal-offspring coadaptation theory: maternal alleles may be selected for imprinted expression to provide the greatest combined fitness between the mother and progeny (Wolf and Hager 2006). Therefore in organisms providing maternal investment (for example most mammals) we expect maternal expression in both sexes for genes involved in maternal-offspring interactions and more specifically maternal care. In schistosome species, it has been proposed that prezygotic paternal investment (transport of the female to the oviposition site, female maturation and feeding) is higher than maternal investment (Beltran and Boissier 2008). Therefore paternal expression in both sexes may be expected.

The evolutionary roles of parent-of-origin expression nevertheless remain controversial and the patterns predicted by those models may be very contrasted but also non-exclusive. Indeed, most of the studies have been carried in plants, mammals and some insects like Coccids, and Bees (da Rocha and Ferguson-Smith 2004; Ferguson-Smith 2011; Kocher et al. 2015; Macdonald 2012) and support an alternative, but not exclusive conjecture: the Kinship theory (Moore and Haig 1991; Haig 2000), which links parent-of-origin gene expression not to sexual, but more generally to parental conflicts. It assumes that parental genomes are not functionally equivalent, and do not have the same reproductive interests. In a polyandrous mating system, maternal alleles tend to preserve mother and progeny by a restriction of resources, while the paternal genome favours growth of offspring. An interesting example for

such a “battle of sexes” was shown by the paternal expression of the insulin-like growth factor 2 (IGF2) inducing growth, while the maternal expression of its antagonist receptor (IGF2R) tends to reduce growth in mammals (Wilkins and Haig 2003). The kinship model therefore predicts that maternal expression will be favoured if a gene has a positive effect when maternally expressed but a negative effect when paternally derived and vice versa for paternal expression. Therefore we would expect paternal expression in both sexes for genes involved in extraction of maternal resources by offspring. Schistosomes are oviparous organisms that shed hundreds of eggs daily per female, and resource is already present in the egg before fertilization (maternal allocation of energy) but once released the subsequent development is independent of parental resources. The expression patterns will therefore depend on the phenotypic effect of the genes.

Differences in gene expression according to parental origin in schistosomes, may be important to identify candidates for sex-specific phenotypes. To this end, we screened male and female transcriptomes in reciprocal hybrids of *S. mansoni* for parent-of-origin expressed genes, considering both known sex-linked and autosomal genes. This approach relied on strain-specific single nucleotide polymorphic (SNP) markers allowing us to identify the potential allelic expression profile of each transcript, while reciprocal crosses allowed us to discriminate parent-of-origin effects from strain-of-origin effects. We show that most SNPs detected in genes with monoallelic expression are located in mitochondrial and Z-specific loci, thus validating our experimental design and analysis pipeline. We also identified a number of SNPs with preferential expression from one parental allele in the transcriptome of male and female schistosomes, suggesting paternal and maternal imprints. As the genes concerned by these parent-of-origin type SNPs are closely related to development and sex-specific functions we suggest that parent-of-origin gene expression needs to be explored in depth because it may be used to resolve intralocus sexual conflicts underlying sexual

dimorphism in this species. Finally, we discuss our results in regard to current knowledge on schistosome parasites life history traits and the evolutionary theories supporting imprinting in other organisms.

Materials and Methods

1) Parasite origin, crossing protocol and sequencing

Hybrid adult parasites were obtained by reciprocally crossing two different geographic isolates of the *Schistosoma mansoni* species: the Guadeloupian strain GH2 and the Brazilian strain BRE. We performed biological duplicates of two independent crosses, F1 male and female hybrids [GH2 mother x BRE father], and the reciprocal male and female crosses [BRE mother x GH2 father] as shown in **Figure 1** and **Table 1**. Each cross was performed in mouse (*Mus musculus*) definitive hosts, by using *Biomphalaria* molluscs that were individually exposed to a single *miracidium* of the BRE or GH2 strain (releasing either male or female clonal populations of BRE or GH2 *cercariae*). The resulting hybrid *miracidiae* were individually used to infect molluscs, and adult worms were recovered after mouse unisexual infestation (**Figure 1a**). Total RNA was extracted from the eight samples separately (**Figure 1b**) and global sequencing was performed on four lanes (double multiplexing) using paired-end (2 x 125 nt) Hiseq Illumina technology.

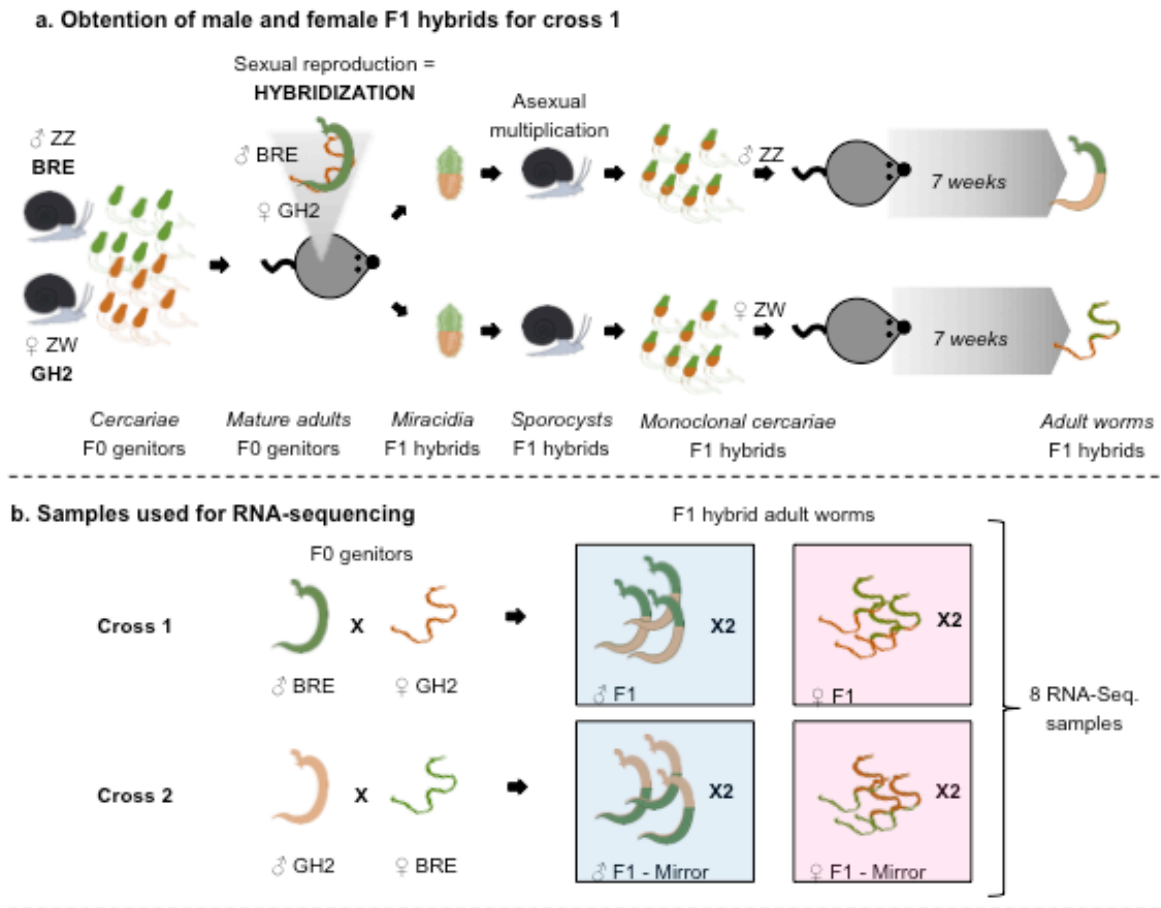

Figure 1: a) Crossing Protocol Example for Cross 1 and, b) Samples used for RNA-sequencing. a) Molluscs releasing clonal populations of male BRE (ZZ) and female GH2 (ZW) *cercariae* were used to infect *Mus musculus* definitive hosts and produce F1 eggs releasing hybrid *miracidia*. These male or female *miracidia* were used to infect molluscs and produce male or female *cercariae*. Unisexual infection of *Mus musculus* allowed us to recover after seven weeks, male and female hybrid adult worms. Notice that Cross 2 (male GH2 x female BRE), which is not presented in this figure, was performed the same way.

Total RNA isolation

For each sex and cross, experiments were performed in two biological replicates. RNA extractions were performed alternatively from 20 adult males or 100 adult females. Briefly, parasites were ground in liquid nitrogen and solubilized in TRIzol (Thermo Fisher Scientific). Total RNA was then extracted by adding chloroform. PureLink RNA Mini kit (Ambion) was

used for further purification following the manufacturer's protocol. Total RNA was eluted in 30 μ l RNasecure (Ambion) and incubated at 65°C for 10 min. Samples were then treated with TURBO DNase (TURBO DNA-free, Ambion) and the reaction was stopped by cooling down on ice for two minutes. RNA was finally purified on a column (RNeasy mini kit, QIAGEN) and eluted in 30 μ l RNase-free water. Quality and concentration were assessed by spectrophotometry with the Agilent 2100 Bioanalyzer system. Further details are available at [Environmental and Evolutionary Epigenetics Webpage. <http://methdb.univ-perp.fr/epievo/>].

Illumina libraries construction and high-throughput sequencing

cDNA library construction and sequencing were performed at the sequencing facility of Montpellier GenomiX (MGX, France). The TruSeq stranded mRNA library construction kit (Illumina Inc., USA) was used according to the manufacturer's recommendations on 300 ng of total RNA per condition. Briefly, poly-A RNAs were purified using oligo-d(T) magnetic beads. The poly-A⁺ RNAs were fragmented and reverse transcribed using random hexamers, Super Script II (Life Technologies, ref. 18064-014) and Actinomycin D. During the second strand generation step, dUTP substituted dTTP to prevent the second strand to be used as a matrix during the final PCR amplification. Double stranded cDNAs were adenylated at their 3' ends before ligation was performed using Illumina's indexed adapters. Ligated cDNAs were amplified following 15 cycles PCR and PCR products were purified using AMPure XP Beads (Beckman Coulter Genomics, ref.A63881). The quantitative and qualitative analysis of the library was carried on Agilent_DNA 1000 chip and qPCR (Applied Biosystems 7500, SYBR Green). The sequencing was performed on a HiSeq2500 in paired-end 2x125nt mode. RNA-Seq reads are available at the NCBI-SRA under the BioProject accession number [PRJNA378178](https://www.ncbi.nlm.nih.gov/bioproject/PRJNA378178).

Table 1: F1 and Mirror individuals from two reciprocal crosses

	F1 Male	F1 Female	F1-Mirror Male	F1-Mirror Female
Biological	♀ GH2 x ♂ BRE	♀ GH2 x ♂ BRE	♀ BRE x ♂ GH2	♀ BRE x ♂ GH2
duplicates	♀ GH2 x ♂ BRE	♀ GH2 x ♂ BRE	♀ BRE x ♂ GH2	♀ BRE x ♂ GH2

2) *RNAseq data processing*

- **Quality control**

Quality control and initial cleaning of the reads was performed with the filter by quality program (version 1.0.0) based on FASTX-toolkit (Blankenberg et al. 2010). Reads with less than 90% of bases with Phred quality score inferior or equal to 30 were discarded (probability of 1 incorrect base call out of 1000, and a base call accuracy of 99,9%). Adaptors used for sequencing were removed using the cutadapt program version 1.6 (Martin 2011).

- **Mapping of the reads against the reference genome**

Each sample's paired-end sequencing reads were independently mapped (i.e., unique reads) to the *Schistosoma mansoni*'s reference genome version 5.2 (Protasio et al. 2012; Berriman et al. 2009) using TopHat2 software (Kim et al. 2013). The alignment was performed in single reads with intron length parameter set between 20-50,000bp. We authorized one mismatch in the anchor region of spliced alignment, applied a micro-exon search because of the presence of micro-exon genes in schistosome genomes (DeMarco et al. 2010), and used the very sensitive Bowtie2 option (Langmead et al. 2009). The GTF annotation file (*Schistosoma mansoni* sex specific transcriptome) produced in a previous work (Picard et al. 2016) served as the reference (<http://ihpe.univ-perp.fr/acces-aux-donnees/>). In order to avoid false positives

in SNP calling we filtered PCR duplicates by eliminating exact reads found more than eight times (option “Tolerated Duplicates” = four) using “Remduplicates” (Althammer et al. 2011).

3) Parent-of-origin gene identification

The approach is based on the analysis of the frequency of SNP markers presenting allelic imbalance within the transcriptomic data of the hybrids. The identity of the base can then be used to distinguish allelic origin, and the reciprocal cross helps to discriminate parent-of-origin from strain-of-origin biases in allelic expression (**Figure1**).

a) Selecting strain-specific SNPs in the genomic data of BRE and GH2

Single nucleotide polymorphisms (SNPs) in the genome of the BRE and GH2 strains were previously described (Clément et al. 2013). We used the Freebayes generated BAM files available at <http://methdb.univ-perp.fr/downloads/> to assess strain specific SNPs. We considered informative, any SNPs showing fixed alternative allele frequency (AF 0.9) in one strain, and absent or having an alternative allele frequency inferior or equal to 0.1 in the other (AF 0.1) compared to the reference genome (NMRI strain, Puerto Rican Origin).

b) SNPs calling in the transcriptomic data

Using SAMtools (Li et al. 2009), we produced mpileup files with read coverage information and call quality from the TopHat2 alignment BAM files. We then performed SNPs calling by using VarScan software (version 0.1) on the mpileup files (Koboldt et al. 2012). The minimum depth at position to make a call was set to 10 reads, the minimum supporting reads for alternative allele at position was set to two. The minimum base quality to count a read was set to 15, minimum variant allele frequency threshold was set to 1%, and the p-value threshold for calling variants was set to 5%. The number of reads, the number of variant allele

and the alternative base identity was visually checked for 10 randomly selected SNPs in each sample with the Integrative Genomics Viewer (IGV) software (Thorvaldsdóttir et al. 2013).

c) Parental origin of the transcripts analysis

In order to discriminate parent-of-origin from strain-of-origin SNP expression, each samples transcriptome variant files were compared with the previous selected strain specific SNPs (BRE or GH2) and that according to variant positions. We only kept SNPs in the transcriptome for which we had parental information in order to identify the origin from which the SNP is expressed. Three categories were defined based on the expression profiles of the SNPs. Those with alternative allele frequency between 0% - 10% or 90% - 100% were defined as monoallelic (or imprinted). Those with alternative allele frequency between 10% - 35% or 65% - 90% were defined as biased (preferential expression), and those with alternative allele frequency between 35% and 65% were considered as biallelic (**Figure 2**). Amongst these, SNPs were conserved only if found in the same category in both replicates. We further added mpileup coverage information to assess if the SNPs weren't detected, or if the regions were not transcribed. When coverage information indicated reads in the region we considered the allele similar to the reference genome and set allele frequency to 0% (minimum coverage of 10 reads). If the region was not covered and therefore not transcribed, we considered position as non-informative.

Detection strategy of parent-of-origin expression for Cross 1

Figure 2: Detection Strategy of Parent-of-Origin Expression: example for Cross 1. Cross 1 was performed using males from the *S. mansoni* Brazilian strain (BRE), and females from the Guadeloupien strain (GH2). Each hybrid contains a chromosome from the mother (GH2) and from the father (BRE). The transcriptomic analysis of hybrid offspring allowed identifying genes i. expressed in equal proportions between the mother's (GH2) and father's (BRE) allele (i.e., biallelic expression), ii. expressed exclusively from the mother's (GH2) or father's (BRE) allele (i.e., monoallelic expression), or iii. expressed preferentially from the mother's (GH2) or the father's (BRE) allele (i.e., biased expression).

d) Comparisons between the reciprocal crosses

SNPs with biased and monoallelic expression profiles were compared between reciprocal crosses. This allowed us to identify genes potentially expressed in a parent-of-origin manner when reciprocal crosses agreed with each other on parent-of-origin bias.

4) Annotation of the transcriptome

The transcriptome file (extracted from the GTF reference (Picard et al. 2016) was *de novo* re-annotated on the local server of the laboratory by searching protein databases using a

translated nucleotide query (Blastx) against the Non-redundant protein sequence database (nr). The 25 best hits were then used to search for gene ontology terms using the Blast2Go program (Conesa et al. 2005). Correspondence between transcript and current version of genome annotation was manually checked using IGV software (Thorvaldssdóttir et al. 2013).

5) *Quantitative PCR validation of Z-specific scaffolds*

Simple or double copy of genomic DNA was assessed with male (ZZ) and female (ZW) DNA extracted from adult worms to verify the Z-specific status of unplaced scaffolds containing genes with monoallelic paternal expression. DNA of single adult worms of each sex were extracted as recommended from the QIAGEN QIAamp DNA Micro Kit protocol for isolation of genomic DNA from tissues. Final elution was performed using 40µl of buffer AE (10 mM Tris·Cl, 0.5 mM EDTA, pH 9.0). Primers were designed using the online Primer3plus program (Rozen and Skaletsky 1999) and aligning the primers against *Schistosoma mansoni*'s reference genome v5.2 to verify for high specificity. We used a known Z-specific (double copy in ZZ males, and single in ZW females) and an autosomal (double copy in each sex) genomic region as internal control. Primer efficiencies were assessed with serial dilutions of genomic DNA in DNase free water (dilutions 1/4, 1/16, 1/64, and 1/256). Primer efficiency was calculated using the slope of the standard curve with efficiency = $-1 + 10 (-1/\text{slope})$. Quantitative PCR reactions were carried out in a total volume of 10µl, containing 5µl of the Takyon 2X reaction mix (Eurogentec), 2µl of 10mM primers (forward and reverse), 2µl of DNA template and 1µl of nuclease free water. The qPCR program was set for 40 cycles containing a 10s denaturation phase at 95°C, annealing-extension phase at 59°C for 20s and 72°C for 25s.

Results

1) RNA sequencing data processing

Between 197 million and 320 million reads were produced after RNA sequencing for each of the eight samples, representing male and female adult progenies of biological duplicate crosses and mirror crosses of a Brazilian (BRE) and Guadeloupian (GH2) strain of *Schistosoma mansoni* (Table 2 and Figure 1). After filtering reads according to their quality Phred score, between 160 million and 239 million (~80%) of them were kept for subsequent read mapping against *Schistosoma mansoni*'s reference genome v5.2 (Berriman et al. 2009; Protasio et al. 2012). At least 90% of the filtered reads were successfully mapped to the reference genome. Because SNPs frequency reliability was essential to detect allele-specific transcripts, potential PCR duplicates (~50% of reads) were removed.

Table 2: Number of sequences remaining after each bioinformatic steps

Crosses	Sex	Quality filtering Q30		TopHat2 mapping		PCR duplicate removal
		Input	Discarded	Input	Mapped	Output
♀ GH2 x ♂ BRE	M	203,732,076	43,590,513	160,141,563	144,201,576 (90%)	64,795,806
♀ GH2 x ♂ BRE	M	278,553,568	62,102,488	216,451,080	197,048,330 (91.0%)	84,039,096
♀ BRE x ♂ GH2	M	249,198,708	54,496,632	194,702,076	179,194,594 (92.0%)	81,242,489

♀ BRE x ♂ GH2	M	237,406,392	52,577,939	184,828,453	169,678,849 (91.8%)	79,231,052
♀ GH2 x ♂ BRE	F	197,048,594	34,868,591	162,180,003	147,618,963 (91.0%)	76,799,603

♀ BRE x ♂ GH2	F	231,467,876	57,694,047	173,773,829	159,153,208 (91.6%)	80,775,575
♀ BRE x ♂ GH2	F	320,963,252	81,771,733	239,191,519	220,417,355 (92.2%)	103,756,971

Identification of parent-of-origin expressed genes

- SNPs discriminating parents

In this work we benefited from 708,898 SNPs identified in the Brazilian (BRE) and Guadeloupian (GH2) strains (Clément et al. 2013). These two inbred strains display low nucleotide diversity within each strain, but a high differentiation level between them (mean $F_{st}=0.73$) (Clément et al. 2013). We selected 230,425 of those SNPs (32%) that were fixed and discriminant between the two strains (“private” SNPs) (genome browser available at <http://genome.univ-perp.fr>). Amongst these, 29,796 SNPs (13%) were found across the transcriptome of the hybrid progenies. The majority (56%) of these SNPs were situated in exons of known genes (16,587 exons from 6,612 genes), while 13,209 (44%) were situated in introns or non-annotated regions.

- **SNPs expression between replicates and reciprocal crosses**

We compared SNP expression patterns between replicates. Between 70% and 77% of the SNPs had the same expression patterns in biological replicates when attributed to one of the three defined categories (*i.e.* biallelic, biased or monoallelic, see description in Materiel and Methodes) (**Table 3**). We thus analysed 10,665 SNPs for males, and 14,412 SNPs for females and compared their allele expression profiles between reciprocal crosses to distinguish strain-of-origin effects from parent-of-origin effects (**Table 3**). Amongst them, 5,422 (51%) and 7,095 (49%) of the SNPs had a biallelic expression pattern for males and females respectively. A hundred and twenty-eight (1%) and 1,063 (7%) SNPs showed a parent-of-origin expression pattern for males and females respectively. Others were either expressed in a strain-of-origin manner, or had a non-concordant expression pattern between reciprocal crosses, representing 6% of all SNPs (*e.g.* biallelic in one and biased in the other (**Table 3**) which could be due to mito-nuclear incompatibilities in the hybrids crosses (Wolf 2009; Wolf et al. 2014). Indeed this type of incompatibilities are expected to be manifested and may lead to aberrant gene expression patterns and/or loss of imprinting in one direction of the cross (Wolff et al. 2014).

Table 3: Summary information of SNPs recovered in the transcriptomic data and associated SNPs expression patterns

	Parental discriminating SNPs in transcriptome	Categorised SNPs between replicates	Number of SNPs in reciprocal crosses	Biallelic SNPs	Strain-of-origin SNPs	Parent-of-origin SNPs	Other SNPs

M: ♀ GH2 x ♂ BRE	29,796	20,273	13,333 (70%)	10,665	5,422 (51%)	4,422 (41%)	128 (1%)	693 (6%)					
M: ♀ GH2 x ♂ BRE		23,509											
M: ♀ BRE x ♂ GH2		24,731	16,455 (72%)										
M: ♀ BRE x ♂GH2		24,966											
F: ♀ GH2 x ♂ BRE		25,092	17,595 (74%)						14,412	7,095 (49%)	5,455 (38%)	1,063 (7%)	799 (6%)
F: ♀ GH2 x ♂ BRE		26,286											
F: ♀ BRE x ♂ GH2		27,349	21,014 (77%)

- **Parent-of-origin expressed genes**

We investigated whether SNPs with parent-of-origin patterns were situated in known genes of *S. mansoni*. In males, 108 SNPs were located in the exons of 15 genes (in addition to one mitochondrial) and expressed from the same parent in both reciprocal crosses. Six different chromosomes were concerned, with three genes on chromosome 1, 2, and 4, and one gene on the unplaced-scaffold_0193 of chromosome 2, the unplaced scaffold_0083 of chromosome 3, chromosome 5, ZW linkage group (Z-specific region), unplaced scaffold_0138 and unplaced scaffold_0164. Most SNPs (n=86) were located in the same gene (cytochrome c oxidase I) of the mitochondrial genome of maternal inheritance and thus providing an internal control as they had a strictly maternal expression pattern (**Table 4**). Amongst the 15 genes in males, one displayed monoallelic expressed SNPs from the maternal allele, while 14 genes showed parentally biased SNPs in equal proportion between the mother's (n=7) and the father's allele (n=7) (**Table 5**).

Table 4: Functional annotation of genes containing parent-of-origin expressed SNPs. Is represented in this table, the localization of the genes in known chromosomes or unassembled portion of *S. mansoni's* genome for male and female adults. Number of SNPs, parental origin, expression pattern, and functional annotation are also presented. Expressed genes detected in this study that were not in the current annotated regions of *S. mansoni's* genome version (v5.2) are mentioned as XLOCs as identified in the GTF transcriptome reference (Picard et al. 2016). Notice that for those genes, the genomic position has been provided.

Chromosomes	Number of genes	Genes or position	Number of discrim	SNPs positions	Origin	SNPs Expression pattern	Genes Function

Table 5: Number of genes containing parent-of-origin SNPs. Genes with parent-of-origin SNPs are categorized according to their expression in i) male and female progenies, and ii) according to their expression pattern (*i.e.* maternal or paternal, and monoallelic or biased).

SNP patterns in reciprocal crosses	Male progeny	Female progeny	Total
Genes with paternal monoallelic SNPs	0	0	0
Genes with paternal biased SNPs	7	4	11
Genes with maternal monoallelic SNPs	1 (+1 mitochondrial)	0 (+1 mitochondrial)	1
Genes with maternal biased SNPs	7	3	10
Total Monoallelic	1	0	1
Total Biased	14	7	21
Total genes with parent-of-origin expressed SNPs	15	7	22

In females, SNPs showing consistent parent-of-origin expression were found in exons of a total of 378 different genes. Amongst these, 278 genes had SNPs with a strict paternal expression and were known to be located in Z-specific regions (*i.e.* Linkage group ZW:

position 3,550,000 to 13,340,000; 13,860,000 to 19,650,000; and 23,230,000 to 30,820,000 of the v5.2 assembly (Protasio et al. 2012) (**Supplementary Table S1**), which is consistent with the heterogametic status of female schistosomes. Indeed, heterogametic female schistosomes inherit their W chromosome from the mother and the Z from the father: such patterns provided again an internal control validating the accuracy of our method for the detection of parent-of-origin genes. Z-specific genes were therefore not considered in further analysis.

Additionally, 92 genes located on 22 individual unplaced scaffolds (including Chr_1.unplaced.SC_0034 and Chr_3.unplaced.SC_0192) contained SNPs with a paternal expression pattern (**Supplementary Table S1**). We thus considered them as potentially Z-specific and verified their status in the four biggest unplaced scaffolds containing the larger amount of genes, for unique (ZW) or double copy (ZZ) of genomic DNA in males and females using a quantitative PCR approach (**Table 6**). Unplaced scaffold_0115 of the ZW linkage group (Chr_ZW.unplaced.SC_0115), as well as the unplaced scaffolds number 0111 (SC_0111), 0129 (SC_0129), and 0136 (SC_0136), were thereafter classed as Z-specific (**Table 6**). The other scaffolds were not validated by qPCR but were considered as potentially Z-specific and excluded from further analysis (**Supplementary Table S1**).

Table 6: Quantitative PCR results: validation of four new Z-specific scaffolds. Two control regions were used with one in a known Z-specific region (see Protasio *et al.* 2012) and one in an autosomal region. Three primers were taken arbitrary in the unplaced scaffolds to be tested. The target positions, primer sequences, as well as the expected product sizes, primer efficiencies and female/male fold changes are presented in the table.

The remaining seven genes in females (in addition to one mitochondrial) presented biased SNPs consistent with parent-of-origin expression. Two distinct regions in the genome were concerned, with SNPs located in five genes on chromosome 1, and two genes on chromosome 2. These genes contained biased SNPs expressed from the maternal (n=3) or paternal (n=4) alleles. And last, the “cytochrome c oxidase” was identified again with 24 SNPs located in the gene and with a maternal expression (**Table 4 and 5**).

- **Function of the Parent-of-origin expressed genes**

The majority of genes identified with a parent-of-origin SNP expression in male and female schistosomes (**Table 4**) had biological processes involved in metabolism, growth, and development. We furthermore identified putative genetic mobile elements of unknown functions. Two types of expression patterns were observed with (i) either the expression of paternal SNPs in males and maternal SNPs in females, or (ii) the opposite feature with paternal SNPs expressed in females or maternal SNPs expressed in males. Interestingly, most

of the genes concerned with these SNPs expression patterns were related to developmental pathways and therefore potentially related to sex-specific and dimorphic phenotypes.

Is first described in this section the function of genes presenting SNPs expressed from the parent of the same sex in progeny. In males, seven genes with paternally expressed SNPs were identified. Amongst those, we pinpointed the putative ATP-dependent RNA helicase *dhx34* (Smp_147330) protein coding gene, which is part of the DEAD box proteins family, conserved in metazoan they are known for their implication in embryogenesis, spermatogenesis, cellular growth and division (Matsumoto et al. 2005; Godbout and Squire 1993; Johnstone et al. 2005). Its orthologue in *Caenorhabditis elegans* (*smgl-2*) is critical for muscle development (Williams and Waterston 1994). Furthermore such helicases are part of a complex called the “compensasome” because they mediate dosage compensation mechanism (Sanjuán and Marín 2000) in other organisms. The Beta-Parvin related gene (Smp_171530) is essential during embryogenesis in other organisms (Montanez et al. 2009; Zhang et al. 2004) and its orthologue in *C. elegans* is required for muscle assembly and function, while mutation of the gene leads to embryonic lethality. The coiled-coil domain-containing protein 60 (Smp_125620) potentially involved in protein demethylation and protein-protein interactions, is also thought to be important for embryonic development in vertebrates, with an identified role in the dorsoventral axial establishment of Zebrafish (Wei et al. 2016). A dehydrogenase reductase *sdr* family member gene (Smp_171960) has also been identified and interestingly a previous association study has shown a paternal parent-of-origin effect of that gene on language impairment (Nudel et al. 2014). At last three genes were identified with paternally expressed SNPs, one being a probable asparagine tRNA mitochondrial coding gene (Smp_169030) and has been related to developmental diseases in humans (Vanlander et al. 2015; Sofou et al. 2015), while two are genetic mobile elements with an endonuclease or endopeptidase activity (XLOC_009689, XLOC_015537).

In females, the genes with maternally expressed SNPs identified had functions linked to development and female specificities. The most relevant gene that can directly be related to female specific phenotypes was the nuclear receptor 2dbd gamma gene (Smp_034860). It contains a domain similar to the ligand-binding domain of *C. elegans* nuclear hormone receptor Sex-1 protein. This transcription factor plays pivotal role in sex fate of *C. elegans* by regulating the transcription of the sex-determination gene *xol-1*, which specifies male fate when active and hermaphrodite fate when inactive (Carmi et al. 1998; Farboud and Meyer 2006). Other genes related to developmental pathways were identified such as the “Strawberry Notch related” gene (Smp_173620). Notch genes encode for transmembrane proteins and have conserved functions in developmental pathways. They are required during embryogenesis and oogenesis in *Drosophila* and Zebrafish (Majumdar et al. 1997; Coyle-Thompson and Banerjee 1993; Takano et al. 2010).

At last, a genetic mobile element (XLOC_001902), identified as a gag-pol polyprotein, was maternally expressed in schistosome females.

The analysis of SNPs with opposite expression patterns in males and females (i.e., from the parent of opposite sex) also revealed genes potentially involved in male and female developmental pathways but may also be relevant in a coevolution context between sexes. Concerning maternally expressed SNPs in males, eight genes were identified including one with monoallelic expressed SNPs (Smp_128980). This aminomethyltransferase gene is nuclear-encoded but confined to the mitochondria and is involved in glycine metabolism. Also, mainly present in the mitochondrial matrix, we identified the Bifunctional coenzyme A synthase gene (Smp_149950). This last gene predicted to be involved in ATP binding activity and dephospho-CoA kinase activity has an orthologue in *C. elegans* (Y65B4A.8), which seems involved in embryo development, feminization of hermaphroditic germ-line, germ cell

development, nematode larval development, regulation of cell proliferation and regulation of meiotic nuclear division (Waters et al. 2010; Kerins et al. 2010).

Other genes with maternally biased SNPs in males were identified. The “putative Beta1-3 glucuronyltransferase” (Smp_083130) which is involved in carbohydrate metabolic process is mainly expressed in the brain of *Drosophila* and is involved in the growth of peripheral nerves during larval development (Pandey et al. 2011). In *C. elegans sqv-8* (homologous to three distinct glucuronyl transferases (GlcAT-I, GlcAT-P and GlcAT-D) which encodes a glucuronyl transferase is required for one-cell embryos and for vulval morphogenesis. *Sqv* mutants have a vulval defect, but also an oocyte and somatic gonad defect, resulting in hermaphrodite sterility. Moreover, some *sqv* mutations cause maternal-effect lethality (Herman et al. 1999; Bulik et al. 2000) It has also been shown that *glct-6* (another Beta1-3 glucuronyltransferase orthologue in *C. elegans*) is involved in determination of adult lifespan (Kim and Sun 2007). The “exosome component 10” gene (Smp_131150), also known as “polymyositis scleroderma autoantigen” in humans, is a cell death-related nuclease, that is required for DNA degradation during apoptosis. It is also thought to participate in dosage compensation mechanism by inactivation of the X chromosome. Indeed, in mouse, a specific nuclear component of the exosome, (*Exosc10*) gene involved in mRNA degradation pathways leads to downregulation of spliced *Xist* transcript production and blocks the onset of the X-inactivation process (Ciaudo et al. 2006). The transcription factor gene “Early growth response protein 1” (Smp_094930) targeting important genes for normal development and differentiation (Silverman et al. 1998; Pagel and Deindl 2011) may also play an important role in *Schistosoma* blood flukes development. Finally, a Steroid dehydrogenase gene (Smp_168560) was detected with a maternal SNPs expression in males. Interestingly, steroid dehydrogenase pathway was also found overrepresented in male schistosomes from cercariae to adult stages (Picard et al. 2016). In *C. elegans* some orthologue genes to Smp_168560 were

found (*stdh-4*, *stdh-1* and *let-767*) they encode for a putative steroid dehydrogenase and expressed in larval and adult pharynx (*stdh-4*) but also in larval intestine, and in both larval and adult body wall muscle and neurons (*stdh-1*) and is required for normally short lifespan. The orthologue gene *let-767* is particularly important for *C. elegans* development, as it is required for embryogenesis, and female reproduction. This gene is zygotically expressed in the intestine, but a maternal-effect lethal allele (*let-767* [s2464]) also exists, indicating that LET-767 is probably provided maternally which is consistent with our maternal expressed SNPs identified. Mutations in this gene cause abnormal embryonic development, slow growth and small adult body size as well as a failure to mature gonads and last, an hypersensitivity to low cholesterol (Kuervers et al. 2003). Other genes with opposite expression patterns in males and females could not be associated to any known functions (Smp_151660) or were predicted as a genetic mobile element with an endonuclease activity (XLOC_017885).

In females, five genes were found containing SNPs expressed from the paternal allele. Amongst them, one gene exhibited a monoallelic expressed SNP, while the four others contained biased SNPs. In this last situation we identified an uncharacterized protein-coding gene (Smp_128970), containing PHD finger domains, related to the “inhibitor of growth protein family” which have been implicated in chromatin-mediated transcriptional regulation in *C. elegans* embryo and is therefore potentially important for schistosome development (Luo et al. 2009). Other genes were involved in protein and vesicle mediated transport (Smp_154960), but also transcriptional regulation of developmental pathways (Smp_142400) (Steingrímsson et al. 1998; Hallsson et al. 2004; Hsu et al. 2004) and mechanosensory response (Smp_122810) (Huang et al. 1995)

Discussion

Parent-of-origin gene expression has been studied in mammals, plants, and some invertebrates (da Rocha and Ferguson-Smith 2004; Ferguson-Smith 2011; Kocher et al. 2015; Macdonald

2012; Arico et al. 2011), and aberrant expression in gene subject to imprinting has severe consequences, mainly on development and growth (Tycko and Morison 2002). The term imprinting was first used to describe the elimination of an entire paternal chromosome in sciara flies (Crouse 1960), and refers to the entire heterochromatization (silencing) of the paternal genome in the soccid mealybug, which is involved in maleness determination (Khosla et al. 2006). In addition to the Kinship theory of genomic imprinting (Haig 2000), another interesting alternative explanation proposes that imprinting may be related to a mechanism for the resolution of intralocus sexual conflict and may be important for traits under sex-specific selection (Day and Bonduriansky 2004; Bonduriansky 2007). This sexual antagonism theory involving male and female coevolution has the potential to act differently for each sex (sex-specific imprinting) and predicts that imprinting may affect organisms with sexual dimorphism (Bonduriansky 2007) as it is the case in schistosomes adult parasites. For that reason, we have investigated *S. mansoni* transcriptome for parent-of-origin gene expression considering intralocus sexual conflicts and sexual antagonism. We have identified genes containing SNPs expressed in a parent-of-origin manner and even if larger scale parent-of-origin gene expression in this species could not be addressed here we argue that regarding to the function of the genes concerned by these pattern, they have the potential to explain sexual differences in schistosomes parasites.

A total of 1,191 SNPs were identified as expressed in a parent-of origin manner in male (128 SNPs) and female (1,063 SNPs) adult schistosomes (**Table 3**). These parental SNPs were located in 15 genes in males (in addition to the Cytochrome C oxidase) and in 378 genes in females. As expected, the mitochondrial cytochrome C oxidase gene was also detected with a maternal expression in both sexes, thus providing validation of our methodology. In females, these parental expressed SNPs also revealed as expected 278 known Z-specific genes expressed exclusively from the paternal allele (monoallelic SNPs expression), which is

consistent with the schistosomes female heterogametic situation. Furthermore, in females, 92 genes situated on 22 unplaced scaffolds were found with a paternal expression pattern. We hypothesised that they might be related to Z specific loci, and tested the four biggest unplaced scaffolds containing the majority of paternal expressed genes using a quantitative PCR approach. This allowed us to identify four new Z-specific genomic regions (Unplaced scaffold 0115 of the ZW linkage group, unplaced scaffold 0111, 0129 and 0136, **Table 6**). We believe that other unplaced scaffolds are potentially Z-Specific and need further validation (**Supplementary Table S1**).

A total of 22 genes showing expressed SNPs consistent with parent-of-origin expression were identified in reciprocal cross duplicates of females (seven genes) and males (15 genes) adult schistosomes. These genes only contained few SNPs consistent with parental expression and the majority of them were biased rather than monoallelic. Notwithstanding, in males gene “Smp_128980” contained seven monoallelic SNPs expressed from the maternal allele and gene “Smp_083130” contained two biased SNPs expressed from the maternal allele, while in females two biased SNPs were identified in XLOC_001902 and Smp_122810 expressed from the maternal and paternal alleles, respectively (**Table 4**). This is probably the consequence of the poor amount of discriminant SNPs from which we have based our analysis and therefore hampers our ability to confirm any existing imprinting at the whole gene level in this species. Another consideration comes from the fact that imprinting may be tissue specific and that working with whole adult worms may mitigate the resulting expression patterns found in this work. Moreover, in the present experimental design the adult worms recovered from single sex infections present an immature phenotype (especially for female worms that rely on males for their maturation), which may have biased the expression and hamper the detection of further imprinted genes. Nevertheless, the genes identified with these parent-of-origin

expressed SNPs in males and females had interesting functions related to sex-specific phenotypes and sexual dimorphism in this species and share interesting common relations with parent-of-origin genes expression theories.

If we base our reflection on the Kinship theory (Haig 2000) defined by parental conflict over resource allocation and offspring fitness, we would of expected to find an impact of gene dosage on the fitness of matrilineal or patrilineal relatives. Moreover, usually schistosomes couples are monogamous, but mate change can occur among these parasites (Tchuem Tchuente et al. 1996; Beltran and Boissier 2009; Beltran et al. 2008) potentially causing a source of relatedness asymmetry for matrigenes and patrigenes in offspring. For example, maternally expressed alleles would be selected to reduce the extraction of resources and therefore reduce organism size, while paternally expressed genes should favour taking more resources from the mother and therefore induce growth. Indeed males are much more muscular than females (i.e. sexual dimorphism), and sexual selection may favour large body in males and the opposite in females, thus paternal genes should be selected in males to extract resources at a greater rate than in females. Schistosomes are oviparous organisms therefore neither the paternal or maternal genome can directly influence resource allocation after spawning. As observed in this study for schistosomes, it is difficult to reconcile these predictions to the function of the genes identified in this work except for genes that may influence growth and development of offspring, but this may overlap with the functions predicted by other models and in particular the sexual antagonism theory.

A clear dimorphic trait found in adult males is their strong musculature compared to the thin females. Interestingly we identified genes containing SNPs expressed from the paternal alleles that seem important for muscle development (Smp_147330, Smp_171530, Smp_125620), which is clearly predicted by the sexual antagonism theory. In some case mutations of orthologous genes in *C. elegans* lead to embryonic lethality (Smp_171530).

Moreover, some of those genes have been related to paternal parent-of-origin effects (Smp_171960) (Nudel et al. 2014) and developmental diseases in humans (Smp_169030) (Vanlander et al. 2015; Sofou et al. 2015), which often find their cause in imprinting defaults. Another interesting point may concern the relationship with dosage compensation mechanism (Smp_147330) as such helicases genes mediate dosage compensation mechanism in other organisms (Sanjuán and Marín 2000). In schistosomes, heterogametic (ZW) females need to balance Z-linked transcript levels relative to homogametic (ZZ) males (Graves 2015; Vicoso and Bachtrog 2011). These previous observations are consistent with the sexual antagonism theory proposed by Day and Bonduriansky (Day and Bonduriansky 2004; Bonduriansky 2007).

Maternal expressed SNPs found in male genes were involved in development (Smp_149950, Smp_094930), with embryogenesis and reproduction (Smp_168560) but also growth (Smp_083130). In *C. elegans* *let-767* (orthologous to Smp_168560) is zygotically expressed in the intestines, and mutations in this gene causes abnormal embryonic development, slow growth and small adult body size as well as a failure to mature gonads and last, a hypersensitivity to low cholesterol (Kuervers et al. 2003). Other mutations of *C. elegans* orthologous genes (*sqv* genes orthologous to Smp_083130; *let-767* orthologous to SMP_168560) cause maternal-effect lethality (Herman et al. 1999; Bulik et al. 2000) indicating that they are probably provided maternally in *C. elegans*, which is similar to our observations in schistosomes. This may suggest that the maternal genome largely contributes to male phenotypes and is probably also indispensable for proper schistosome development. Moreover, we identified a probable candidate gene (Smp_131150, Exosome component 10) known to be involved in dosage compensation mechanism in mouse (*Exosc10*) as it leads to down regulation of spliced Xist transcript production and blocks the onset of the X-inactivation process (Ciaudo et al. 2006). This seems to indicate a strong coadaptation

between sexes in schistosomes. Moreover, consistent with such coadaptation we identified in males two genes (Smp_128980, aminomethyltransferase, containing maternal monoallelic SNPs together with the Bifunctional coenzyme A synthase gene (Smp_149950) containing maternal biased SNPs) that are mainly confined to the mitochondria. This may underlie coevolved complexes between the maternal inherited mitochondrial genome and nuclear maternally expressed genes in males, and therefore male and female coadaptation. Cytonuclear interacting genes seem important in the evolution of genomic imprinting (Wolf 2009). Such genes are important in a coevolution context between sexes because it may allow stronger coadaptation between the maternal inherited mitochondrial genome and the expression of maternal nuclear alleles in males (Beekman et al. 2014).

In females, we identified genes involved developmental pathways (Smp_173620), embryogenesis and oogenesis and also in transcriptional regulation of embryo development and animal reproduction (Smp_142400). Others were related to protein and vesicle mediated transport (Smp_154960), but also to mechanosensory response (Smp_122810) (Huang et al. 1995). Interestingly, we identified an uncharacterized protein-coding gene (Smp_128970), which seems to play a role in chromatin-mediated transcriptional regulation, and also contain a PHD finger domain, related to the “inhibitor of growth protein family”. This gene found in females has SNPs expressed from the paternal allele and together with other genes expressed from the paternal allele in females may once more allow a better coadaptation between sexes. Indeed, the paternal genome may influence the transcriptomic profile of females in order to increase the adaptive integration of offspring and the paternal genome leading to higher female’s fitness. This observation is also consistent with the sexual antagonism theory, but rather than expressing males or females specific coding genes in the same sexes, it shows that the opposite parent may influence the phenotype of the progeny in order to stick with its own sexual features (e.g., Smp_128970; inhibitor of growth protein family expressed from the

paternal allele in females potentially tends to reduce females size which is one important dimorphic trait representative of schistosome sexual features). This again shows how difficult the patterns observed in our organism can be reconciled with any particular model on the evolution of parent-of-origin gene expression and be non-exclusive.

Importantly, this also suggests that parent-of-origin gene expression or imprinting may occur in systems that have previously not been the focus of research because of the absence of conflict over maternal investment, but that imprinting shall be present in organisms where co-adapted traits may have fitness effects for progeny (Wolf and Hager 2006). This theory described in the Maternal-Offspring Coadaptation Theory (Wolf and Hager 2006), in any case does not reject the possibility of having coadaptation between paternal and offspring traits (Wolf and Hager 2006). Therefore we may have stronger coadaptation between the paternal genome and offspring in schistosomes rather than relative to the maternal genome. Thus the maternal-offspring coadaptation theory may not be obvious in schistosomes and this may be a reason why we do not observe any particular features predicted by this model. Furthermore this is plausible considering the strong influence that male schistosomes have on their female's fitness (Boissier and Moné 2001; Lu et al. 2016; Popiel 1986). An example of such coevolution at the phenotypic level can be observed from the fact that the male schistosomes continuously feed the female via the tegument and that female cannot reach sexual maturity without pairing with a male (Popiel 1986; Beltran and Boissier 2008). In order to explain the monogamous mating system of schistosomes it has been proposed that prezygotic paternal investment (transport of the female to the oviposition site, female maturation and feeding) is higher than maternal investment (Beltran and Boissier 2008) in contrast with other models on which imprinting has been studied. Second, it is well established that the sex ratio is male-based making the male the more competitive sex (Boissier and Moné 2000; Boissier et al. 2004; Beltran and Boissier 2010).

At last in females the genes expressed from the maternal allele once more provide interesting elements concordant with the sexual antagonism theory. Indeed some had particular conserved functions in developmental pathway (Smp_173620; Strawberry Notch related), and required during embryogenesis and oogenesis in other organisms (Majumdar et al. 1997; Coyle-Thompson and Banerjee 1993; Takano et al. 2010). Moreover, we identified a gene with a maternal biased SNP in females (Smp_034860) containing a domain similar to the ligand-binding domain of *Caenorhabditis elegans* nuclear hormone receptor Sex-1 protein. It is used as an X-chromosome signal that determines nematode sex and may also plays a role in dosage compensation mechanisms (Farboud and Meyer 2006; Carmi et al. 1998). As the molecular determinants of sex determination are not yet known in schistosomes besides that it is genetically determined during egg fertilization, this gene seem to be an interesting candidate to explore.

Why is parent-of-origin expression an interesting phenomenon to explain gonochorism and sexual dimorphism in schistosomes and may need further consideration?

As seen, most of the expression patterns observed in this work are difficult to reconcile with all predictions made by the different models of the evolution of genomic imprinting, namely the kinship theory (Moore and Haig 1991; Haig 2000), the maternal-offspring coadaptation theory (Wolf and Hager 2006) and the sexual antagonism theory (Day and Bonduriansky 2004; Bonduriansky 2007). Nevertheless regarding sexual dimorphism, we have mainly focused here on patterns predicted by the sexual antagonism theory. Day and Bonduriansky predicted in their sexual antagonism theory (Day and Bonduriansky 2004) that sex-specific imprinting may occur, and in combination with sexually antagonistic selection result in sexual dimorphism. Studies have clearly shown that some parentally expressed genes are expressed in a sex-specific manner and might be at the base of sexual dimorphism and differences in

behaviour like for example maternal care (Gregg et al. 2010), but also have effects on complex traits (Hager et al. 2008). Sex-specific parent-of-origin expression in adults can thus contribute to transcriptional differences leading to morphological and or physiological changes at the base of male and female adult phenotypes in contrast with the schistosomes morphologically indistinguishable larval stages. Therefore, sex-specific imprinting would allow males and females to approach their phenotypic optima and may contribute to the evolution of sexual dimorphism (Bonduriansky 2007). In this work we highlighted interesting elements concordant with such predictions.

First, most of the genes identified have functions related to development and sex-specific functions. As we know that schistosomes have evolved from hermaphroditic ancestors, both sexes have therefore obligatorily coevolved and parent-of-origin gene expression may allow stronger coadaptation between sexes as seen previously. Second, gonochorism is thought to have appeared with the colonization of warm-blooded species (Loker and Brant 2006). The diversity generated by sexual reproduction was proposed to allow the parasite to counter vertebrate's immune system. Moreover, sexual dimorphism is essential for schistosomes, and allows males and females schistosomes to have complementary roles in the definitive hosts (Basch 1990). Indeed, males are much more muscular than females (*i.e.* sexual dimorphism), and sexual selection may favour large body in males and the opposite in females. It is interesting to consider that parent-of-origin expression may have allowed sexual reproduction maintenance in order to generate diversity in these species, as imprinting defaults can have detrimental effects in other organisms (Swales and Spears 2005) and cause embryonic lethality. Furthermore, it might have contributed to the evolution of sexual dimorphism as proposed by Day and Bonduriansky's predictions (Day and Bonduriansky 2004). At last, the identification of genetic mobile elements with parent-of-origin expressed SNPs is also an interesting point as it has been shown that imprinted regions tend to show significantly more

transposon insertions or more generally, retroviral repeats, than other regions (Pignatta et al. 2014). Thus, imprinting in schistosomes could also be the side effect of host defence mechanism against foreign DNA (McDonald et al. 2005) that was thereafter selected because of its adaptive significance. It has recently been shown that “captured” genes of retroviral origin (Syncytins) have sex-dependent effects in mice, and that they are involved in the development of the placenta in females, and have a role in muscle development in males (Redelsperger et al. 2016). This again underlies a possible contribution of imprinted genes to sexual dimorphism in schistosome parasites.

Conclusion

Schistosomes are diploid metazoan parasites with separate sexes, thus the maternal and paternal genomes are thought to contribute equally to the fitness of their offspring. In this work, we explored the transcriptome of male and female adult worms to search for parent-of-origin expressed genes. It allowed us to identify new Z-Specific loci, but also detect genes containing SNPs consistent with parent-of-origin patterns. Because of the poor amount of SNP markers available, we cannot conclusively affirm that imprinting exists at a larger scale in this species, but suggest that it needs further considerations. Interestingly, in males and females an important number of genes identified with parent-of-origin SNPs are related to developmental processes such as embryogenesis, spermatogenesis and oogenesis and may act as fundamental contributors to male and female phenotypes and more specifically to sexual dimorphism. Other genes related to dosage compensation mechanisms also seem important for sex-specific phenotypes, especially in males, and the identification of the Sex-1 protein gene ortholog found in females is an important candidate to explore the molecular bases of sexual determination in schistosomes. We propose that parent-of-origin gene expression may be a mechanism allowing to mitigate conflict linked to parenthood and potentially solve

intralocus sexual conflict in this species as it has been proposed from Day and Bonduriansky's sexual conflict theory, defining imprinting as a mechanism for the evolution of sex specific traits. In schistosomes, it is appealing to think that if imprinting exists in this species, it may coincide with the shift from hermaphroditism to gonochorism and thus may be at the base sexual reproduction and sexual dimorphism maintenance. Importantly, future studies on parent-of-origin expression in schistosomes should address the question of the underlying molecular mechanisms. Indeed, the imprinting by the usual mechanism of DNA methylation could be controversial in this species for which such mechanism is still under debate (Raddatz et al. 2013), therefore other epigenetic actors will have to be explored, such as histone modifications. Growing evidences show that chromatin modifications are indeed involved in schistosomes development (Roquis et al. 2015), moreover in a sex specific manner (Picard et al. 2016). Another interesting perspective would be to look for parental biased expression in the non-differentiated cercarial stage. Finally, by detecting genes with strain specific expressions, our unprecedented analysis opens new perspectives to understand hybridization mechanisms in schistosomes and thus on the disease dynamics, including interspecific interactions in the context of the modification of species geographical distribution due to climate change (Boissier et al. 2016).

Acknowledgments

We would like to thank Anne Rognon and Nathalie Arancibia for rodent and snail maintenance, and Jean-Francois Allienne for technical assistance. We also acknowledge the contribution of the MGX-Montpellier GenomiX sequencing platform. This work was supported by the Région Languedoc-Roussillon.

Ethic Statement

All experiments were carried out according to national ethical standards established in the writ of February 1st, 2013 (NOR: AGRG1238753A), setting the conditions for approval, planning and operation of establishments, breeders and suppliers of animals used for scientific purposes and controls. The French Ministère de l'Agriculture et de la Pêche and the French Ministère de l'Education Nationale de la Recherche et de la Technologie provided permit A66040 to the laboratory for animal experiments and certificate to the experimenters (authorization 007083, decree 87–848).
